Here [AB] denotes either an intermediate or an activated complex. The rates of appearance and disappearance of the various species are determined by observing time-dependent changes in the absorption spectrum of the sample during the course of the reaction. This monitoring is done by passing a weak pulse of white light, the *probe*, through the sample at different times after the laser pulse. Pulsed ‘white’ light can be generated directly from the laser pulse by the phenomenon of **continuum generation**, in which focusing an ultrafast laser pulse on a vessel containing a liquid such as water, carbon tetrachloride, CaF, or sapphire results in an outgoing beam with a wide distribution of frequencies. A time delay between the strong laser pulse and the ‘white’ light pulse can be introduced by allowing one of the beams to travel a longer distance before reaching the sample. For example, a difference in travel distance of $\Delta d = 3$ mm corresponds to a time delay $\Delta t = \Delta d/c \approx 10$ ps between two beams, where c is the speed of light. The relative distances travelled by the two beams in Fig. 14.39 are controlled by directing the ‘white’ light beam to a motorized stage carrying a pair of mirrors.

Variations of the arrangement in Fig. 14.39 allow for the observation of fluorescence decay kinetics of A* and time-resolved Raman spectra during the course of the reaction. The fluorescence lifetime of A* can be determined by exciting A as before and measuring the decay of the fluorescence intensity after the pulse with a fast photo-detector system. In this case, continuum generation is not necessary. Time-resolved resonance Raman spectra of A, A*, B, [AB], or C can be obtained by initiating the reaction with a strong laser pulse of a certain wavelength and then, some time later, irradiating the sample with another laser pulse that can excite the resonance Raman

Fig. 14.39 A configuration used for time-resolved absorption spectroscopy, in which the same pulsed laser is used to generate a monochromatic pump pulse and, after continuum generation in a suitable liquid, a ‘white’ light probe pulse. The time delay between the pump and probe pulses may be varied by moving the motorized stage in the direction shown by the double arrow.

spectrum of the desired species. Also in this case continuum generation is not necessary. Instead, the Raman excitation beam may be generated in a dye laser (see *Further information 14.1*) or by stimulated Raman scattering of the laser pulse in a medium such as $\text{H}_2(\text{g})$ or $\text{CH}_4(\text{g})$.

(f) Spectroscopy of single molecules

There is great interest in the development of new experimental probes of very small specimens. On the one hand, our understanding of biochemical processes, such as enzymatic catalysis, protein folding, and the insertion of DNA into the cell's nucleus, will be enhanced if it is possible to visualize individual biopolymers at work. On the other hand, techniques that can probe the structure, dynamics, and reactivity of single molecules will be needed to advance research on nanometre-sized materials (*Impact I20.2*).

We saw in *Impact I13.3* that it is possible to obtain the vibrational spectrum of samples with areas of more than $10\ \mu\text{m}^2$. Fluorescence microscopy (*Impact I14.2*) has also been used for many years to image biological cells, but the diffraction limit prevents the visualization of samples that are smaller than the wavelength of light used as a probe (*Impact I13.3*). Most molecules—including biological polymers—have dimensions that are much smaller than visible wavelengths, so special techniques had to be developed to make single-molecule spectroscopy possible.

The bulk of the work done in the field of single-molecule spectroscopy is based on fluorescence microscopy with laser excitation. The laser is the radiation source of choice because it provides the high excitance required to increase the rate of arrival of photons on to the detector from small illuminated areas. Two techniques are commonly used to circumvent the diffraction limit. First, the concentration of the sample is kept so low that, on average, only one fluorescent molecule is in the illuminated area. Second, special strategies are used to illuminate very small volumes. In **near-field optical microscopy** (NSOM), a very thin metal-coated optical fibre is used to deliver light to a small area. It is possible to construct fibres with tip diameters in the range of 50 to 100 nm, which are indeed smaller than visible wavelengths. The fibre tip is placed very close to the sample, in a region known as the *near field*, where, according to classical physics, photons do not diffract. Figure 14.40 shows the image of a $4.5\ \mu\text{m} \times 4.5\ \mu\text{m}$ sample of oxazine 720 dye molecules embedded in a polymer film and obtained with NSOM by measuring the fluorescence intensity as the tip is scanned over the film surface. Each peak corresponds to a single dye molecule.

In **far-field confocal microscopy**, laser light focused by an objective lens is used to illuminate about $1\ \mu\text{m}^3$ of a very dilute sample placed beyond the near field. This illumination scheme is limited by diffraction and, as a result, data from far-field microscopy have less structural detail than data from NSOM. However, far-field microscopes are very easy to construct and the technique can be used to probe single molecules as long as there is one molecule, on average, in the illuminated area.

In the **wide-field epifluorescence method**, a two-dimensional array detector (*Further information 13.1*) detects fluorescence excited by a laser and scattered back from the sample (Fig. 14.41a). If the fluorescing molecules are well separated in the specimen, then it is possible to obtain a map of the distribution of fluorescent molecules in the illuminated area. For example, Fig. 14.41b shows how epifluorescence microscopy can be used to observe single molecules of the major histocompatibility (MHC) protein on the surface of a cell.

Though still a relatively new technique, single-molecule spectroscopy has already been used to address important problems in chemistry and biology. Nearly all the techniques discussed in this text measure the average value of a property in a large ensemble of molecules. Single-molecule methods allow a chemist to study the nature

Fig. 14.40 Image of a $4.5\ \mu\text{m} \times 4.5\ \mu\text{m}$ sample of oxazine-720 dye molecules embedded in a polymer film and obtained with NSOM. Each peak corresponds to a single dye molecule. Reproduced with permission from X.S. Xie. *Acc. Chem. Res.* 1996, **29**, 598.

Fig. 14.41 (a) Layout of an epifluorescence microscope. Laser radiation is diverted to a sample by a special optical filter that reflects radiation with a specified wavelength (in this case the laser excitation wavelength) but transmits radiation with other wavelengths (in this case, wavelengths at which the fluorescent label emits). A CCD detector (see *Further information 13.1*) analyses the spatial distribution of the fluorescence signal from the illuminated area. (b) Observation of fluorescence from single MHC proteins that have been labelled with a fluorescent marker and are bound to the surface of a cell (the area shown has dimensions of $12\ \mu\text{m} \times 12\ \mu\text{m}$). Image provided by Professor W.E. Moerner, Stanford University, USA.

of distributions of physical and chemical properties in an ensemble of molecules. For example, it is possible to measure the fluorescence lifetime of a molecule by moving the laser focus to a location on the sample that contains a molecule and then measuring the decay of fluorescence intensity after excitation with a pulsed laser. Such studies have shown that not every molecule in a sample has the same fluorescence lifetime, probably because each molecule interacts with its immediate environment in a slightly different way. These details are not apparent from conventional measurements of fluorescence lifetimes, in which many molecules are excited electronically and only an average lifetime for the ensemble can be measured.

Checklist of key ideas

- ☐ 1. The selection rules for electronic transitions that are concerned with changes in angular momentum are: $\Delta L = 0, \pm 1$, $\Delta S = 0$, $\Delta \Sigma = 0$, $\Delta \Omega = 0, \pm 1$.
- ☐ 2. The Laporte selection rule (for centrosymmetric molecules) states that the only allowed transitions are transitions that are accompanied by a change of parity.
- ☐ 3. The Franck–Condon principle states that, because the nuclei are so much more massive than the electrons, an electronic transition takes place very much faster than the nuclei can respond.
- ☐ 4. The intensity of an electronic transition is proportional to the Franck–Condon factor, the quantity $|S(v_f, v_i)|^2$, with $S(v_f, v_i) = \langle v_f | v_i \rangle$.
- ☐ 5. Examples of electronic transitions include $d-d$ transitions in d -metal complexes, charge-transfer transitions (a transition in which an electron moves from metal to ligand or from ligand to metal in a complex), $\pi^* \leftarrow \pi$, and $\pi^* \leftarrow n$ transitions.
- ☐ 6. A Jablonski diagram is a schematic diagram of the various types of nonradiative and radiative transitions that can occur in molecules.
- ☐ 7. Fluorescence is the spontaneous emission of radiation arising from a transition between states of the same multiplicity.
- ☐ 8. Phosphorescence is the spontaneous emission of radiation arising from a transition between states of different multiplicity.
- ☐ 9. Intersystem crossing is a nonradiative transition between states of different multiplicity.
- ☐ 10. Internal conversion is a nonradiative transition between states of the same multiplicity.
- ☐ 11. Laser action depends on the achievement of population inversion, an arrangement in which there are more molecules in an upper state than in a lower state, and the stimulated emission of radiation.
- ☐ 12. Resonant modes are the wavelengths that can be sustained by an optical cavity and contribute to the laser action. Q-switching is the modification of the resonance characteristics of the laser cavity and, consequently, of the laser output.
- ☐ 13. Mode locking is a technique for producing pulses of picosecond duration and less by matching the phases of many resonant cavity modes.
- ☐ 14. Applications of lasers in chemistry include multiphoton spectroscopy, Raman spectroscopy, precision-specified transitions, isotope separation, time-resolved spectroscopy, and single-molecule spectroscopy.

Further information

Further information 14.1 Examples of practical lasers

Figure 14.42 summarizes the requirements for an efficient laser. In practice, the requirements can be satisfied by using a variety of different systems, and this section reviews some that are commonly available. We also include some lasers that operate by using other than electronic transitions. Noticeably absent from this discussion are solid state lasers (including the ubiquitous diode lasers), which we discuss in Chapter 20.

Comment 14.3

The web site for this text contains links to databases on the optical properties of laser materials.

Fig. 14.42 A summary of the features needed for efficient laser action.

Gas lasers

Because gas lasers can be cooled by a rapid flow of the gas through the cavity, they can be used to generate high powers. The pumping is normally achieved using a gas that is different from the gas responsible for the laser emission itself.

In the **helium–neon laser** the active medium is a mixture of helium and neon in a mole ratio of about 5:1 (Fig. 14.43). The initial step is the excitation of an He atom to the metastable $1s^1 2s^1$

Fig. 14.43 The transitions involved in a helium–neon laser. The pumping (of the neon) depends on a coincidental matching of the helium and neon energy separations, so excited He atoms can transfer their excess energy to Ne atoms during a collision.

Fig. 14.44 The transitions involved in an argon-ion laser.

configuration by using an electric discharge (the collisions of electrons and ions cause transitions that are not restricted by electric-dipole selection rules). The excitation energy of this transition happens to match an excitation energy of neon, and during an He–Ne collision efficient transfer of energy may occur, leading to the production of highly excited, metastable Ne atoms with unpopulated intermediate states. Laser action generating 633 nm radiation (among about 100 other lines) then occurs.

The **argon-ion laser** (Fig. 14.44), one of a number of ‘ion lasers’, consists of argon at about 1 Torr, through which is passed an electric discharge. The discharge results in the formation of Ar^+ and Ar^{2+} ions in excited states, which undergo a laser transition to a lower state. These ions then revert to their ground states by emitting hard ultraviolet radiation (at 72 nm), and are then neutralized by a series of electrodes in the laser cavity. One of the design problems is to find materials that can withstand this damaging residual radiation. There are many lines in the laser transition because the excited ions may make transitions to many lower states, but two strong emissions from Ar^+ are at 488 nm (blue) and 514 nm (green); other transitions occur elsewhere in the visible region, in the infrared, and in the ultraviolet. The **krypton-ion laser** works similarly. It is less efficient, but gives a wider range of wavelengths, the most intense being at 647 nm (red), but it can also generate yellow, green, and violet lines. Both lasers are widely used in laser light shows (for this application argon and krypton are often used simultaneously in the same cavity) as well as laboratory sources of high-power radiation.

The **carbon dioxide laser** works on a slightly different principle (Fig. 14.45), for its radiation (between 9.2 μm and 10.8 μm , with the strongest emission at 10.6 μm , in the infrared) arises from vibrational transitions. Most of the working gas is nitrogen, which becomes vibrationally excited by electronic and ionic collisions in an electric discharge. The vibrational levels happen to coincide with the ladder of antisymmetric stretch (v_3 , see Fig. 13.40) energy levels of CO_2 , which pick up the energy during a collision. Laser action then occurs from the lowest excited level of v_3 to the lowest excited level of the symmetric stretch (v_1), which has remained unpopulated during the collisions. This transition is allowed by anharmonicities in the molecular potential energy. Some helium is included in the gas to

Fig. 14.45 The transitions involved in a carbon dioxide laser. The pumping also depends on the coincidental matching of energy separations; in this case the vibrationally excited N_2 molecules have excess energies that correspond to a vibrational excitation of the antisymmetric stretch of CO_2 . The laser transition is from $v_3 = 1$ to $v_1 = 1$.

help remove energy from this state and maintain the population inversion.

In a **nitrogen laser**, the efficiency of the stimulated transition (at 337 nm, in the ultraviolet, the transition $\text{C}^3\Pi_u \rightarrow \text{B}^3\Pi_g$) is so great that a single passage of a pulse of radiation is enough to generate laser radiation and mirrors are unnecessary: such lasers are said to be **superradiant**.

Chemical and exciplex lasers

Chemical reactions may also be used to generate molecules with nonequilibrium, inverted populations. For example, the photolysis of Cl_2 leads to the formation of Cl atoms which attack H_2 molecules in the mixture and produce HCl and H. The latter then attacks Cl_2 to produce vibrationally excited (‘hot’) HCl molecules. Because the newly formed HCl molecules have nonequilibrium vibrational populations, laser action can result as they return to lower states. Such processes are remarkable examples of the direct conversion of chemical energy into coherent electromagnetic radiation.

The population inversion needed for laser action is achieved in a more underhand way in **exciplex lasers**, for in these (as we shall see) the lower state does not effectively exist. This odd situation is achieved by forming an **exciplex**, a combination of two atoms that survives only in an excited state and which dissociates as soon as the excitation energy has been discarded. An exciplex can be formed in a mixture of xenon, chlorine, and neon (which acts as a buffer gas). An electric discharge through the mixture produces excited Cl atoms, which attach to the Xe atoms to give the exciplex XeCl^* . The exciplex survives for about 10 ns, which is time for it to participate in laser action at 308 nm (in the ultraviolet). As soon as XeCl^* has discarded a

Fig. 14.46 The molecular potential energy curves for an exciplex. The species can survive only as an excited state, because on discarding its energy it enters the lower, dissociative state. Because only the upper state can exist, there is never any population in the lower state.

photon, the atoms separate because the molecular potential energy curve of the ground state is dissociative, and the ground state of the exciplex cannot become populated (Fig. 14.46). The KrF^* exciplex laser is another example: it produces radiation at 249 nm.

Comment 14.4

The term ‘excimer laser’ is also widely encountered and used loosely when ‘exciplex laser’ is more appropriate. An exciplex has the form AB^* whereas an excimer, an excited dimer, is AA^* .

Dye lasers

Gas lasers and most solid state lasers operate at discrete frequencies and, although the frequency required may be selected by suitable optics, the laser cannot be tuned continuously. The tuning problem is overcome by using a titanium sapphire laser (see above) or a **dye laser**, which has broad spectral characteristics because the solvent broadens the vibrational structure of the transitions into bands. Hence, it is possible to scan the wavelength continuously (by rotating the diffraction grating in the cavity) and achieve laser action at any chosen wavelength. A commonly used dye is rhodamine 6G in methanol (Fig. 14.47). As the gain is very high, only a short length of

Fig. 14.47 The optical absorption spectrum of the dye Rhodamine 6G and the region used for laser action.

the optical path need be through the dye. The excited states of the active medium, the dye, are sustained by another laser or a flash lamp, and the dye solution is flowed through the laser cavity to avoid thermal degradation (Fig. 14.48).

Fig. 14.48 The configuration used for a dye laser. The dye is flowed through the cell inside the laser cavity. The flow helps to keep it cool and prevents degradation.

Discussion questions

14.1 Explain the origin of the term symbol $^3\Sigma_g^-$ for the ground state of dioxygen.

14.2 Explain the basis of the Franck–Condon principle and how it leads to the formation of a vibrational progression.

14.3 How do the band heads in P and R branches arise? Could the Q branch show a head?

14.4 Explain how colour can arise from molecules.

14.5 Describe the mechanism of fluorescence. To what extent is a fluorescence spectrum not the exact mirror image of the corresponding absorption spectrum?

14.6 What is the evidence for the correctness of the mechanism of fluorescence?

14.7 Describe the principles of laser action, with actual examples.

14.8 What features of laser radiation are applied in chemistry? Discuss two applications of lasers in chemistry.

Exercises

14.1a The term symbol for the ground state of N_2^+ is $^2\Sigma_g^+$. What is the total spin and total orbital angular momentum of the molecule? Show that the term symbol agrees with the electron configuration that would be predicted using the building-up principle.

14.1b One of the excited states of the C_2 molecule has the valence electron configuration $1\sigma_g^2 1\sigma_u^2 1\pi_u^3 1\pi_g^1$. Give the multiplicity and parity of the term.

14.2a The molar absorption coefficient of a substance dissolved in hexane is known to be $855 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$ at 270 nm. Calculate the percentage reduction in intensity when light of that wavelength passes through 2.5 mm of a solution of concentration $3.25 \text{ mmol dm}^{-3}$.

14.2b The molar absorption coefficient of a substance dissolved in hexane is known to be $327 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$ at 300 nm. Calculate the percentage reduction in intensity when light of that wavelength passes through 1.50 mm of a solution of concentration $2.22 \text{ mmol dm}^{-3}$.

14.3a A solution of an unknown component of a biological sample when placed in an absorption cell of path length 1.00 cm transmits 20.1 per cent of light of 340 nm incident upon it. If the concentration of the component is $0.111 \text{ mmol dm}^{-3}$, what is the molar absorption coefficient?

14.3b When light of wavelength 400 nm passes through 3.5 mm of a solution of an absorbing substance at a concentration $0.667 \text{ mmol dm}^{-3}$, the transmission is 65.5 per cent. Calculate the molar absorption coefficient of the solute at this wavelength and express the answer in $\text{cm}^2 \text{ mol}^{-1}$.

14.4a The molar absorption coefficient of a solute at 540 nm is $286 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$. When light of that wavelength passes through a 6.5 mm cell containing a solution of the solute, 46.5 per cent of the light is absorbed. What is the concentration of the solution?

14.4b The molar absorption coefficient of a solute at 440 nm is $323 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$. When light of that wavelength passes through a 7.50 mm cell containing a solution of the solute, 52.3 per cent of the light is absorbed. What is the concentration of the solution?

14.5a The absorption associated with a particular transition begins at 230 nm, peaks sharply at 260 nm, and ends at 290 nm. The maximum value of the molar absorption coefficient is $1.21 \times 10^4 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$. Estimate the integrated absorption coefficient of the transition assuming a triangular lineshape (see eqn 13.5).

14.5b The absorption associated with a certain transition begins at 199 nm, peaks sharply at 220 nm, and ends at 275 nm. The maximum value of the molar absorption coefficient is $2.25 \times 10^4 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$. Estimate the integrated absorption coefficient of the transition assuming an inverted parabolic lineshape (Fig. 14.49; use eqn 13.5).

14.6a The two compounds, 2,3-dimethyl-2-butene and 2,5-dimethyl-2,4-hexadiene, are to be distinguished by their ultraviolet absorption spectra. The maximum absorption in one compound occurs at 192 nm and in the other at 243 nm. Match the maxima to the compounds and justify the assignment.

14.6b 1,3,5-hexatriene (a kind of 'linear' benzene) was converted into benzene itself. On the basis of a free-electron molecular orbital model (in which hexatriene is treated as a linear box and benzene as a ring), would you expect the lowest energy absorption to rise or fall in energy?

14.7a The following data were obtained for the absorption by Br_2 in carbon tetrachloride using a 2.0 mm cell. Calculate the molar absorption coefficient of bromine at the wavelength employed:

$[\text{Br}_2]/(\text{mol dm}^{-3})$	0.0010	0.0050	0.0100	0.0500
$T/(\text{per cent})$	81.4	35.6	12.7	3.0×10^{-3}

Fig. 14.49

14.7b The following data were obtained for the absorption by a dye dissolved in methylbenzene using a 2.50 mm cell. Calculate the molar absorption coefficient of the dye at the wavelength employed:

$[\text{dye}]/(\text{mol dm}^{-3})$	0.0010	0.0050	0.0100	0.0500
$T/(\text{per cent})$	73	21	4.2	1.33×10^{-5}

14.8a A 2.0-mm cell was filled with a solution of benzene in a non-absorbing solvent. The concentration of the benzene was $0.010 \text{ mol dm}^{-3}$ and the wavelength of the radiation was 256 nm (where there is a maximum in the absorption). Calculate the molar absorption coefficient of benzene at this wavelength given that the transmission was 48 per cent. What will the transmittance be in a 4.0-mm cell at the same wavelength?

14.8b A 2.50-mm cell was filled with a solution of a dye. The concentration of the dye was $15.5 \text{ mmol dm}^{-3}$. Calculate the molar absorption coefficient of benzene at this wavelength given that the transmission was 32 per cent. What will the transmittance be in a 4.50-mm cell at the same wavelength?

14.9a A swimmer enters a gloomier world (in one sense) on diving to greater depths. Given that the mean molar absorption coefficient of sea water in the visible region is $6.2 \times 10^{-3} \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$, calculate the depth at which a diver will experience (a) half the surface intensity of light, (b) one tenth the surface intensity.

14.9b Given that the maximum molar absorption coefficient of a molecule containing a carbonyl group is $30 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$ near 280 nm, calculate the thickness of a sample that will result in (a) half the initial intensity of radiation, (b) one-tenth the initial intensity.

14.10a The electronic absorption bands of many molecules in solution have half-widths at half-height of about 5000 cm^{-1} . Estimate the integrated absorption coefficients of bands for which (a) $\epsilon_{\text{max}} \approx 1 \times 10^4 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$, (b) $\epsilon_{\text{max}} \approx 5 \times 10^2 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$.

14.10b The electronic absorption band of a compound in solution had a Gaussian lineshape and a half-width at half-height of 4233 cm^{-1} and $\epsilon_{\text{max}} = 1.54 \times 10^4 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$. Estimate the integrated absorption coefficient.

14.11a The photoionization of H_2 by 21 eV photons produces H_2^+ . Explain why the intensity of the $\nu = 2 \leftarrow 0$ transition is stronger than that of the $0 \leftarrow 0$ transition.

14.11b The photoionization of F_2 by 21 eV photons produces F_2^+ . Would you expect the $2 \leftarrow 0$ transition to be weaker or stronger than the $0 \leftarrow 0$ transition? Justify your answer.

Problems*

Numerical problems

14.1 The vibrational wavenumber of the oxygen molecule in its electronic ground state is 1580 cm^{-1} , whereas that in the first excited state ($B\ ^3\Sigma_u^-$), to which there is an allowed electronic transition, is 700 cm^{-1} . Given that the separation in energy between the minima in their respective potential energy curves of these two electronic states is 6.175 eV , what is the wavenumber of the lowest energy transition in the band of transitions originating from the $v=0$ vibrational state of the electronic ground state to this excited state? Ignore any rotational structure or anharmonicity.

14.2 A Birge–Sponer extrapolation yields 7760 cm^{-1} as the area under the curve for the B state of the oxygen molecule described in Problem 14.1. Given that the B state dissociates to ground-state atoms (at zero energy, ^3P) and $15\,870\text{ cm}^{-1}$ (^1D) and the lowest vibrational state of the B state is $49\,363\text{ cm}^{-1}$ above the lowest vibrational state of the ground electronic state, calculate the dissociation energy of the molecular ground state to the ground-state atoms.

14.3 The electronic spectrum of the IBr molecule shows two low-lying, well defined convergence limits at $14\,660$ and $18\,345\text{ cm}^{-1}$. Energy levels for the iodine and bromine atoms occur at 0 , 7598 ; and 0 , 3685 cm^{-1} , respectively. Other atomic levels are at much higher energies. What possibilities exist for the numerical value of the dissociation energy of IBr? Decide which is the correct possibility by calculating this quantity from $\Delta_f H^\circ(\text{IBr}, g) = +40.79\text{ kJ mol}^{-1}$ and the dissociation energies of $\text{I}_2(g)$ and $\text{Br}_2(g)$ which are 146 and 190 kJ mol^{-1} , respectively.

14.4 In many cases it is possible to assume that an absorption band has a Gaussian lineshape (one proportional to e^{-x^2}) centred on the band maximum. Assume such a line shape, and show that $A \approx 1.0645 \epsilon_{\text{max}} \Delta \tilde{\nu}_{1/2}$, where $\Delta \tilde{\nu}_{1/2}$ is the width at half-height. The absorption spectrum of azoethane ($\text{CH}_3\text{CH}_2\text{N}_2$) between $24\,000\text{ cm}^{-1}$ and $34\,000\text{ cm}^{-1}$ is shown in Fig. 14.50. First, estimate A for the band by assuming that it is Gaussian. Then integrate the absorption band graphically. The latter can be done either by ruling and counting squares, or by tracing the lineshape on to paper and weighing. A more sophisticated procedure would be to use mathematical software to fit a

Fig. 14.50

polynomial to the absorption band (or a Gaussian), and then to integrate the result analytically.

14.5 A lot of information about the energy levels and wavefunctions of small inorganic molecules can be obtained from their ultraviolet spectra. An example of a spectrum with considerable vibrational structure, that of gaseous SO_2 at 25°C , is shown in Fig. 14.6. Estimate the integrated absorption coefficient for the transition. What electronic states are accessible from the A_1 ground state of this C_v molecule by electric dipole transitions?

14.6‡ J.G. Dojahn, E.C.M. Chen, and W.E. Wentworth (*J. Phys. Chem.* **100**, 9649 (1996)) characterized the potential energy curves of the ground and electronic states of homonuclear diatomic halogen anions. These anions have a $^2\Sigma_u^+$ ground state and $^2\Pi_g$, $^2\Pi_u$, and $^2\Sigma_g^+$ excited states. To which of the excited states are transitions by absorption of photons allowed? Explain.

14.7 A transition of particular importance in O_2 gives rise to the ‘Schumann–Runge band’ in the ultraviolet region. The wavenumbers (in cm^{-1}) of transitions from the ground state to the vibrational levels of the first excited state ($^3\Sigma_u^-$) are $50\,062.6$, $50\,725.4$, $51\,369.0$, $51\,988.6$, $52\,579.0$, $53\,143.4$, $53\,679.6$, $54\,177.0$, $54\,641.8$, $55\,078.2$, $55\,460.0$, $55\,803.1$, $56\,107.3$, $56\,360.3$, $56\,570.6$. What is the dissociation energy of the upper electronic state? (Use a Birge–Sponer plot.) The same excited state is known to dissociate into one ground-state O atom and one excited-state atom with an energy 190 kJ mol^{-1} above the ground state. (This excited atom is responsible for a great deal of photochemical mischief in the atmosphere.) Ground-state O_2 dissociates into two ground-state atoms. Use this information to calculate the dissociation energy of ground-state O_2 from the Schumann–Runge data.

14.8 The compound $\text{CH}_3\text{CH}=\text{CHCHO}$ has a strong absorption in the ultraviolet at $46\,950\text{ cm}^{-1}$ and a weak absorption at $30\,000\text{ cm}^{-1}$. Justify these features in terms of the structure of the molecule.

14.9 Aromatic hydrocarbons and I_2 form complexes from which charge-transfer electronic transitions are observed. The hydrocarbon acts as an electron donor and I_2 as an electron acceptor. The energies $h\nu_{\text{max}}$ of the charge-transfer transitions for a number of hydrocarbon– I_2 complexes are given below:

Hydrocarbon	benzene	biphenyl	naphthalene	phenanthrene	pyrene	anthracene
$h\nu_{\text{max}}/\text{eV}$	4.184	3.654	3.452	3.288	2.989	2.890

Investigate the hypothesis that there is a correlation between the energy of the HOMO of the hydrocarbon (from which the electron comes in the charge-transfer transition) and $h\nu_{\text{max}}$. Use one of the molecular electronic structure methods discussed in Chapter 11 to determine the energy of the HOMO of each hydrocarbon in the data set.¹

14.10 A certain molecule fluoresces at a wavelength of 400 nm with a half-life of 1.0 ns . It phosphoresces at 500 nm . If the ratio of the transition probabilities for stimulated emission for the $S^* \rightarrow S$ to the $T \rightarrow S$ transitions is 1.0×10^5 , what is the half-life of the phosphorescent state?

14.11 Consider some of the precautions that must be taken when conducting single-molecule spectroscopy experiments. (a) What is the molar concentration of a solution in which there is, on average, one solute molecule in $1.0\ \mu\text{m}^3$ (1.0 fL) of solution? (b) It is important to use pure solvents in single-molecule spectroscopy because optical signals from fluorescent

* Problems denoted with the symbol ‡ were supplied by Charles Trapp and Carmen Giunta.

¹ The web site contains links to molecular modelling freeware and to other sites where you may perform molecular orbital calculations directly from your web browser.

impurities in the solvent may mask optical signals from the solute. Suppose that water containing a fluorescent impurity of molar mass 100 g mol^{-1} is used as solvent and that analysis indicates the presence of 0.10 mg of impurity per 1.0 kg of solvent. On average, how many impurity molecules will be present in $1.0 \mu\text{m}^3$ of solution? You may take the density of water as 1.0 g cm^{-3} . Comment on the suitability of this solvent for single-molecule spectroscopy experiments.

14.12 Light-induced degradation of molecules, also called *photobleaching*, is a serious problem in single-molecule spectroscopy. A molecule of a fluorescent dye commonly used to label biopolymers can withstand about 10^6 excitations by photons before light-induced reactions destroy its π system and the molecule no longer fluoresces. For how long will a single dye molecule fluoresce while being excited by 1.0 mW of 488 nm radiation from a continuous-wave argon ion laser? You may assume that the dye has an absorption spectrum that peaks at 488 nm and that every photon delivered by the laser is absorbed by the molecule.

Theoretical problems

14.13 Assume that the electronic states of the π electrons of a conjugated molecule can be approximated by the wavefunctions of a particle in a one-dimensional box, and that the dipole moment can be related to the displacement along this length by $\mu = -ex$. Show that the transition probability for the transition $n = 1 \rightarrow n = 2$ is nonzero, whereas that for $n = 1 \rightarrow n = 3$ is zero. *Hint.* The following relations will be useful:

$$\sin x \sin y = \frac{1}{2} \cos(x - y) - \frac{1}{2} \cos(x + y)$$

$$\int x \cos ax \, dx = \frac{1}{a^2} \cos ax + \frac{x}{a} \sin ax$$

14.14 Use a group theoretical argument to decide which of the following transitions are electric-dipole allowed: (a) the $\pi^* \leftarrow \pi$ transition in ethene, (b) the $\pi^* \leftarrow n$ transition in a carbonyl group in a C_{2v} environment.

14.15 Suppose that you are a colour chemist and had been asked to intensify the colour of a dye without changing the type of compound, and that the dye in question was a polyene. Would you choose to lengthen or to shorten the chain? Would the modification to the length shift the apparent colour of the dye towards the red or the blue?

14.16 One measure of the intensity of a transition of frequency ν is the *oscillator strength*, f , which is defined as

$$f = \frac{8\pi^2 m_e \nu |\mu_{fi}|^2}{3\hbar e^2}$$

Consider an electron in an atom to be oscillating harmonically in one dimension (the three-dimensional version of this model was used in early attempts to describe atomic structure). The wavefunctions for such an electron are those in Table 9.1. Show that the oscillator strength for the transition of this electron from its ground state is exactly $\frac{1}{3}$.

14.17 Estimate the oscillator strength (see Problem 14.16) of a charge-transfer transition modelled as the migration of an electron from an H1s orbital on one atom to another H1s orbital on an atom a distance R away. Approximate the transition moment by $-eRS$ where S is the overlap integral of the two orbitals. Sketch the oscillator strength as a function of R using the curve for S given in Fig. 11.29. Why does the intensity fall to zero as R approaches 0 and infinity?

14.18 The line marked A in Fig. 14.51 is the fluorescence spectrum of benzophenone in solid solution in ethanol at low temperatures observed when the sample is illuminated with 360 nm light. What can be said about the vibrational energy levels of the carbonyl group in (a) its ground electronic state and (b) its excited electronic state? When naphthalene is illuminated with 360 nm light it does not absorb, but the line marked B in

Fig. 14.51

the illustration is the phosphorescence spectrum of a solid solution of a mixture of naphthalene and benzophenone in ethanol. Now a component of fluorescence from naphthalene can be detected. Account for this observation.

14.19 The fluorescence spectrum of anthracene vapour shows a series of peaks of increasing intensity with individual maxima at 440 nm , 410 nm , 390 nm , and 370 nm followed by a sharp cut-off at shorter wavelengths. The absorption spectrum rises sharply from zero to a maximum at 360 nm with a trail of peaks of lessening intensity at 345 nm , 330 nm , and 305 nm . Account for these observations.

14.20 The Beer–Lambert law states that the absorbance of a sample at a wavenumber $\bar{\nu}$ is proportional to the molar concentration $[J]$ of the absorbing species J and to the length l of the sample (eqn 13.4). In this problem you will show that the intensity of fluorescence emission from a sample of J is also proportional to $[J]$ and l . Consider a sample of J that is illuminated with a beam of intensity $I_0(\bar{\nu})$ at the wavenumber $\bar{\nu}$. Before fluorescence can occur, a fraction of $I_0(\bar{\nu})$ must be absorbed and an intensity $I(\bar{\nu})$ will be transmitted. However, not all of the absorbed intensity is emitted and the intensity of fluorescence depends on the fluorescence quantum yield, ϕ_f , the efficiency of photon emission. The fluorescence quantum yield ranges from 0 to 1 and is proportional to the ratio of the integral of the fluorescence spectrum over the integrated absorption coefficient. Because of a Stokes shift of magnitude $\Delta\bar{\nu}_{\text{Stokes}}$, fluorescence occurs at a wavenumber $\bar{\nu}_f$ with $\bar{\nu}_f + \Delta\bar{\nu}_{\text{Stokes}} = \bar{\nu}$. It follows that the fluorescence intensity at $\bar{\nu}_f$, $I_f(\bar{\nu}_f)$, is proportional to ϕ_f and to the intensity of exciting radiation that is absorbed by J , $I_{\text{abs}}(\bar{\nu}) = I_0(\bar{\nu}) - I(\bar{\nu})$. (a) Use the Beer–Lambert law to express $I_{\text{abs}}(\bar{\nu})$ in terms of $I_0(\bar{\nu})$, $[J]$, l , and $\epsilon(\bar{\nu})$, the molar absorption coefficient of J at $\bar{\nu}$. (b) Use your result from part (a) to show that $I_f(\bar{\nu}_f) \propto I_0(\bar{\nu})\epsilon(\bar{\nu})\phi_f[J]l$.

14.21 Spin angular momentum is conserved when a molecule dissociates into atoms. What atom multiplicities are permitted when (a) an O_2 molecule, (b) an N_2 molecule dissociates into atoms?

Applications: to biochemistry, environmental science, and astrophysics

14.22 The protein haemerythrin (Her) is responsible for binding and carrying O_2 in some invertebrates. Each protein molecule has two Fe^{2+} ions that are in very close proximity and work together to bind one molecule of O_2 . The Fe_2O_2 group of oxygenated haemerythrin is coloured and has an electronic absorption band at 500 nm . Figure 14.52 shows the UV-visible absorption spectrum of a derivative of haemerythrin in the presence of different concentrations of CNS^- ions. What may be inferred from the spectrum?

Fig. 14.52

14.23 The flux of visible photons reaching Earth from the North Star is about $4 \times 10^3 \text{ mm}^{-2} \text{ s}^{-1}$. Of these photons, 30 per cent are absorbed or scattered by the atmosphere and 25 per cent of the surviving photons are scattered by the surface of the cornea of the eye. A further 9 per cent are absorbed inside the cornea. The area of the pupil at night is about 40 mm^2 and the response time of the eye is about 0.1 s. Of the photons passing through the pupil, about 43 per cent are absorbed in the ocular medium. How many photons from the North Star are focused on to the retina in 0.1 s? For a continuation of this story, see R.W. Rodieck, *The first steps in seeing*, Sinauer, Sunderland (1998).

14.24 Use molecule (7) as a model of the *trans* conformation of the chromophore found in rhodopsin. In this model, the methyl group bound to the nitrogen atom of the protonated Schiff's base replaces the protein. (a) Using molecular modelling software and the computational method of your instructor's choice, calculate the energy separation between the HOMO and LUMO of (7). (b) Repeat the calculation for the 11-*cis* form of (7). (c) Based on your results from parts (a) and (b), do you expect the experimental frequency for the $\pi^* \leftarrow \pi$ visible absorption of the *trans* form of (7) to be higher or lower than that for the 11-*cis* form of (7)?

14.25† Ozone absorbs ultraviolet radiation in a part of the electromagnetic spectrum energetic enough to disrupt DNA in biological organisms and that is absorbed by no other abundant atmospheric constituent. This spectral range, denoted UV-B, spans the wavelengths of about 290 nm to 320 nm. The molar extinction coefficient of ozone over this range is given in the table below (W.B. DeMore, S.P. Sander, D.M. Golden, R.F. Hampson, M.J. Kurylo, C.J. Howard, A.R. Ravishankara, C.E. Kolb, and M.J. Molina, *Chemical kinetics and photochemical data for use in stratospheric modeling: Evaluation Number 11*, JPL Publication 94–26 (1994)).

λ/nm	292.0	296.3	300.8	305.4	310.1	315.0	320.0
$\epsilon/(\text{dm}^3 \text{ mol}^{-1} \text{ cm}^{-1})$	1512	865	477	257	135.9	69.5	34.5

Compute the integrated absorption coefficient of ozone over the wavelength range 290–320 nm. (Hint. $\epsilon(\tilde{\nu})$ can be fitted to an exponential function quite well.)

14.26† The abundance of ozone is typically inferred from measurements of UV absorption and is often expressed in terms of *Dobson units* (DU): 1 DU is equivalent to a layer of pure ozone 10^{-3} cm thick at 1 atm and 0°C . Compute the absorbance of UV radiation at 300 nm expected for an ozone abundance of 300 DU (a typical value) and 100 DU (a value reached during seasonal Antarctic ozone depletions) given a molar absorption coefficient of $476 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$.

14.27† G.C.G. Wachowsky, R. Horansky, and V. Vaida (*J. Phys. Chem.* **100**, 11559 (1996)) examined the UV absorption spectrum of CH_3I , a species of interest in connection with stratospheric ozone chemistry. They found the integrated absorption coefficient to be dependent on temperature and pressure to an extent inconsistent with internal structural changes in isolated CH_3I molecules; they explained the changes as due to dimerization of a substantial fraction of the CH_3I , a process that would naturally be pressure and temperature dependent. (a) Compute the integrated absorption coefficient over a triangular lineshape in the range $31\,250$ to $34\,483 \text{ cm}^{-1}$ and a maximal molar absorption coefficient of $150 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$ at $31\,250 \text{ cm}^{-1}$. (b) Suppose 1 per cent of the CH_3I units in a sample at 2.4 Torr and 373 K exists as dimers. Compute the absorbance expected at $31\,250 \text{ cm}^{-1}$ in a sample cell of length 12.0 cm. (c) Suppose 18 per cent of the CH_3I units in a sample at 100 Torr and 373 K exists as dimers. Compute the absorbance expected at $31\,250 \text{ cm}^{-1}$ in a sample cell of length 12.0 cm; compute the molar absorption coefficient that would be inferred from this absorbance if dimerization was not considered.

14.28† The molecule Cl_2O_2 is believed to participate in the seasonal depletion of ozone over Antarctica. M. Schwell, H.-W. Jochims, B. Wassermann, U. Rockland, R. Flesch, and E. Rühl (*J. Phys. Chem.* **100**, 10070 (1996)) measured the ionization energies of Cl_2O_2 by photoelectron spectroscopy in which the ionized fragments were detected using a mass spectrometer. From their data, we can infer that the ionization enthalpy of Cl_2O_2 is 11.05 eV and the enthalpy of the dissociative ionization $\text{Cl}_2\text{O}_2 \rightarrow \text{Cl} + \text{OCIO}^+ + e^-$ is 10.95 eV. They used this information to make some inferences about the structure of Cl_2O_2 . Computational studies had suggested that the lowest energy isomer is ClOOCl , but that ClClO_2 (C_{2v}) and ClOClO are not very much higher in energy. The Cl_2O_2 in the photoionization step is the lowest energy isomer, whatever its structure may be, and its enthalpy of formation had previously been reported as $+133 \text{ kJ mol}^{-1}$. The Cl_2O_2 in the dissociative ionization step is unlikely to be ClOOCl , for the product can be derived from it only with substantial rearrangement. Given $\Delta_f H^\circ(\text{OCIO}^+) = +1096 \text{ kJ mol}^{-1}$ and $\Delta_f H^\circ(e^-) = 0$, determine whether the Cl_2O_2 in the dissociative ionization is the same as that in the photoionization. If different, how much greater is its $\Delta_f H^\circ$? Are these results consistent with or contradictory to the computational studies?

14.29† One of the principal methods for obtaining the electronic spectra of unstable radicals is to study the spectra of comets, which are almost entirely due to radicals. Many radical spectra have been found in comets, including that due to CN. These radicals are produced in comets by the absorption of far ultraviolet solar radiation by their parent compounds. Subsequently, their fluorescence is excited by sunlight of longer wavelength. The spectra of comet Hale–Bopp (C/1995 O1) have been the subject of many recent studies. One such study is that of the fluorescence spectrum of CN in the comet at large heliocentric distances by R.M. Wagner and D.G. Schleicher (*Science* **275**, 1918 (1997)), in which the authors determine the spatial distribution and rate of production of CN in the coma. The (0–0) vibrational band is centred on 387.6 nm and the weaker (1–1) band with relative intensity 0.1 is centred on 386.4 nm. The band heads for (0–0) and (0–1) are known to be 388.3 and 421.6 nm, respectively. From these data, calculate the energy of the excited S_1 state relative to the ground S_0 state, the vibrational wavenumbers and the difference in the vibrational wavenumbers of the two states, and the relative populations of the $v = 0$ and $v = 1$ vibrational levels of the S_1 state. Also estimate the effective temperature of the molecule in the excited S_1 state. Only eight rotational levels of the S_1 state are thought to be populated. Is that observation consistent with the effective temperature of the S_1 state?

Molecular spectroscopy 3: magnetic resonance

One of the most widely used spectroscopic procedures in chemistry makes use of the classical concept of resonance. The chapter begins with an account of conventional nuclear magnetic resonance, which shows how the resonance frequency of a magnetic nucleus is affected by its electronic environment and the presence of magnetic nuclei in its vicinity. Then we turn to the modern versions of NMR, which are based on the use of pulses of electromagnetic radiation and the processing of the resulting signal by Fourier transform techniques. The experimental techniques for electron paramagnetic resonance resemble those used in the early days of NMR. The information obtained is very useful for the determination of the properties of species with unpaired electrons.

When two pendulums share a slightly flexible support and one is set in motion, the other is forced into oscillation by the motion of the common axle. As a result, energy flows between the two pendulums. The energy transfer occurs most efficiently when the frequencies of the two pendulums are identical. The condition of strong effective coupling when the frequencies of two oscillators are identical is called **resonance**. Resonance is the basis of a number of everyday phenomena, including the response of radios to the weak oscillations of the electromagnetic field generated by a distant transmitter. In this chapter we explore some spectroscopic applications that, as originally developed (and in some cases still), depend on matching a set of energy levels to a source of monochromatic radiation and observing the strong absorption that occurs at resonance.

The effect of magnetic fields on electrons and nuclei

The Stern–Gerlach experiment (Section 9.8) provided evidence for electron spin. It turns out that many nuclei also possess spin angular momentum. Orbital and spin angular momenta give rise to magnetic moments, and to say that electrons and nuclei have magnetic moments means that, to some extent, they behave like small bar magnets. First, we establish how the energies of electrons and nuclei depend on the strength of an external field. Then we see how to use this dependence to study the structure and dynamics of complex molecules.

15.1 The energies of electrons in magnetic fields

Classically, the energy of a magnetic moment μ in a magnetic field $\mathcal{B}$ is equal to the scalar product

Problems

Comment 15.1

More formally, $\mathcal{B}$ is the magnetic induction and is measured in tesla, T; $1 \text{ T} = 1 \text{ kg s}^{-2} \text{ A}^{-1}$. The (non-SI) unit gauss, G, is also occasionally used: $1 \text{ T} = 10^4 \text{ G}$.

Comment 15.2

The scalar product (or 'dot product') of two vectors $\mathbf{a}$ and $\mathbf{b}$ is given by $\mathbf{a} \cdot \mathbf{b} = ab \cos \theta$, where a and b are the magnitudes of $\mathbf{a}$ and $\mathbf{b}$, respectively, and θ is the angle between them.

$$E = -\boldsymbol{\mu} \cdot \mathcal{B} \quad (15.1)$$

Quantum mechanically, we write the hamiltonian as

$$\hat{H} = -\hat{\boldsymbol{\mu}} \cdot \mathcal{B} \quad (15.2)$$

To write an expression for $\hat{\boldsymbol{\mu}}$, we recall from Section 9.8 that the magnetic moment is proportional to the angular momentum. For an electron possessing orbital angular momentum we write

$$\hat{\boldsymbol{\mu}} = \gamma_e \hat{\mathbf{l}} \quad \text{and} \quad \hat{H} = -\gamma_e \mathcal{B} \cdot \hat{\mathbf{l}} \quad (15.3)$$

where $\hat{\mathbf{l}}$ is the orbital angular momentum operator and

$$\gamma_e = -\frac{e}{2m_e} \quad (15.4)$$

γ_e is called the **magnetogyric ratio** of the electron: The negative sign (arising from the sign of the electron's charge) shows that the orbital moment is antiparallel to its orbital angular momentum (as was depicted in Fig 10.26).

For a magnetic field $\mathcal{B}_0$ along the z -direction, eqn 15.3 becomes

$$\hat{\mu}_z = \gamma_e \hat{l}_z \quad \text{and} \quad \hat{H} = -\gamma_e \mathcal{B}_0 \hat{l}_z = -\hat{\mu}_z \mathcal{B}_0 \quad (15.5a)$$

Because the eigenvalues of the operator $\hat{l}_z$ are $m_l \hbar$, the z -component of the orbital magnetic moment and the energy of interaction are, respectively,

$$\mu_z = \gamma_e m_l \hbar \quad \text{and} \quad E = -\gamma_e m_l \hbar \mathcal{B}_0 = m_l \mu_B \mathcal{B}_0 \quad (15.5b)$$

where the **Bohr magneton**, μ_B , is

$$\mu_B = -\gamma_e \hbar = \frac{e\hbar}{2m_e} = 9.724 \times 10^{-24} \text{ J T}^{-1} \quad [15.6]$$

The Bohr magneton is often regarded as the fundamental quantum of magnetic moment.

The spin magnetic moment of an electron, which has a spin quantum number $s = \frac{1}{2}$ (Section 9.8), is also proportional to its spin angular momentum. However, instead of eqn 15.3, the spin magnetic moment and hamiltonian operators are, respectively,

$$\hat{\boldsymbol{\mu}} = g_e \gamma_e \hat{\mathbf{s}} \quad \text{and} \quad \hat{H} = -g_e \gamma_e \mathcal{B} \cdot \hat{\mathbf{s}} \quad (15.7)$$

where $\hat{\mathbf{s}}$ is the spin angular momentum operator and the extra factor g_e is called the **g-value** of the electron: $g_e = 2.002\,319 \dots$. The g -value arises from relativistic effects and from interactions of the electron with the electromagnetic fluctuations of the vacuum that surrounds the electron. For a magnetic field $\mathcal{B}_0$ in the z -direction,

$$\hat{\mu}_z = g_e \gamma_e \hat{s}_z \quad \text{and} \quad \hat{H} = -g_e \gamma_e \mathcal{B}_0 \hat{s}_z \quad (15.8a)$$

Because the eigenvalues of the operator $\hat{s}_z$ are $m_s \hbar$ with $m_s = +\frac{1}{2}(\alpha)$ and $m_s = -\frac{1}{2}(\beta)$, it follows that the energies of an electron spin in a magnetic field are

$$\mu_z = g_e \gamma_e m_s \hbar \quad \text{and} \quad E_{m_s} = -g_e \gamma_e m_s \hbar \mathcal{B}_0 = g_e \mu_B m_s \mathcal{B}_0 \quad (15.8b)$$

with $m_s = \pm \frac{1}{2}$.

In the absence of a magnetic field, the states with different values of m_l and m_s are degenerate. When a field is present, the degeneracy is removed: the state with $m_s = +\frac{1}{2}$ moves up in energy by $\frac{1}{2} g_e \mu_B \mathcal{B}_0$ and the state with $m_s = -\frac{1}{2}$ moves down by $\frac{1}{2} g_e \mu_B \mathcal{B}_0$. The different energies arising from an interaction with an external field are sometimes represented on the vector model by picturing the vectors as **precessing**, or sweeping

Table 15.1 Nuclear constitution and the nuclear spin quantum number*

Number of protons	Number of neutrons	I
even	even	0
odd	odd	integer (1, 2, 3, ...)
even	odd	half-integer ($\frac{1}{2}, \frac{3}{2}, \frac{5}{2}, \dots$)
odd	even	half-integer ($\frac{1}{2}, \frac{3}{2}, \frac{5}{2}, \dots$)

* The spin of a nucleus may be different if it is in an excited state; throughout this chapter we deal only with the ground state of nuclei.

round their cones (Fig. 15.1), with the rate of precession equal to the **Larmor frequency**, ν_L :

$$\nu_L = \frac{\gamma_e \mathcal{B}_0}{2\pi} \quad (15.9)$$

Equation 15.9 shows that the Larmor frequency increases with the strength of the magnetic field. For a field of 1 T, the Larmor frequency is 30 GHz.

15.2 The energies of nuclei in magnetic fields

The spin quantum number, I , of a nucleus is a fixed characteristic property of a nucleus and is either an integer or a half-integer (Table 15.1). A nucleus with spin quantum number I has the following properties:

1. An angular momentum of magnitude $\{I(I+1)\}^{1/2}\hbar$.
2. A component of angular momentum $m_I\hbar$ on a specified axis ('the z -axis'), where $m_I = I, I-1, \dots, -I$.
3. If $I > 0$, a magnetic moment with a constant magnitude and an orientation that is determined by the value of m_I .

According to the second property, the spin, and hence the magnetic moment, of the nucleus may lie in $2I+1$ different orientations relative to an axis. A proton has $I = \frac{1}{2}$ and its spin may adopt either of two orientations; a ^{14}N nucleus has $I = 1$ and its spin may adopt any of three orientations; both ^{12}C and ^{16}O have $I = 0$ and hence zero magnetic moment.

The energy of interaction between a nucleus with a magnetic moment $\boldsymbol{\mu}$ and an external magnetic field $\boldsymbol{\mathcal{B}}$ may be calculated by using operators analogous to those of eqn 15.3:

$$\hat{\boldsymbol{\mu}} = \gamma \hat{\mathbf{I}} \quad \text{and} \quad H = -\gamma \boldsymbol{\mathcal{B}} \cdot \hat{\mathbf{I}} \quad (15.10a)$$

where γ is the magnetogyric ratio of the specified nucleus, an empirically determined characteristic arising from the internal structure of the nucleus (Table 15.2). The corresponding energies are

$$E_{m_I} = -\mu_z \mathcal{B}_0 = -\gamma \hbar \mathcal{B}_0 m_I \quad (15.10b)$$

As for electrons, the nuclear spin may be pictured as precessing around the direction of the applied field at a rate proportional to the applied field. For protons, a field of 1 T corresponds to a Larmor frequency (eqn 15.9, with γ_e replaced by γ) of about 40 MHz.

Fig. 15.1 The interactions between the m_s states of an electron and an external magnetic field may be visualized as the precession of the vectors representing the angular momentum.

Synoptic table 15.2* Nuclear spin properties

Nuclide	Natural abundance/%	Spin I	g -factor, g_I	Magnetogyric ratio, $\gamma/(10^7 \text{ T}^{-1} \text{ s}^{-1})$	NMR frequency at 1 T, ν/MHz
^1n		$\frac{1}{2}$	-3.826	-18.32	29.165
^1H	99.98	$\frac{1}{2}$	5.586	26.75	42.577

^{13}C	1.11	$\frac{1}{2}$	1.405	6.73	10.705
^{14}N	99.64	1	0.404	1.93	3.076

* More values are given in the *Data section*.

The magnetic moment of a nucleus is sometimes expressed in terms of the **nuclear g -factor**, g_I , a characteristic of the nucleus, and the **nuclear magneton**, μ_N , a quantity independent of the nucleus, by using

$$\gamma\hbar = g_I\mu_N \quad \mu_N = \frac{e\hbar}{2m_p} = 5.051 \times 10^{-27} \text{ J T}^{-1} \quad [15.11]$$

where m_p is the mass of the proton. Nuclear g -factors vary between -6 and $+6$ (see Table 15.2): positive values of g_I and γ denote a magnetic moment that is parallel to the spin; negative values indicate that the magnetic moment and spin are antiparallel. For the remainder of this chapter we shall assume that γ is positive, as is the case for the majority of nuclei. In such cases, the states with negative values of m_I lie above states with positive values of m_I . The nuclear magneton is about 2000 times smaller than the Bohr magneton, so nuclear magnetic moments—and consequently the energies of interaction with magnetic fields—are about 2000 times weaker than the electron spin magnetic moment.

Fig. 15.2 Electron spin levels in a magnetic field. Note that the β state is lower in energy than the α state (because the magnetogyric ratio of an electron is negative). Resonance is achieved when the frequency of the incident radiation matches the frequency corresponding to the energy separation.

15.3 Magnetic resonance spectroscopy

In its original form, the magnetic resonance experiment is the resonant absorption of radiation by nuclei or unpaired electrons in a magnetic field. From eqn 15.8b, the separation between the $m_s = -\frac{1}{2}$ and $m_s = +\frac{1}{2}$ levels of an electron spin in a magnetic field B_0 is

$$\Delta E = E_\alpha - E_\beta = g_e\mu_B B_0 \quad (15.12a)$$

If the sample is exposed to radiation of frequency ν , the energy separations come into resonance with the radiation when the frequency satisfies the **resonance condition** (Fig. 15.2):

$$h\nu = g_e\mu_B B_0 \quad (15.12b)$$

At resonance there is strong coupling between the electron spins and the radiation, and strong absorption occurs as the spins make the transition $\beta \rightarrow \alpha$. **Electron paramagnetic resonance** (EPR), or **electron spin resonance** (ESR), is the study of molecules and ions containing unpaired electrons by observing the magnetic fields at which they come into resonance with monochromatic radiation. Magnetic fields of about 0.3 T (the value used in most commercial EPR spectrometers) correspond to resonance with an electromagnetic field of frequency 10 GHz (10^{10} Hz) and wavelength 3 cm. Because 3 cm radiation falls in the microwave region of the electromagnetic spectrum, EPR is a microwave technique.

The energy separation between the $m_I = +\frac{1}{2}$ ($\uparrow$ or α) and the $m_I = -\frac{1}{2}$ ($\downarrow$ or β) states of **spin- $\frac{1}{2}$ nuclei**, which are nuclei with $I = \frac{1}{2}$, is

$$\Delta E = E_\beta - E_\alpha = \frac{1}{2}\gamma\hbar B_0 - (-\frac{1}{2}\gamma\hbar B_0) = \gamma\hbar B_0 \quad (15.13a)$$

and resonant absorption occurs when the resonance condition (Fig. 15.3)

$$h\nu = \gamma\hbar B_0 \quad (15.13b)$$

is fulfilled. Because $\gamma\hbar B_0/h$ is the Larmor frequency of the nucleus, this resonance occurs when the frequency of the electromagnetic field matches the Larmor frequency ($\nu = \nu_L$). In its simplest form, **nuclear magnetic resonance (NMR)** is the study of the properties of molecules containing magnetic nuclei by applying a magnetic field and observing the frequency of the resonant electromagnetic field. Larmor frequencies of nuclei at the fields normally employed (about 12 T) typically lie in the radiofrequency region of the electromagnetic spectrum (close to 500 MHz), so NMR is a radiofrequency technique.

For much of this chapter we consider spin- $\frac{1}{2}$ nuclei, but NMR is applicable to nuclei with any non-zero spin. As well as protons, which are the most common nuclei studied by NMR, spin- $\frac{1}{2}$ nuclei include ^{13}C , ^{19}F , and ^{31}P .

Nuclear magnetic resonance

Although the NMR technique is simple in concept, NMR spectra can be highly complex. However, they have proved invaluable in chemistry, for they reveal so much structural information. A magnetic nucleus is a very sensitive, non-invasive probe of the surrounding electronic structure.

15.4 The NMR spectrometer

An NMR spectrometer consists of the appropriate sources of radiofrequency electromagnetic radiation and a magnet that can produce a uniform, intense field. In simple instruments, the magnetic field is provided by a permanent magnet. For serious work, a **superconducting magnet** capable of producing fields of the order of 10 T and more is used (Fig. 15.4). The sample is placed in the cylindrically wound magnet. In some cases the sample is rotated rapidly to average out magnetic inhomogeneities. However, sample spinning can lead to irreproducible results, and is often avoided. Although a superconducting magnet operates at the temperature of liquid helium (4 K), the sample itself is normally at room temperature.

The intensity of an NMR transition depends on a number of factors. We show in the following *Justification* that

$$\text{Intensity} \propto (N_\alpha - N_\beta)B_0 \quad (15.14a)$$

where

$$N_\alpha - N_\beta \approx \frac{N\gamma\hbar B_0}{2kT} \quad (15.14b)$$

with N the total number of spins ($N = N_\alpha + N_\beta$). It follows that decreasing the temperature increases the intensity by increasing the population difference. By combining these two equations we see that the intensity is proportional to B_0^2 , so NMR transitions can be enhanced significantly by increasing the strength of the applied magnetic field. We shall also see (Section 15.6) that the use of high magnetic fields simplifies the

Fig. 15.3 The nuclear spin energy levels of a spin- $\frac{1}{2}$ nucleus with positive magnetogyric ratio (for example, ^1H or ^{13}C) in a magnetic field. Resonance occurs when the energy separation of the levels matches the energy of the photons in the electromagnetic field.

Fig. 15.4 The layout of a typical NMR spectrometer. The link from the transmitter to the detector indicates that the high frequency of the transmitter is subtracted from the high frequency received signal to give a low frequency signal for processing.

appearance of spectra and so allows them to be interpreted more readily. We also conclude that absorptions of nuclei with large magnetogyric ratios (^1H , for instance) are more intense than those with small magnetogyric ratios (^{13}C , for instance)

Justification 15.1 Intensities in NMR spectra

From the general considerations of transition intensities in Section 13.2, we know that the rate of absorption of electromagnetic radiation is proportional to the population of the lower energy state (N_α in the case of a proton NMR transition) and the rate of stimulated emission is proportional to the population of the upper state (N_β). At the low frequencies typical of magnetic resonance, we can neglect spontaneous emission as it is very slow. Therefore, the net rate of absorption is proportional to the difference in populations, and we can write

$$\text{Rate of absorption} \propto N_\alpha - N_\beta$$

The intensity of absorption, the rate at which energy is absorbed, is proportional to the product of the rate of absorption (the rate at which photons are absorbed) and the energy of each photon, and the latter is proportional to the frequency ν of the incident radiation (through $E = h\nu$). At resonance, this frequency is proportional to the applied magnetic field (through $\nu = \nu_L = \gamma B_0/2\pi$), so we can write

$$\text{Intensity of absorption} \propto (N_\alpha - N_\beta) B_0$$

as in eqn 15.14a. To write an expression for the population difference, we use the Boltzmann distribution (*Molecular interpretation* 3.1) to write the ratio of populations as

$$\frac{N_\beta}{N_\alpha} = e^{-\Delta E/kT} \approx 1 - \frac{\Delta E}{kT} = 1 - \frac{\gamma B_0}{kT}$$

where $\Delta E = E_\beta - E_\alpha$. The expansion of the exponential term is appropriate for $\Delta E \ll kT$, a condition usually met for nuclear spins. It follows after rearrangement that

$$\begin{aligned} \frac{N_\alpha - N_\beta}{N_\alpha + N_\beta} &= \frac{N_\alpha(1 - N_\beta/N_\alpha)}{N_\alpha(1 + N_\beta/N_\alpha)} = \frac{1 - N_\beta/N_\alpha}{1 + N_\beta/N_\alpha} \\ &\approx \frac{1 - (1 - \gamma \hbar B_0/kT)}{1 + (1 - \gamma \hbar B_0/kT)} \approx \frac{\gamma \hbar B_0/kT}{2} \end{aligned}$$

Then, with $N_\alpha + N_\beta = N$, the total number of spins, we obtain eqn 15.14b.

Comment 15.3

The expansion of an exponential function used here is

$e^{-x} = 1 - x + \frac{1}{2}x^2 - \dots$. If $x \ll 1$, then $e^{-x} \approx 1 - x$.

15.5 The chemical shift

Nuclear magnetic moments interact with the *local* magnetic field. The local field may differ from the applied field because the latter induces electronic orbital angular momentum (that is, the circulation of electronic currents) which gives rise to a small additional magnetic field δB at the nuclei. This additional field is proportional to the applied field, and it is conventional to write

$$\delta B = -\sigma B_0 \quad [15.15]$$

where the dimensionless quantity σ is called the **shielding constant** of the nucleus (σ is usually positive but may be negative). The ability of the applied field to induce an electronic current in the molecule, and hence affect the strength of the resulting local magnetic field experienced by the nucleus, depends on the details of the electronic structure near the magnetic nucleus of interest, so nuclei in different chemical groups have

different shielding constants. The calculation of reliable values of the shielding constant is very difficult, but trends in it are quite well understood and we concentrate on them.

(a) The δ scale of chemical shifts

Because the total local field is

$$\mathcal{B}_{\text{loc}} = \mathcal{B}_0 + \delta\mathcal{B} = (1 - \sigma)\mathcal{B}_0 \quad (15.16)$$

the nuclear Larmor frequency is

$$\nu_{\text{L}} = \frac{\gamma\mathcal{B}_{\text{loc}}}{2\pi} = (1 - \sigma)\frac{\gamma\mathcal{B}_0}{2\pi} \quad (15.17)$$

This frequency is different for nuclei in different environments. Hence, different nuclei, even of the same element, come into resonance at different frequencies.

It is conventional to express the resonance frequencies in terms of an empirical quantity called the **chemical shift**, which is related to the difference between the resonance frequency, ν , of the nucleus in question and that of a reference standard, ν° :

$$\delta = \frac{\nu - \nu^\circ}{\nu^\circ} \times 10^6 \quad [15.18]$$

The standard for protons is the proton resonance in tetramethylsilane ($\text{Si}(\text{CH}_3)_4$, commonly referred to as TMS), which bristles with protons and dissolves without reaction in many liquids. Other references are used for other nuclei. For ^{13}C , the reference frequency is the ^{13}C resonance in TMS; for ^{31}P it is the ^{31}P resonance in 85 per cent $\text{H}_3\text{PO}_4(\text{aq})$. The advantage of the δ -scale is that shifts reported on it are independent of the applied field (because both numerator and denominator are proportional to the applied field).

Illustration 15.1 Using the chemical shift

From eqn 15.18,

$$\nu - \nu^\circ = \nu^\circ \delta \times 10^{-6}$$

A nucleus with $\delta = 1.00$ in a spectrometer operating at 500 MHz will have a shift relative to the reference equal to

$$\nu - \nu^\circ = (500 \text{ MHz}) \times 1.00 \times 10^{-6} = 500 \text{ Hz}$$

In a spectrometer operating at 100 MHz, the shift relative to the reference would be only 100 Hz.

A note on good practice In much of the literature, chemical shifts are reported in ‘parts per million’, ppm, in recognition of the factor of 10^6 in the definition. This practice is unnecessary.

The relation between δ and σ is obtained by substituting eqn 15.17 into eqn 15.18:

$$\delta = \frac{(1 - \sigma)\mathcal{B}_0 - (1 - \sigma^\circ)\mathcal{B}_0}{(1 - \sigma^\circ)\mathcal{B}_0} \times 10^6 = \frac{\sigma^\circ - \sigma}{1 - \sigma^\circ} \times 10^6 \approx (\sigma^\circ - \sigma) \times 10^6 \quad (15.19)$$

As the shielding, σ , gets smaller, δ increases. Therefore, we speak of nuclei with large chemical shift as being strongly **deshielded**. Some typical chemical shifts are given in Fig. 15.5. As can be seen from the illustration, the nuclei of different elements have

Fig. 15.5 The range of typical chemical shifts for (a) ^1H resonances and (b) ^{13}C resonances.

Fig. 15.6 The ^1H -NMR spectrum of ethanol. The bold letters denote the protons giving rise to the resonance peak, and the step-like curve is the integrated signal.

very different ranges of chemical shifts. The ranges exhibit the variety of electronic environments of the nuclei in molecules: the heavier the element, the greater the number of electrons around the nucleus and hence the greater the range of shieldings.

By convention, NMR spectra are plotted with δ increasing from right to left. Consequently, in a given applied magnetic field the Larmor frequency also increases from right to left. In the original continuous wave (CW) spectrometers, in which the radiofrequency was held constant and the magnetic field varied (a ‘field sweep experiment’), the spectrum was displayed with the applied magnetic field increasing from left to right: a nucleus with a small chemical shift experiences a relatively low local magnetic field, so it needs a higher applied magnetic field to bring it into resonance with the radiofrequency field. Consequently, the right-hand (low chemical shift) end of the spectrum became known as the ‘high field end’ of the spectrum.

(b) Resonance of different groups of nuclei

The existence of a chemical shift explains the general features of the spectrum of ethanol shown in Fig. 15.6. The CH_3 protons form one group of nuclei with $\delta \approx 1$. The two CH_2 protons are in a different part of the molecule, experience a different local magnetic field, and resonate at $\delta \approx 3$. Finally, the OH proton is in another environment, and has a chemical shift of $\delta \approx 4$. The increasing value of δ (that is, the decrease in shielding) is consistent with the electron-withdrawing power of the O atom: it reduces the electron density of the OH proton most, and that proton is strongly deshielded. It reduces the electron density of the distant methyl protons least, and those nuclei are least deshielded.

The relative intensities of the signals (the areas under the absorption lines) can be used to help distinguish which group of lines corresponds to which chemical group. The determination of the area under an absorption line is referred to as the **integration** of the signal (just as any area under a curve may be determined by mathematical integration). Spectrometers can integrate the absorption automatically (as indicated in Fig. 15.6). In ethanol the group intensities are in the ratio 3:2:1 because there are three CH₃ protons, two CH₂ protons, and one OH proton in each molecule. Counting the number of magnetic nuclei as well as noting their chemical shifts helps to identify a compound present in a sample.

(c) The origin of shielding constants

The calculation of shielding constants is difficult, even for small molecules, for it requires detailed information about the distribution of electron density in the ground and excited states and the excitation energies of the molecule. Nevertheless, considerable success has been achieved with the calculation for diatomic molecules and small molecules such as H₂O and CH₄ and even large molecules, such as proteins, are within the scope of some types of calculation. Nevertheless, it is easier to understand the different contributions to chemical shifts by studying the large body of empirical information now available for large molecules.

The empirical approach supposes that the observed shielding constant is the sum of three contributions:

$$\sigma = \sigma(\text{local}) + \sigma(\text{neighbour}) + \sigma(\text{solvent}) \quad (15.20)$$

The **local contribution**, $\sigma(\text{local})$, is essentially the contribution of the electrons of the atom that contains the nucleus in question. The **neighbouring group contribution**, $\sigma(\text{neighbour})$, is the contribution from the groups of atoms that form the rest of the molecule. The **solvent contribution**, $\sigma(\text{solvent})$, is the contribution from the solvent molecules.

(d) The local contribution

It is convenient to regard the local contribution to the shielding constant as the sum of a **diamagnetic contribution**, σ_d , and a **paramagnetic contribution**, σ_p :

$$\sigma(\text{local}) = \sigma_d + \sigma_p \quad (15.21)$$

A diamagnetic contribution to $\sigma(\text{local})$ opposes the applied magnetic field and shields the nucleus in question. A paramagnetic contribution to $\sigma(\text{local})$ reinforces the applied magnetic field and deshields the nucleus in question. Therefore, $\sigma_d > 0$ and $\sigma_p < 0$. The total local contribution is positive if the diamagnetic contribution dominates, and is negative if the paramagnetic contribution dominates.

The diamagnetic contribution arises from the ability of the applied field to generate a circulation of charge in the ground-state electron distribution of the atom. The circulation generates a magnetic field that opposes the applied field and hence shields the nucleus. The magnitude of σ_d depends on the electron density close to the nucleus and can be calculated from the **Lamb formula** (see *Further reading* for a derivation):

$$\sigma_d = \frac{e^2 \mu_0}{12\pi m_e} \left\langle \frac{1}{r} \right\rangle \quad (15.22)$$

where μ_0 is the vacuum permeability (a fundamental constant, see inside the front cover) and r is the electron–nucleus distance.

Illustration 15.2 Calculating the diamagnetic contribution to the chemical shift of a proton

To calculate σ_d for the proton in a free H atom, we need to calculate the expectation value of $1/r$ for a hydrogen 1s orbital. Wavefunctions are given in Table 10.1, and a useful integral is given in Example 8.7. Because $d\tau = r^2 dr \sin \theta d\theta d\phi$, we can write

$$\left\langle \frac{1}{r} \right\rangle = \int \frac{\psi^* \psi}{r} d\tau = \frac{1}{\pi a_0^3} \int_0^{2\pi} d\phi \int_0^\pi \sin \theta d\theta \int_0^\infty r e^{-2r/a_0} dr = \frac{4}{a_0^3} \int_0^\infty r e^{-2r/a_0} dr = \frac{1}{a_0}$$

Therefore,

$$\sigma_d = \frac{e^2 \mu_0}{12\pi m_e a_0}$$

With the values of the fundamental constants inside the front cover, this expression evaluates to 1.78×10^{-5} .

The diamagnetic contribution is the only contribution in closed-shell free atoms. It is also the only contribution to the local shielding for electron distributions that have spherical or cylindrical symmetry. Thus, it is the only contribution to the local shielding from inner cores of atoms, for cores remain spherical even though the atom may be a component of a molecule and its valence electron distribution highly distorted. The diamagnetic contribution is broadly proportional to the electron density of the atom containing the nucleus of interest. It follows that the shielding is decreased if the electron density on the atom is reduced by the influence of an electronegative atom nearby. That reduction in shielding translates into an increase in deshielding, and hence to an increase in the chemical shift δ as the electronegativity of a neighbouring atom increases (Fig. 15.7). That is, as the electronegativity increases, δ decreases.

The local paramagnetic contribution, σ_p , arises from the ability of the applied field to force electrons to circulate through the molecule by making use of orbitals that are unoccupied in the ground state. It is zero in free atoms and around the axes of linear molecules (such as ethyne, $\text{HC}\equiv\text{CH}$) where the electrons can circulate freely and a field applied along the internuclear axis is unable to force them into other orbitals. We can expect large paramagnetic contributions from small atoms in molecules with low-lying excited states. In fact, the paramagnetic contribution is the dominant local contribution for atoms other than hydrogen.

Fig. 15.7 The variation of chemical shielding with electronegativity. The shifts for the methylene protons agree with the trend expected with increasing electronegativity. However, to emphasize that chemical shifts are subtle phenomena, notice that the trend for the methyl protons is opposite to that expected. For these protons another contribution (the magnetic anisotropy of C—H and C—X bonds) is dominant.

(e) Neighbouring group contributions

The neighbouring group contribution arises from the currents induced in nearby groups of atoms. Consider the influence of the neighbouring group X on the proton H in a molecule such as H—X. The applied field generates currents in the electron distribution of X and gives rise to an induced magnetic moment proportional to the applied field; the constant of proportionality is the magnetic susceptibility, χ (chi), of the group X. The proton H is affected by this induced magnetic moment in two ways. First, the strength of the additional magnetic field the proton experiences is inversely proportional to the cube of the distance r between H and X. Second, the field at H depends on the anisotropy of the magnetic susceptibility of X, the variation of χ with the angle that X makes to the applied field. We assume that the magnetic susceptibility of X has two components, $\chi_{\parallel}$ and $\chi_{\perp}$, which are parallel and perpendicular to the axis of symmetry of X, respectively. The axis of symmetry of X makes an angle θ to the

vector connecting X to H (1, where X is represented by the ellipse and H is represented by the circle).

To examine the effect of anisotropy of the magnetic susceptibility of X on the shielding constant, consider the case $\theta = 0$ for a molecule H—X that is free to tumble (2 and 3). Some of the time the H—X axis will be perpendicular to the applied field and then only $\chi_{\perp}$ will contribute to the induced magnetic moment that shields X from the applied field. The result is deshielding of the proton H, or $\sigma(\text{neighbour}) < 0$ (2). When the applied field is parallel to the H—X axis, only $\chi_{\parallel}$ contributes to the induced magnetic moment at X. The result is shielding of the proton H (3). We conclude that, as the molecule tumbles and the H—X axis takes all possible angles with respect to the applied field, the effects of anisotropic magnetic susceptibility do not average to zero because $\chi_{\parallel} \neq \chi_{\perp}$.

Self-test 15.1 For a tumbling H—X molecule, show that when $\theta = 90^\circ$: (a) contributions from the $\chi_{\perp}$ component lead to shielding of H, or $\sigma(\text{neighbour}) > 0$, and (b) contributions from the $\chi_{\parallel}$ component lead to deshielding of H, or $\sigma(\text{neighbour}) < 0$. Comparison between the $\theta = 0$ and $\theta = 90^\circ$ cases shows that the patterns of shielding and deshielding by neighbouring groups depend not only on differences between $\chi_{\parallel}$ and $\chi_{\perp}$, but also the angle θ .

[Draw diagrams similar to 2 and 3 where the $\chi_{\perp}$ component is parallel to the H—X axis and then analyse the problem as above.]

To a good approximation, the shielding constant $\sigma(\text{neighbour})$ depends on the distance r , the difference $\chi_{\parallel} - \chi_{\perp}$, as (see *Further reading* for a derivation)

$$\sigma(\text{neighbour}) \propto (\chi_{\parallel} - \chi_{\perp}) \left(\frac{1 - 3 \cos^2 \theta}{r^3} \right) \quad (15.23)$$

where $\chi_{\parallel}$ and $\chi_{\perp}$ are both negative for a diamagnetic group X. Equation 15.23 shows that the neighbouring group contribution may be positive or negative according to the relative magnitudes of the two magnetic susceptibilities and the relative orientation of the nucleus with respect to X. The latter effect is easy to anticipate: if $54.7^\circ < \theta < 125.3^\circ$, then $1 - 3 \cos^2 \theta$ is positive, but it is negative otherwise (Fig. 15.8).

A special case of a neighbouring group effect is found in aromatic compounds. The strong anisotropy of the magnetic susceptibility of the benzene ring is ascribed to the

Fig. 15.8 The variation of the function $1 - 3 \cos^2 \theta$ with the angle θ .

Fig. 15.9 The shielding and deshielding effects of the ring current induced in the benzene ring by the applied field. Protons attached to the ring are deshielded but a proton attached to a substituent that projects above the ring is shielded.

Fig. 15.10 An aromatic solvent (benzene here) can give rise to local currents that shield or deshield a proton in a solvent molecule. In this relative orientation of the solvent and solute, the proton on the solute molecule is shielded.

ability of the field to induce a **ring current**, a circulation of electrons around the ring, when it is applied perpendicular to the molecular plane. Protons in the plane are deshielded (Fig. 15.9), but any that happen to lie above or below the plane (as members of substituents of the ring) are shielded.

(f) The solvent contribution

A solvent can influence the local magnetic field experienced by a nucleus in a variety of ways. Some of these effects arise from specific interactions between the solute and the solvent (such as hydrogen-bond formation and other forms of Lewis acid–base complex formation). The anisotropy of the magnetic susceptibility of the solvent molecules, especially if they are aromatic, can also be the source of a local magnetic field. Moreover, if there are steric interactions that result in a loose but specific interaction between a solute molecule and a solvent molecule, then protons in the solute molecule may experience shielding or deshielding effects according to their location relative to the solvent molecule (Fig. 15.10). We shall see that the NMR spectra of species that contain protons with widely different chemical shifts are easier to interpret than those in which the shifts are similar, so the appropriate choice of solvent may help to simplify the appearance and interpretation of a spectrum.

15.6 The fine structure

The splitting of resonances into individual lines in Fig. 15.6 is called the **fine structure** of the spectrum. It arises because each magnetic nucleus may contribute to the local field experienced by the other nuclei and so modify their resonance frequencies. The strength of the interaction is expressed in terms of the **scalar coupling constant**, J , and reported in hertz (Hz). The scalar coupling constant is so called because the energy of interaction it describes is proportional to the scalar product of the two interacting spins: $E \propto \mathbf{I}_1 \cdot \mathbf{I}_2$. The constant of proportionality in this expression is $hJ/\hbar^2$, because each angular momentum is proportional to $\hbar$.

Spin coupling constants are independent of the strength of the applied field because they do not depend on the latter for their ability to generate local fields. If the resonance line of a particular nucleus is split by a certain amount by a second nucleus, then the resonance line of the second nucleus is split by the first to the same extent.

(a) The energy levels of coupled systems

It will be useful for later discussions to consider an NMR spectrum in terms of the energy levels of the nuclei and the transitions between them. In NMR, letters far apart in the alphabet (typically A and X) are used to indicate nuclei with very different chemical shifts; letters close together (such as A and B) are used for nuclei with similar chemical shifts. We shall consider first an AX system, a molecule that contains two spin- $\frac{1}{2}$ nuclei A and X with very different chemical shifts in the sense that the difference in chemical shift corresponds to a frequency that is large compared to their spin–spin coupling.

The energy level diagram for a single spin- $\frac{1}{2}$ nucleus and its single transition were shown in Fig. 15.3, and nothing more needs to be said. For a spin- $\frac{1}{2}$ AX system there are four spin states:

$$\alpha_A \alpha_X \quad \alpha_A \beta_X \quad \beta_A \alpha_X \quad \beta_A \beta_X$$

The energy depends on the orientation of the spins in the external magnetic field, and if spin–spin coupling is neglected

$$E = -\gamma \hbar (1 - \sigma_A) \mathcal{B} m_A - \gamma \hbar (1 - \sigma_X) \mathcal{B} m_X = -h \nu_A m_A - h \nu_X m_X \quad (15.24)$$

Fig. 15.11 The energy levels of an AX system. The four levels on the left are those of the two spins in the absence of spin–spin coupling. The four levels on the right show how a positive spin–spin coupling constant affects the energies. The transitions shown are for $\beta \leftarrow \alpha$ of A or X, the other nucleus (X or A, respectively) remaining unchanged. We have exaggerated the effect for clarity; in practice, the splitting caused by spin–spin coupling is much smaller than that caused by the applied field.

where ν_A and ν_X are the Larmor frequencies of A and X and m_A and m_X are their quantum numbers. This expression gives the four lines on the left of Fig. 15.11. The spin–spin coupling depends on the relative orientation of the two nuclear spins, so it is proportional to the product $m_A m_X$. Therefore, the energy including spin–spin coupling is

$$E = -h\nu_A m_A - h\nu_X m_X + hJ m_A m_X \quad (15.25)$$

If $J > 0$, a lower energy is obtained when $m_A m_X < 0$, which is the case if one spin is α and the other is β . A higher energy is obtained if both spins are α or both spins are β . The opposite is true if $J < 0$. The resulting energy level diagram (for $J > 0$) is shown on the right of Fig. 15.11. We see that the $\alpha\alpha$ and $\beta\beta$ states are both raised by $\frac{1}{4}hJ$ and that the $\alpha\beta$ and $\beta\alpha$ states are both lowered by $\frac{1}{4}hJ$.

When a transition of nucleus A occurs, nucleus X remains unchanged. Therefore, the A resonance is a transition for which $\Delta m_A = +1$ and $\Delta m_X = 0$. There are two such transitions, one in which $\beta_A \leftarrow \alpha_A$ occurs when the X nucleus is α_X , and the other in which $\beta_A \leftarrow \alpha_A$ occurs when the X nucleus is β_X . They are shown in Fig. 15.11 and in a slightly different form in Fig. 15.12. The energies of the transitions are

$$\Delta E = h\nu_A \pm \frac{1}{2}hJ \quad (15.26a)$$

Therefore, the A resonance consists of a doublet of separation J centred on the chemical shift of A (Fig. 15.13). Similar remarks apply to the X resonance, which consists of two transitions according to whether the A nucleus is α or β (as shown in Fig. 15.12). The transition energies are

$$\Delta E = h\nu_X \pm \frac{1}{2}hJ \quad (15.26b)$$

It follows that the X resonance also consists of two lines of separation J , but they are centred on the chemical shift of X (as shown in Fig. 15.13).

Fig. 15.12 An alternative depiction of the energy levels and transitions shown in Fig. 15.11. Once again, we have exaggerated the effect of spin–spin coupling.

Fig. 15.13 The effect of spin–spin coupling on an AX spectrum. Each resonance is split into two lines separated by J . The pairs of resonances are centred on the chemical shifts of the protons in the absence of spin–spin coupling.

(b) Patterns of coupling

We have seen that in an AX system, spin–spin coupling will result in four lines in the NMR spectrum. Instead of a single line from A, we get a doublet of lines separated by J and centred on the chemical shift characteristic of A. The same splitting occurs in the X resonance: instead of a single line, the resonance is a doublet with splitting J (the same value as for the splitting of A) centred on the chemical shift characteristic of X. These features are summarized in Fig. 15.13.

A subtle point is that the X resonance in an AX_n species (such as an AX_2 or AX_3 species) is also a doublet with splitting J . As we shall explain below, *a group of equivalent nuclei resonates like a single nucleus*. The only difference for the X resonance of an AX_n species is that the intensity is n times as great as that of an AX species (Fig. 15.14). The A resonance in an AX_n species, though, is quite different from the A resonance in an AX species. For example, consider an AX_2 species with two equivalent X nuclei. The resonance of A is split into a doublet of separation J by one X, and each line of that doublet is split again by the same amount by the second X (Fig. 15.15). This splitting results in three lines in the intensity ratio 1:2:1 (because the central frequency can be obtained in two ways). The A resonance of an A_nX_2 species would also be a 1:2:1 triplet of splitting J , the only difference being that the intensity of the A resonance would be n times as great as that of AX_2 .

Three equivalent X nuclei (an AX_3 species) split the resonance of A into four lines of intensity ratio 1:3:3:1 and separation J (Fig. 15.16). The X resonance, though, is still a doublet of separation J . In general, n equivalent spin- $\frac{1}{2}$ nuclei split the resonance of a nearby spin or group of equivalent spins into $n + 1$ lines with an intensity distribution given by ‘Pascal’s triangle’ in which each entry is the sum of the two entries immediately above (4). The easiest way of constructing the pattern of fine structure is to draw a diagram in which successive rows show the splitting of a subsequent proton. The procedure is illustrated in Fig. 15.17 and was used in Figs. 15.15 and 15.16. It is easily extended to molecules containing nuclei with $I > \frac{1}{2}$ (Fig. 15.18).

Fig. 15.14 The X resonance of an AX_2 species is also a doublet, because the two equivalent X nuclei behave like a single nucleus; however, the overall absorption is twice as intense as that of an AX species.

Fig. 15.15 The origin of the 1:2:1 triplet in the A resonance of an AX_2 species. The resonance of A is split into two by coupling with one X nucleus (as shown in the inset), and then each of those two lines is split into two by coupling to the second X nucleus. Because each X nucleus causes the same splitting, the two central transitions are coincident and give rise to an absorption line of double the intensity of the outer lines.

Fig. 15.16 The origin of the 1:3:3:1 quartet in the A resonance of an AX_3 species. The third X nucleus splits each of the lines shown in Fig. 15.15 for an AX_2 species into a doublet, and the intensity distribution reflects the number of transitions that have the same energy.

Fig. 15.17 The intensity distribution of the A resonance of an AX_n resonance can be constructed by considering the splitting caused by 1, 2, . . . n protons, as in Figs. 15.15 and 15.16. The resulting intensity distribution has a binomial distribution and is given by the integers in the corresponding row of Pascal's triangle. Note that, although the lines have been drawn side-by-side for clarity, the members of each group are coincident. Four protons, in AX_4 , split the A resonance into a 1:4:6:4:1 quintet.

Fig. 15.18 The intensity distribution arising from spin-spin interaction with nuclei with $I = 1$ can be constructed similarly, but each successive nucleus splits the lines into three equal intensity components. Two equivalent spin-1 nuclei give rise to a 1:2:3:2:1 quintet.

Example 15.1 Accounting for the fine structure in a spectrum

Account for the fine structure in the NMR spectrum of the C—H protons of ethanol.

Method Consider how each group of equivalent protons (for instance, three methyl protons) split the resonances of the other groups of protons. There is no splitting within groups of equivalent protons. Each splitting pattern can be decided by referring to Pascal's triangle.

Answer The three protons of the CH_3 group split the resonance of the CH_2 protons into a 1:3:3:1 quartet with a splitting J . Likewise, the two protons of the CH_2 group split the resonance of the CH_3 protons into a 1:2:1 triplet with the same splitting J . The CH_2 and CH_3 protons all interact with the OH proton, but these couplings do not cause any splitting because the OH protons migrate rapidly from molecule to molecule and their effect averages to zero.

Self-test 15.2 What fine-structure can be expected for the protons in $^{14}\text{NH}_4^+$? The spin quantum number of nitrogen is 1. [1:1:1 triplet from N]

(c) The magnitudes of coupling constants

The scalar coupling constant of two nuclei separated by N bonds is denoted $^N J$, with subscripts for the types of nuclei involved. Thus, $^1J_{\text{CH}}$ is the coupling constant for a proton joined directly to a ^{13}C atom, and $^2J_{\text{CH}}$ is the coupling constant when the same two nuclei are separated by two bonds (as in $^{13}\text{C}-\text{C}-\text{H}$). A typical value of $^1J_{\text{CH}}$ is in the range 120 to 250 Hz; $^2J_{\text{CH}}$ is between -10 and $+20$ Hz. Both ^3J and ^4J can give detectable effects in a spectrum, but couplings over larger numbers of bonds can generally

Fig. 15.19 The variation of the spin–spin coupling constant with angle predicted by the Karplus equation for an HCCH group and an HNCH group.

Exploration Draw a family of curves showing the variation of ${}^3J_{\text{HH}}$ with ϕ for which $A = +7.0$ Hz, $B = -1.0$ Hz, and C varies slightly from a typical value of $+5.0$ Hz. What is the effect of changing the value of the parameter C on the shape of the curve? In a similar fashion, explore the effect of the values of A and B on the shape of the curve.

Comment 15.4

The average (or mean value) of a function $f(x)$ over the range $x = a$ to $x = b$ is $\int_a^b f(x) dx / (b - a)$. The volume element in polar coordinates is proportional to $\sin \theta d\theta$, and θ ranges from 0 to π . Therefore the average value of $(1 - 3 \cos^2 \theta)$ is $\int_0^\pi (1 - 3 \cos^2 \theta) \sin \theta d\theta / \pi = 0$.

be ignored. One of the longest range couplings that has been detected is ${}^9J_{\text{HH}} = 0.4$ Hz between the CH_3 and CH_2 protons in $\text{CH}_3\text{C}\equiv\text{CC}\equiv\text{CC}\equiv\text{CCH}_2\text{OH}$.

The sign of J_{XY} indicates whether the energy of two spins is lower when they are parallel ($J < 0$) or when they are antiparallel ($J > 0$). It is found that ${}^1J_{\text{CH}}$ is often positive, ${}^2J_{\text{HH}}$ is often negative, ${}^3J_{\text{HH}}$ is often positive, and so on. An additional point is that J varies with the angle between the bonds (Fig. 15.19). Thus, a ${}^3J_{\text{HH}}$ coupling constant is often found to depend on the dihedral angle ϕ (5) according to the **Karplus equation**:

$$J = A + B \cos \phi + C \cos 2\phi \quad (15.27)$$

with A , B , and C empirical constants with values close to $+7$ Hz, -1 Hz, and $+5$ Hz, respectively, for an HCCH fragment. It follows that the measurement of ${}^3J_{\text{HH}}$ in a series of related compounds can be used to determine their conformations. The coupling constant ${}^1J_{\text{CH}}$ also depends on the hybridization of the C atom, as the following values indicate:

	sp	sp^2	sp^3
${}^1J_{\text{CH}}/\text{Hz}$:	250	160	125

(d) The origin of spin–spin coupling

Spin–spin coupling is a very subtle phenomenon, and it is better to treat J as an empirical parameter than to use calculated values. However, we can get some insight into its origins, if not its precise magnitude—or always reliably its sign—by considering the magnetic interactions within molecules.

A nucleus with spin projection m_I gives rise to a magnetic field with z -component $\mathcal{B}_{\text{nuc}}$ at a distance R , where, to a good approximation,

$$\mathcal{B}_{\text{nuc}} = -\frac{\gamma \hbar \mu_0}{4\pi R^3} (1 - 3 \cos^2 \theta) m_I \quad (15.28)$$

The angle θ is defined in (6). The magnitude of this field is about 0.1 mT when $R = 0.3$ nm, corresponding to a splitting of resonance signal of about 10^4 Hz, and is of the order of magnitude of the splitting observed in solid samples (see Section 15.3a).

In a liquid, the angle θ sweeps over all values as the molecule tumbles, and $1 - 3 \cos^2 \theta$ averages to zero. Hence the direct dipolar interaction between spins cannot account for the fine structure of the spectra of rapidly tumbling molecules. The direct interaction does make an important contribution to the spectra of solid samples and is a very useful indirect source of structure information through its involvement in spin relaxation (Section 15.11).

Spin–spin coupling in molecules in solution can be explained in terms of the **polarization mechanism**, in which the interaction is transmitted through the bonds. The simplest case to consider is that of ${}^1J_{\text{XY}}$ where X and Y are spin- $\frac{1}{2}$ nuclei joined by an electron-pair bond (Fig. 15.20). The coupling mechanism depends on the fact that in some atoms it is favourable for the nucleus and a nearby electron spin to be parallel (both α or both β), but in others it is favourable for them to be antiparallel (one α and the other β). The electron–nucleus coupling is magnetic in origin, and may be either a dipolar interaction between the magnetic moments of the electron and nuclear spins or a **Fermi contact interaction**. A pictorial description of the Fermi contact interaction is as follows. First, we regard the magnetic moment of the nucleus as arising from the circulation of a current in a tiny loop with a radius similar to that of the nucleus (Fig. 15.21). Far from the nucleus the field generated by this loop is indistinguishable from the field generated by a point magnetic dipole. Close to the loop, however, the field differs from that of a point dipole. The magnetic interaction between this non-dipolar field and the electron's magnetic moment is the contact

Fig. 15.20 The polarization mechanism for spin–spin coupling ($^1J_{\text{HH}}$). The two arrangements have slightly different energies. In this case, J is positive, corresponding to a lower energy when the nuclear spins are antiparallel.

Fig. 15.21 The origin of the Fermi contact interaction. From far away, the magnetic field pattern arising from a ring of current (representing the rotating charge of the nucleus, the pale green sphere) is that of a point dipole. However, if an electron can sample the field close to the region indicated by the sphere, the field distribution differs significantly from that of a point dipole. For example, if the electron can penetrate the sphere, then the spherical average of the field it experiences is not zero.

interaction. The lines of force depicted in Fig. 15.21 correspond to those for a proton with α spin. The lower energy state of an electron spin in such a field is the β state. In conclusion, the contact interaction depends on the very close approach of an electron to the nucleus and hence can occur only if the electron occupies an s orbital (which is the reason why $^1J_{\text{CH}}$ depends on the hybridization ratio). We shall suppose that it is energetically favourable for an electron spin and a nuclear spin to be antiparallel (as is the case for a proton and an electron in a hydrogen atom).

If the X nucleus is α , a β electron of the bonding pair will tend to be found nearby (because that is energetically favourable for it). The second electron in the bond, which must have α spin if the other is β , will be found mainly at the far end of the bond (because electrons tend to stay apart to reduce their mutual repulsion). Because it is energetically favourable for the spin of Y to be antiparallel to an electron spin, a Y nucleus with β spin has a lower energy, and hence a lower Larmor frequency, than a Y nucleus with α spin. The opposite is true when X is β , for now the α spin of Y has the lower energy. In other words, the antiparallel arrangement of nuclear spins lies lower in energy than the parallel arrangement as a result of their magnetic coupling with the bond electrons. That is, $^1J_{\text{HH}}$ is positive.

To account for the value of $^2J_{\text{XY}}$, as in H–C–H, we need a mechanism that can transmit the spin alignments through the central C atom (which may be ^{12}C , with no nuclear spin of its own). In this case (Fig. 15.22), an X nucleus with α spin polarizes the electrons in its bond, and the α electron is likely to be found closer to the C nucleus. The more favourable arrangement of two electrons on the same atom is with their spins parallel (Hund's rule, Section 10.4d), so the more favourable arrangement is for the α electron of the neighbouring bond to be close to the C nucleus. Consequently, the β electron of that bond is more likely to be found close to the Y nucleus, and therefore that nucleus will have a lower energy if it is α . Hence, according to this mechanism, the lower Larmor frequency of Y will be obtained if its spin is parallel to that of X. That is, $^2J_{\text{HH}}$ is negative.

Fig. 15.22 The polarization mechanism for $^2J_{\text{HH}}$ spin–spin coupling. The spin information is transmitted from one bond to the next by a version of the mechanism that accounts for the lower energy of electrons with parallel spins in different atomic orbitals (Hund's rule of maximum multiplicity). In this case, $J < 0$, corresponding to a lower energy when the nuclear spins are parallel.

The coupling of nuclear spin to electron spin by the Fermi contact interaction is most important for proton spins, but it is not necessarily the most important mechanism for other nuclei. These nuclei may also interact by a dipolar mechanism with the electron magnetic moments and with their orbital motion, and there is no simple way of specifying whether J will be positive or negative.

(e) Equivalent nuclei

A group of nuclei are **chemically equivalent** if they are related by a symmetry operation of the molecule and have the same chemical shifts. Chemically equivalent nuclei are nuclei that would be regarded as 'equivalent' according to ordinary chemical criteria. Nuclei are **magnetically equivalent** if, as well as being chemically equivalent, they also have identical spin-spin interactions with any other magnetic nuclei in the molecule.

The difference between chemical and magnetic equivalence is illustrated by CH_2F_2 and $\text{H}_2\text{C}=\text{CF}_2$. In each of these molecules the protons are chemically equivalent: they are related by symmetry and undergo the same chemical reactions. However, although the protons in CH_2F_2 are magnetically equivalent, those in $\text{CH}_2=\text{CF}_2$ are not. One proton in the latter has a *cis* spin-coupling interaction with a given F nucleus whereas the other proton has a *trans* interaction with it. In contrast, in CH_2F_2 both protons are connected to a given F nucleus by identical bonds, so there is no distinction between them. Strictly speaking, the CH_3 protons in ethanol (and other compounds) are magnetically inequivalent on account of their different interactions with the CH_2 protons in the next group. However, they are in practice made magnetically equivalent by the rapid rotation of the CH_3 group, which averages out any differences. Magnetically inequivalent species can give very complicated spectra (for instance, the proton and ^{19}F spectra of $\text{H}_2\text{C}=\text{CF}_2$ each consist of 12 lines), and we shall not consider them further.

An important feature of chemically equivalent magnetic nuclei is that, although they do couple together, the coupling has no effect on the appearance of the spectrum. The reason for the invisibility of the coupling is set out in the following *Justification*, but qualitatively it is that all allowed nuclear spin transitions are *collective* reorientations of groups of equivalent nuclear spins that do not change the relative orientations of the spins within the group (Fig. 15.23). Then, because the relative orientations of nuclear spins are not changed in any transition, the magnitude of the coupling between them is undetectable. Hence, an isolated CH_3 group gives a single, unsplit line because all the allowed transitions of the group of three protons occur without change of their relative orientations.

Fig. 15.23 (a) A group of two equivalent nuclei realigns as a group, without change of angle between the spins, when a resonant absorption occurs. Hence it behaves like a single nucleus and the spin-spin coupling between the individual spins of the group is undetectable. (b) Three equivalent nuclei also realign as a group without change of their relative orientations.

Justification 15.2 *The energy levels of an A₂ system*

Consider an A₂ system of two chemically equivalent spin- $\frac{1}{2}$ nuclei. First, consider the energy levels in the absence of spin–spin coupling. There are four spin states that (just as for two electrons) can be classified according to their total spin I (the analogue of S for two electrons) and their total projection M_I on the z -axis. The states are analogous to those we developed for two electrons in singlet and triplet states:

Spins parallel, $I = 1$:	$M_I = +1$	$\alpha\alpha$
	$M_I = 0$	$(1/2^{1/2})\{\alpha\beta + \beta\alpha\}$
	$M_I = -1$	$\beta\beta$
Spins paired, $I = 0$:	$M_I = 0$	$(1/2^{1/2})\{\alpha\beta - \beta\alpha\}$

The effect of a magnetic field on these four states is shown in Fig. 15.24: the energies of the two states with $M_I = 0$ are unchanged by the field because they are composed of equal proportions of α and β spins.

As remarked in Section 15.6a, the spin–spin coupling energy is proportional to the scalar product of the vectors representing the spins, $E = (hJ/\hbar^2)\mathbf{I}_1 \cdot \mathbf{I}_2$. The scalar product can be expressed in terms of the total nuclear spin by noting that

$$I^2 = (\mathbf{I}_1 + \mathbf{I}_2) \cdot (\mathbf{I}_1 + \mathbf{I}_2) = I_1^2 + I_2^2 + 2\mathbf{I}_1 \cdot \mathbf{I}_2$$

rearranging this expression to

$$\mathbf{I}_1 \cdot \mathbf{I}_2 = \frac{1}{2}\{I^2 - I_1^2 - I_2^2\}$$

and replacing the magnitudes by their quantum mechanical values:

$$\mathbf{I}_1 \cdot \mathbf{I}_2 = \frac{1}{2}\{I(I+1) - I_1(I_1+1) - I_2(I_2+1)\}\hbar^2$$

Then, because $I_1 = I_2 = \frac{1}{2}$, it follows that

$$E = \frac{1}{2}hJ\{I(I+1) - \frac{3}{2}\}$$

For parallel spins, $I = 1$ and $E = +\frac{1}{4}hJ$; for antiparallel spins $I = 0$ and $E = -\frac{3}{4}hJ$, as in Fig. 15.24. We see that three of the states move in energy in one direction and the fourth (the one with antiparallel spins) moves three times as much in the opposite direction. The resulting energy levels are shown on the right in Fig. 15.24.

Comment 15.5

As in Section 10.7, the states we have selected in *Justification 15.2* are those with a definite resultant, and hence a well defined value of I . The + sign in $\alpha\beta + \beta\alpha$ signifies an in-phase alignment of spins and $I = 1$; the – sign in $\alpha\beta - \beta\alpha$ signifies an alignment out of phase by π , and hence $I = 0$. See Fig. 10.24.

Fig. 15.24 The energy levels of an A₂ system in the absence of spin–spin coupling are shown on the left. When spin–spin coupling is taken into account, the energy levels on the right are obtained. Note that the three states with total nuclear spin $I = 1$ correspond to parallel spins and give rise to the same increase in energy (J is positive); the one state with $I = 0$ (antiparallel nuclear spins) has a lower energy in the presence of spin–spin coupling. The only allowed transitions are those that preserve the angle between the spins, and so take place between the three states with $I = 1$. They occur at the same resonance frequency as they would have in the absence of spin–spin coupling.

The NMR spectrum of the A₂ species arises from transitions between the levels. However, the radiofrequency field affects the two equivalent protons equally, so it cannot change the orientation of one proton relative to the other; therefore, the transitions take place within the set of states that correspond to parallel spin (those labelled $I = 1$), and no spin-parallel state can change to a spin-antiparallel state (the state with $I = 0$). Put another way, the allowed transitions are subject to the selection rule $\Delta I = 0$. This selection rule is in addition to the rule $\Delta M_I = \pm 1$ that arises from the conservation of angular momentum and the unit spin of the photon. The allowed transitions are shown in Fig. 15.24: we see that there are only two transitions, and that they occur at the same resonance frequency that the nuclei would have in the absence of spin–spin coupling. Hence, the spin–spin coupling interaction does not affect the appearance of the spectrum.

(f) Strongly coupled nuclei

NMR spectra are usually much more complex than the foregoing simple analysis suggests. We have described the extreme case in which the differences in chemical shifts

Fig. 15.25 The NMR spectra of an A_2 system (top) and an AX system (bottom) are simple ‘first-order’ spectra. At intermediate relative values of the chemical shift difference and the spin–spin coupling, complex ‘strongly coupled’ spectra are obtained. Note how the inner two lines of the bottom spectrum move together, grow in intensity, and form the single central line of the top spectrum. The two outer lines diminish in intensity and are absent in the top spectrum.

Fig. 15.26 When a molecule changes from one conformation to another, the positions of its protons are interchanged and jump between magnetically distinct environments.

are much greater than the spin–spin coupling constants. In such cases it is simple to identify groups of magnetically equivalent nuclei and to think of the groups of nuclear spins as reorientating relative to each other. The spectra that result are called **first-order spectra**.

Transitions cannot be allocated to definite groups when the differences in their chemical shifts are comparable to their spin–spin coupling interactions. The complicated spectra that are then obtained are called **strongly coupled spectra** (or ‘second-order spectra’) and are much more difficult to analyse (Fig. 15.25). Because the difference in resonance frequencies increases with field, but spin–spin coupling constants are independent of it, a second-order spectrum may become simpler (and first-order) at high fields because individual groups of nuclei become identifiable again.

A clue to the type of analysis that is appropriate is given by the notation for the types of spins involved. Thus, an AX spin system (which consists of two nuclei with a large chemical shift difference) has a first-order spectrum. An AB system, on the other hand (with two nuclei of similar chemical shifts), gives a spectrum typical of a strongly coupled system. An AX system may have widely different Larmor frequencies because A and X are nuclei of different elements (such as ^{13}C and ^1H), in which case they form a **heteronuclear spin system**. AX may also denote a **homonuclear spin system** in which the nuclei are of the same element but in markedly different environments.

15.7 Conformational conversion and exchange processes

The appearance of an NMR spectrum is changed if magnetic nuclei can jump rapidly between different environments. Consider a molecule, such as *N,N*-dimethylformamide, that can jump between conformations; in its case, the methyl shifts depend on whether they are *cis* or *trans* to the carbonyl group (Fig. 15.26). When the jumping rate is low, the spectrum shows two sets of lines, one each from molecules in each conformation. When the interconversion is fast, the spectrum shows a single line at the mean of the two chemical shifts. At intermediate inversion rates, the line is very broad. This maximum broadening occurs when the lifetime, τ , of a conformation gives rise to a linewidth that is comparable to the difference of resonance frequencies, $\delta\nu$, and both broadened lines blend together into a very broad line. Coalescence of the two lines occurs when

$$\tau = \frac{\sqrt{2}}{\pi\delta\nu} \quad (15.29)$$

Example 15.2 Interpreting line broadening

The NO group in *N,N*-dimethylnitrosamine, $(\text{CH}_3)_2\text{N}-\text{NO}$, rotates about the N–N bond and, as a result, the magnetic environments of the two CH_3 groups are interchanged. The two CH_3 resonances are separated by 390 Hz in a 600 MHz spectrometer. At what rate of interconversion will the resonance collapse to a single line?

Method Use eqn 15.29 for the average lifetimes of the conformations. The rate of interconversion is the inverse of their lifetime.

Answer With $\delta\nu = 390$ Hz,

$$\tau = \frac{\sqrt{2}}{\pi \times (390 \text{ s}^{-1})} = 1.2 \text{ ms}$$

It follows that the signal will collapse to a single line when the interconversion rate exceeds about 830 s^{-1} . The dependence of the rate of exchange on the temperature is used to determine the energy barrier to interconversion.

Self-test 15.3 What would you deduce from the observation of a single line from the same molecule in a 300 MHz spectrometer?

[Conformation lifetime less than 2.3 ms]

A similar explanation accounts for the loss of fine structure in solvents able to exchange protons with the sample. For example, hydroxyl protons are able to exchange with water protons. When this **chemical exchange** occurs, a molecule ROH with an α -spin proton (we write this ROH_α) rapidly converts to ROH_β and then perhaps to ROH_α again because the protons provided by the solvent molecules in successive exchanges have random spin orientations. Therefore, instead of seeing a spectrum composed of contributions from both ROH_α and ROH_β molecules (that is, a spectrum showing a doublet structure due to the OH proton) we see a spectrum that shows no splitting caused by coupling of the OH proton (as in Fig. 15.6). The effect is observed when the lifetime of a molecule due to this chemical exchange is so short that the lifetime broadening is greater than the doublet splitting. Because this splitting is often very small (a few hertz), a proton must remain attached to the same molecule for longer than about 0.1 s for the splitting to be observable. In water, the exchange rate is much faster than that, so alcohols show no splitting from the OH protons. In dry dimethylsulfoxide (DMSO), the exchange rate may be slow enough for the splitting to be detected.

Pulse techniques in NMR

Modern methods of detecting the energy separation between nuclear spin states are more sophisticated than simply looking for the frequency at which resonance occurs. One of the best analogies that has been suggested to illustrate the difference between the old and new ways of observing an NMR spectrum is that of detecting the spectrum of vibrations of a bell. We could stimulate the bell with a gentle vibration at a gradually increasing frequency, and note the frequencies at which it resonated with the stimulation. A lot of time would be spent getting zero response when the stimulating frequency was between the bell's vibrational modes. However, if we were simply to hit the bell with a hammer, we would immediately obtain a clang composed of all the frequencies that the bell can produce. The equivalent in NMR is to monitor the radiation nuclear spins emit as they return to equilibrium after the appropriate stimulation. The resulting **Fourier-transform NMR** gives greatly increased sensitivity, so opening up the entire periodic table to the technique. Moreover, multiple-pulse FT-NMR gives chemists unparalleled control over the information content and display of spectra. We need to understand how the equivalent of the hammer blow is delivered and how the signal is monitored and interpreted. These features are generally expressed in terms of the vector model of angular momentum introduced in Section 9.7d.

15.8 The magnetization vector

Consider a sample composed of many identical spin- $\frac{1}{2}$ nuclei. As we saw in Section 9.7d, an angular momentum can be represented by a vector of length $\{I(I+1)\}^{1/2}$ units

Fig. 15.27 The vector model of angular momentum for a single spin- $\frac{1}{2}$ nucleus. The angle around the z -axis is indeterminate.

Fig. 15.28 The magnetization of a sample of spin- $\frac{1}{2}$ nuclei is the resultant of all their magnetic moments. (a) In the absence of an externally applied field, there are equal numbers of α and β spins at random angles around the z -axis (the field direction) and the magnetization is zero. (b) In the presence of a field, the spins precess around their cones (that is, there is an energy difference between the α and β states) and there are slightly more α spins than β spins. As a result, there is a net magnetization along the z -axis.

with a component of length m_l units along the z -axis. As the uncertainty principle does not allow us to specify the x - and y -components of the angular momentum, all we know is that the vector lies somewhere on a cone around the z -axis. For $I = \frac{1}{2}$, the length of the vector is $\frac{1}{2}\sqrt{3}$ and it makes an angle of 55° to the z -axis (Fig. 15.27).

In the absence of a magnetic field, the sample consists of equal numbers of α and β nuclear spins with their vectors lying at random angles on the cones. These angles are unpredictable, and at this stage we picture the spin vectors as stationary. The **magnetization**, $\mathbf{M}$, of the sample, its net nuclear magnetic moment, is zero (Fig. 15.28a).

(a) The effect of the static field

Two changes occur in the magnetization when a magnetic field is present. First, the energies of the two orientations change, the α spins moving to low energy and the β spins to high energy (provided $\gamma > 0$). At 10 T, the Larmor frequency for protons is 427 MHz, and in the vector model the individual vectors are pictured as precessing at this rate. This motion is a pictorial representation of the difference in energy of the spin states (it is not an actual representation of reality). As the field is increased, the Larmor frequency increases and the precession becomes faster. Secondly, the populations of the two spin states (the numbers of α and β spins) at thermal equilibrium change, and there will be more α spins than β spins. Because $h\nu_L/kT \approx 7 \times 10^{-5}$ for protons at 300 K and 10 T, it follows from the Boltzmann distribution that $N_\beta/N_\alpha = e^{-h\nu_L/kT}$ is only slightly less than 1. That is, there is only a tiny imbalance of populations, and it is even smaller for other nuclei with their smaller magnetogyric ratios. However, despite its smallness, the imbalance means that there is a net magnetization that we can represent by a vector $\mathbf{M}$ pointing in the z -direction and with a length proportional to the population difference (Fig. 15.28b).

(b) The effect of the radiofrequency field

We now consider the effect of a radiofrequency field circularly polarized in the xy -plane, so that the magnetic component of the electromagnetic field (the only component we need to consider) is rotating around the z -direction, the direction of the applied field $\mathcal{B}_0$, in the same sense as the Larmor precession. The strength of the rotating magnetic field is $\mathcal{B}_1$. Suppose we choose the frequency of this field to be equal to the Larmor frequency of the spins, $\nu_L = (\gamma/2\pi)\mathcal{B}_0$; this choice is equivalent to selecting the resonance condition in the conventional experiment. The nuclei now experience a steady $\mathcal{B}_1$ field because the rotating magnetic field is in step with the precessing spins (Fig. 15.29a). Just as the spins precess about the strong static field $\mathcal{B}_0$ at a frequency $\gamma\mathcal{B}_0/2\pi$, so under the influence of the field $\mathcal{B}_1$ they precess about $\mathcal{B}_1$ at a frequency $\gamma\mathcal{B}_1/2\pi$.

To interpret the effects of radiofrequency pulses on the magnetization, it is often useful to look at the spin system from a different perspective. If we were to imagine stepping on to a platform, a so-called **rotating frame**, that rotates around the direction of the applied field at the radiofrequency, then the nuclear magnetization appears stationary if the radiofrequency is the same as the Larmor frequency (Fig. 15.29b). If the $\mathcal{B}_1$ field is applied in a pulse of duration $\pi/2\gamma\mathcal{B}_1$, the magnetization tips through 90° in the rotating frame and we say that we have applied a **90° pulse**, or a ' $\pi/2$ pulse' (Fig. 15.30a). The duration of the pulse depends on the strength of the $\mathcal{B}_1$ field, but is typically of the order of microseconds.

Now imagine stepping out of the rotating frame. To an external observer (the role played by a radiofrequency coil) in this stationary frame, the magnetization vector is now rotating at the Larmor frequency in the xy -plane (Fig. 15.30b). The rotating magnetization induces in the coil a signal that oscillates at the Larmor frequency and that

Fig. 15.29 (a) In a resonance experiment, a circularly polarized radiofrequency magnetic field $\mathcal{B}_1$ is applied in the xy -plane (the magnetization vector lies along the z -axis). (b) If we step into a frame rotating at the radiofrequency, $\mathcal{B}_1$ appears to be stationary, as does the magnetization $\mathbf{M}$ if the Larmor frequency is equal to the radiofrequency. When the two frequencies coincide, the magnetization vector of the sample rotates around the direction of the $\mathcal{B}_1$ field.

Fig. 15.30 (a) If the radiofrequency field is applied for a certain time, the magnetization vector is rotated into the xy -plane. (b) To an external stationary observer (the coil), the magnetization vector is rotating at the Larmor frequency, and can induce a signal in the coil.

Fig. 15.31 A simple free-induction decay of a sample of spins with a single resonance frequency.

can be amplified and processed. In practice, the processing takes place after subtraction of a constant high frequency component (the radiofrequency used for $\mathcal{B}_1$), so that all the signal manipulation takes place at frequencies of a few kilohertz.

As time passes, the individual spins move out of step (partly because they are precessing at slightly different rates, as we shall explain later), so the magnetization vector shrinks exponentially with a time constant T_2 and induces an ever weaker signal in the detector coil. The form of the signal that we can expect is therefore the oscillating-decaying **free-induction decay** (FID) shown in Fig. 15.31. The y -component of the magnetization varies as

$$M_y(t) = M_0 \cos(2\pi\nu_L t) e^{-t/T_2} \quad (15.30)$$

We have considered the effect of a pulse applied at exactly the Larmor frequency. However, virtually the same effect is obtained off resonance, provided that the pulse is applied close to ν_L . If the difference in frequency is small compared to the inverse of the duration of the 90° pulse, the magnetization will end up in the xy -plane. Note that we do not need to know the Larmor frequency beforehand: the short pulse is the analogue of the hammer blow on the bell, exciting a range of frequencies. The detected signal shows that a particular resonant frequency is present.

Fig. 15.32 (a) A free induction decay signal of a sample of AX species and (b) its analysis into its frequency components.

Exploration The *Living graphs* section of the text's web site has an applet that allows you to calculate and display the FID curve from an AX system. Explore the effect on the shape of the FID curve of changing the chemical shifts (and therefore the Larmor frequencies) of the A and X nuclei.

Comment 15.6

The web site for this text contains links to databases of NMR spectra and to sites that allow for interactive simulation of NMR spectra.

Fig. 15.33 A free induction decay signal of a sample of ethanol. Its Fourier transform is the frequency-domain spectrum shown in Fig. 15.6. The total length of the image corresponds to about 1 s.

(c) Time- and frequency-domain signals

We can think of the magnetization vector of a homonuclear AX spin system with $J = 0$ as consisting of two parts, one formed by the A spins and the other by the X spins. When the 90° pulse is applied, both magnetization vectors are rotated into the xy -plane. However, because the A and X nuclei precess at different frequencies, they induce two signals in the detector coils, and the overall FID curve may resemble that in Fig. 15.32a. The composite FID curve is the analogue of the struck bell emitting a rich tone composed of all the frequencies at which it can vibrate.

The problem we must address is how to recover the resonance frequencies present in a free-induction decay. We know that the FID curve is a sum of oscillating functions, so the problem is to analyse it into its component frequencies by carrying out a Fourier transformation (*Further information* 13.2 and 15.1). When the signal in Fig. 15.32a is transformed in this way, we get the frequency-domain spectrum shown in Fig. 15.32b. One line represents the Larmor frequency of the A nuclei and the other that of the X nuclei.

The FID curve in Fig. 15.33 is obtained from a sample of ethanol. The frequency-domain spectrum obtained from it by Fourier transformation is the one that we have already discussed (Fig. 15.6). We can now see why the FID curve in Fig. 15.33 is so complex: it arises from the precession of a magnetization vector that is composed of eight components, each with a characteristic frequency.

15.9 Spin relaxation

There are two reasons why the component of the magnetization vector in the xy -plane shrinks. Both reflect the fact that the nuclear spins are not in thermal equilibrium with their surroundings (for then $\mathbf{M}$ lies parallel to z). The return to equilibrium is the process called **spin relaxation**.

(a) Longitudinal and transverse relaxation

At thermal equilibrium the spins have a Boltzmann distribution, with more α spins than β spins; however, a magnetization vector in the xy -plane immediately after a 90° pulse has equal numbers of α and β spins.

Now consider the effect of a **180° pulse**, which may be visualized in the rotating frame as a flip of the net magnetization vector from one direction along the z -axis to the opposite direction. That is, the 180° pulse leads to population inversion of the spin system, which now has more β spins than α spins. After the pulse, the populations revert to their thermal equilibrium values exponentially. As they do so, the z -component of magnetization reverts to its equilibrium value M_0 with a time constant called the **longitudinal relaxation time**, T_1 (Fig. 15.34):

$$M_z(t) - M_0 \propto e^{-t/T_1} \quad (15.31)$$

Because this relaxation process involves giving up energy to the surroundings (the 'lattice') as β spins revert to α spins, the time constant T_1 is also called the **spin-lattice relaxation time**. Spin-lattice relaxation is caused by local magnetic fields that fluctuate at a frequency close to the resonance frequency of the $\alpha \rightarrow \beta$ transition. Such fields can arise from the tumbling motion of molecules in a fluid sample. If molecular tumbling is too slow or too fast compared to the resonance frequency, it will give rise to a fluctuating magnetic field with a frequency that is either too low or too high to stimulate a spin change from β to α , so T_1 will be long. Only if the molecule tumbles at about the resonance frequency will the fluctuating magnetic field be able to induce spin changes effectively, and only then will T_1 be short. The rate of molecular tumbling

Fig. 15.34 In longitudinal relaxation the spins relax back towards their thermal equilibrium populations. On the left we see the precessional cones representing spin- $\frac{1}{2}$ angular momenta, and they do not have their thermal equilibrium populations (there are more α -spins than β -spins). On the right, which represents the sample a long time after a time T_1 has elapsed, the populations are those characteristic of a Boltzmann distribution (see *Molecular interpretation 3.1*). In actuality, T_1 is the time constant for relaxation to the arrangement on the right and $T_1 \ln 2$ is the half-life of the arrangement on the left.

Fig. 15.36 The transverse relaxation time, T_2 , is the time constant for the phases of the spins to become randomized (another condition for equilibrium) and to change from the orderly arrangement shown on the left to the disorderly arrangement on the right (long after a time T_2 has elapsed). Note that the populations of the states remain the same; only the relative phase of the spins relaxes. In actuality, T_2 is the time constant for relaxation to the arrangement on the right and $T_2 \ln 2$ is the half-life of the arrangement on the left.

increases with temperature and with reducing viscosity of the solvent, so we can expect a dependence like that shown in Fig. 15.35.

A second aspect of spin relaxation is the fanning-out of the spins in the xy -plane if they precess at different rates (Fig. 15.36). The magnetization vector is large when all the spins are bunched together immediately after a 90° pulse. However, this orderly bunching of spins is not at equilibrium and, even if there were no spin-lattice relaxation, we would expect the individual spins to spread out until they were uniformly distributed with all possible angles around the z -axis. At that stage, the component of magnetization vector in the plane would be zero. The randomization of the spin directions occurs exponentially with a time constant called the **transverse relaxation time**, T_2 :

$$M_y(t) \propto e^{-t/T_2} \quad (15.32)$$

Fig. 15.35 The variation of the two relaxation times with the rate at which the molecules move (either by tumbling or migrating through the solution). The horizontal axis can be interpreted as representing temperature or viscosity. Note that, at rapid rates of motion, the two relaxation times coincide.

Fig. 15.37 A Lorentzian absorption line. The width at half-height is inversely proportional to the parameter T_2 and the longer the transverse relaxation time, the narrower the line.

 **Exploration** The *Living graphs* section of the text's web site has an applet that allows you to calculate and display Lorentzian absorption lines. Explore the effect of the parameter T_2 on the width and the maximal intensity of a Lorentzian line. Rationalize your observations.

Fig. 15.38 The result of applying a 180° pulse to the magnetization in the rotating frame and the effect of a subsequent 90° pulse. The amplitude of the frequency-domain spectrum varies with the interval between the two pulses because spin–lattice relaxation has time to occur.

Because the relaxation involves the relative orientation of the spins, T_2 is also known as the **spin–spin relaxation time**. Any relaxation process that changes the balance between α and β spins will also contribute to this randomization, so the time constant T_2 is almost always less than or equal to T_1 .

Local magnetic fields also affect spin–spin relaxation. When the fluctuations are slow, each molecule lingers in its local magnetic environment and the spin orientations randomize quickly around the applied field direction. If the molecules move rapidly from one magnetic environment to another, the effects of differences in local magnetic field average to zero: individual spins do not precess at very different rates, they can remain bunched for longer, and spin–spin relaxation does not take place as quickly. In other words, slow molecular motion corresponds to short T_2 and fast motion corresponds to long T_2 (as shown in Fig. 15.35). Calculations show that, when the motion is fast, $T_2 \approx T_1$.

If the y -component of magnetization decays with a time constant T_2 , the spectral line is broadened (Fig. 15.37), and its width at half-height becomes

$$\Delta\nu_{1/2} = \frac{1}{\pi T_2} \quad (15.33)$$

Typical values of T_2 in proton NMR are of the order of seconds, so linewidths of around 0.1 Hz can be anticipated, in broad agreement with observation.

So far, we have assumed that the equipment, and in particular the magnet, is perfect, and that the differences in Larmor frequencies arise solely from interactions within the sample. In practice, the magnet is not perfect, and the field is different at different locations in the sample. The inhomogeneity broadens the resonance, and in most cases this **inhomogeneous broadening** dominates the broadening we have discussed so far. It is common to express the extent of inhomogeneous broadening in terms of an **effective transverse relaxation time**, T_2^* , by using a relation like eqn 15.33, but writing

$$T_2^* = \frac{1}{\pi \Delta\nu_{1/2}} \quad [15.34]$$

where $\Delta\nu_{1/2}$ is the observed width at half-height of a line with a Lorentzian shape of the form $I \propto 1/(1 + \nu^2)$. As an example, consider a line in a spectrum with a width of 10 Hz. It follows from eqn 15.34 that the effective transverse relaxation time is

$$T_2^* = \frac{1}{\pi \times (10 \text{ s}^{-1})} = 32 \text{ ms}$$

(b) The measurement of T_1

The longitudinal relaxation time T_1 can be measured by the **inversion recovery technique**. The first step is to apply a 180° pulse to the sample. A 180° pulse is achieved by applying the B_1 field for twice as long as for a 90° pulse, so the magnetization vector precesses through 180° and points in the $-z$ -direction (Fig. 15.38). No signal can be seen at this stage because there is no component of magnetization in the xy -plane (where the coil can detect it). The β spins begin to relax back into α spins, and the magnetization vector first shrinks exponentially, falling through zero to its thermal equilibrium value, M_z . After an interval τ , a 90° pulse is applied that rotates the magnetization into the xy -plane, where it generates an FID signal. The frequency-domain spectrum is then obtained by Fourier transformation.

The intensity of the spectrum obtained in this way depends on the length of the magnetization vector that is rotated into the xy -plane. The length of that vector changes exponentially as the interval between the two pulses is increased, so the intensity of the spectrum also changes exponentially with increasing τ . We can therefore measure T_1 by fitting an exponential curve to the series of spectra obtained with different values of τ .

(c) Spin echoes

The measurement of T_2 (as distinct from T_2^*) depends on being able to eliminate the effects of inhomogeneous broadening. The cunning required is at the root of some of the most important advances that have been made in NMR since its introduction.

A **spin echo** is the magnetic analogue of an audible echo: transverse magnetization is created by a radiofrequency pulse, decays away, is reflected by a second pulse, and grows back to form an echo. The sequence of events is shown in Fig. 15.39. We can consider the overall magnetization as being made up of a number of different magnetizations, each of which arises from a **spin packet** of nuclei with very similar precession frequencies. The spread in these frequencies arises because the applied field $\mathcal{B}_0$ is inhomogeneous, so different parts of the sample experience different fields. The precession frequencies also differ if there is more than one chemical shift present. As will be seen, the importance of a spin echo is that it can suppress the effects of both field inhomogeneities and chemical shifts.

First, a 90° pulse is applied to the sample. We follow events by using the rotating frame, in which $\mathcal{B}_1$ is stationary along the x -axis and causes the magnetization to be into the xy -plane. The spin packets now begin to fan out because they have different Larmor frequencies, with some above the radiofrequency and some below. The detected signal depends on the resultant of the spin-packet magnetization vectors, and decays with a time-constant T_2^* because of the combined effects of field inhomogeneity and spin-spin relaxation.

After an evolution period τ , a 180° pulse is applied to the sample; this time, about the y -axis of the rotating frame (the axis of the pulse is changed from x to y by a 90° phase shift of the radiofrequency radiation). The pulse rotates the magnetization vectors of the faster spin packets into the positions previously occupied by the slower spin packets, and vice versa. Thus, as the vectors continue to precess, the fast vectors are now behind the slow; the fan begins to close up again, and the resultant signal begins to grow back into an echo. At time 2τ , all the vectors will once more be aligned along the y -axis, and the fanning out caused by the field inhomogeneity is said to have been **refocused**: the spin echo has reached its maximum. Because the effects of field inhomogeneities have been suppressed by the refocusing, the echo signal will have been attenuated by the factor $e^{-2\tau/T_2}$ caused by spin-spin relaxation alone. After the time 2τ , the magnetization will continue to precess, fanning out once again, giving a resultant that decays with time constant T_2^* .

The important feature of the technique is that the size of the echo is independent of any local fields that remain constant during the two τ intervals. If a spin packet is 'fast' because it happens to be composed of spins in a region of the sample that experiences higher than average fields, then it remains fast throughout both intervals, and what it gains on the first interval it loses on the second interval. Hence, the size of the echo is independent of inhomogeneities in the magnetic field, for these remain constant. The true transverse relaxation arises from fields that vary on a molecular distance scale, and there is no guarantee that an individual 'fast' spin will remain 'fast' in the refocusing phase: the spins within the packets therefore spread with a time constant T_2 . Hence, the effects of the true relaxation are not refocused, and the size of the echo decays with the time constant T_2 (Fig. 15.40).

Fig. 15.39 The sequence of pulses leading to the observation of a spin echo.

Fig. 15.40 The exponential decay of spin echoes can be used to determine the transverse relaxation time.

Fig. 15.41 In a magnetic field that varies linearly over a sample, all the protons within a given slice (that is, at a given field value) come into resonance and give a signal of the corresponding intensity. The resulting intensity pattern is a map of the numbers in all the slices, and portrays the shape of the sample. Changing the orientation of the field shows the shape along the corresponding direction, and computer manipulation can be used to build up the three-dimensional shape of the sample.

IMPACT ON MEDICINE

15.1 Magnetic resonance imaging

One of the most striking applications of nuclear magnetic resonance is in medicine. *Magnetic resonance imaging* (MRI) is a portrayal of the concentrations of protons in a solid object. The technique relies on the application of specific pulse sequences to an object in an inhomogeneous magnetic field.

If an object containing hydrogen nuclei (a tube of water or a human body) is placed in an NMR spectrometer and exposed to a *homogeneous* magnetic field, then a single resonance signal will be detected. Now consider a flask of water in a magnetic field that varies linearly in the z -direction according to $\mathcal{B}_0 + G_z z$, where G_z is the field gradient along the z -direction (Fig. 15.41). Then the water protons will be resonant at the frequencies

$$\nu_L(z) = \frac{\gamma}{2\pi} (\mathcal{B}_0 + G_z z) \quad (15.35)$$

(Similar equations may be written for gradients along the x - and y -directions.) Application of a 90° radiofrequency pulse with $\nu = \nu_L(z)$ will result in a signal with an intensity that is proportional to the numbers of protons at the position z . This is an example of *slice selection*, the application of a selective 90° pulse that excites nuclei in a specific region, or slice, of the sample. It follows that the intensity of the NMR signal will be a projection of the numbers of protons on a line parallel to the field gradient. The image of a three-dimensional object such as a flask of water can be obtained if the slice selection technique is applied at different orientations (see Fig. 15.41). In *projection reconstruction*, the projections can be analysed on a computer to reconstruct the three-dimensional distribution of protons in the object.

In practice, the NMR signal is not obtained by direct analysis of the FID curve after application of a single 90° pulse. Instead, spin echoes are often detected with several variations of the 90° – τ – 180° pulse sequence (Section 15.9c). In *phase encoding*, field gradients are applied during the evolution period and the detection period of a spin-echo pulse sequence. The first step consists of a 90° pulse that results in slice selection along the z -direction. The second step consists of application of a *phase gradient*, a field gradient along the y -direction, during the evolution period. At each position along the gradient, a spin packet will precess at a different Larmor frequency due to chemical shift effects and the field inhomogeneity, so each packet will dephase to a different extent by the end of the evolution period. We can control the extent of dephasing by changing the duration of the evolution period, so Fourier transformation on τ gives information about the location of a proton along the y -direction.¹ For each value of τ , the next steps are application of the 180° pulse and then of a *read gradient*, a field gradient along the x -direction, during detection of the echo. Protons at different positions along x experience different fields and will resonate at different frequencies. Therefore Fourier transformation of the FID gives different signals for protons at different positions along x .

A common problem with the techniques described above is image contrast, which must be optimized in order to show spatial variations in water content in the sample. One strategy for solving this problem takes advantage of the fact that the relaxation times of water protons are shorter for water in biological tissues than for the pure liquid. Furthermore, relaxation times from water protons are also different in healthy and diseased tissues. A T_1 -*weighted image* is obtained by repeating the spin echo sequence

¹ For technical reasons, it is more common to vary the magnitude of the phase gradient. See *Further reading* for details.

before spin–lattice relaxation can return the spins in the sample to equilibrium. Under these conditions, differences in signal intensities are directly related to differences in T_1 . A T_2 -weighted image is obtained by using an evolution period τ that is relatively long. Each point on the image is an echo signal that behaves in the manner shown in Fig. 15.40, so signal intensities are strongly dependent on variations in T_2 . However, allowing so much of the decay to occur leads to weak signals even for those protons with long spin–spin relaxation times. Another strategy involves the use of *contrast agents*, paramagnetic compounds that shorten the relaxation times of nearby protons. The technique is particularly useful in enhancing image contrast and in diagnosing disease if the contrast agent is distributed differently in healthy and diseased tissues.

The MRI technique is used widely to detect physiological abnormalities and to observe metabolic processes. With *functional MRI*, blood flow in different regions of the brain can be studied and related to the mental activities of the subject. The technique is based on differences in the magnetic properties of deoxygenated and oxygenated haemoglobin, the iron-containing protein that transports O_2 in red blood cells. The more paramagnetic deoxygenated haemoglobin affects the proton resonances of tissue differently from the oxygenated protein. Because there is greater blood flow in active regions of the brain than in inactive regions, changes in the intensities of proton resonances due to changes in levels of oxygenated haemoglobin can be related to brain activity.

The special advantage of MRI is that it can image *soft* tissues (Fig. 15.42), whereas X-rays are largely used for imaging hard, bony structures and abnormally dense regions, such as tumours. In fact, the invisibility of hard structures in MRI is an advantage, as it allows the imaging of structures encased by bone, such as the brain and the spinal cord. X-rays are known to be dangerous on account of the ionization they cause; the high magnetic fields used in MRI may also be dangerous but, apart from anecdotes about the extraction of loose fillings from teeth, there is no convincing evidence of their harmfulness, and the technique is considered safe.

15.10 Spin decoupling

Carbon-13 is a **dilute-spin species** in the sense that it is unlikely that more than one ^{13}C nucleus will be found in any given small molecule (provided the sample has not been enriched with that isotope; the natural abundance of ^{13}C is only 1.1 per cent). Even in large molecules, although more than one ^{13}C nucleus may be present, it is unlikely that they will be close enough to give an observable splitting. Hence, it is not normally necessary to take into account ^{13}C – ^{13}C spin–spin coupling within a molecule.

Protons are **abundant-spin species** in the sense that a molecule is likely to contain many of them. If we were observing a ^{13}C -NMR spectrum, we would obtain a very complex spectrum on account of the coupling of the one ^{13}C nucleus with many of the protons that are present. To avoid this difficulty, ^{13}C -NMR spectra are normally observed using the technique of **proton decoupling**. Thus, if the CH_3 protons of ethanol are irradiated with a second, strong, resonant radiofrequency pulse, they undergo rapid spin reorientations and the ^{13}C nucleus senses an average orientation. As a result, its resonance is a single line and not a 1:3:3:1 quartet. Proton decoupling has the additional advantage of enhancing sensitivity, because the intensity is concentrated into a single transition frequency instead of being spread over several transition frequencies (see Section 15.11). If care is taken to ensure that the other parameters on which the strength of the signal depends are kept constant, the intensities of proton-decoupled spectra are proportional to the number of ^{13}C nuclei present. The technique is widely used to characterize synthetic polymers.

Fig. 15.42 The great advantage of MRI is that it can display soft tissue, such as in this cross-section through a patient's head. (Courtesy of the University of Manitoba.)

Comment 15.7

In a dipole–dipole interaction between two nuclei, one nucleus influences the behaviour of another nucleus in much the same way that the orientation of a bar magnet is influenced by the presence of another bar magnet nearby.

Dipole–dipole interactions are discussed in Chapter 18.

Fig. 15.43 The energy levels of an AX system and an indication of their relative populations. Each grey square above the line represents an excess population and each white square below the line represents a population deficit. The transitions of A and X are marked.

15.11 The nuclear Overhauser effect

We have seen already that one advantage of protons in NMR is their high magnetogyric ratio, which results in relatively large Boltzmann population differences and hence greater resonance intensities than for most other nuclei. In the steady-state **nuclear Overhauser effect** (NOE), spin relaxation processes involving internuclear dipole–dipole interactions are used to transfer this population advantage to another nucleus (such as ^{13}C or another proton), so that the latter's resonances are modified.

To understand the effect, we consider the populations of the four levels of a homonuclear (for instance, proton) AX system; these were shown in Fig. 15.12. At thermal equilibrium, the population of the $\alpha_A\alpha_X$ level is the greatest, and that of the $\beta_A\beta_X$ level is the least; the other two levels have the same energy and an intermediate population. The thermal equilibrium absorption intensities reflect these populations as shown in Fig. 15.43. Now consider the combined effect of spin relaxation and keeping the X spins saturated. When we saturate the X transition, the populations of the X levels are equalized ($N_{\alpha_X} = N_{\beta_X}$) and all transitions involving $\alpha_X \leftrightarrow \beta_X$ spin flips are no longer observed. At this stage there is no change in the populations of the A levels. If that were all there were to happen, all we would see would be the loss of the X resonance and no effect on the A resonance.

Now consider the effect of spin relaxation. Relaxation can occur in a variety of ways if there is a dipolar interaction between the A and X spins. One possibility is for the magnetic field acting between the two spins to cause them both to flop from β to α , so the $\alpha_A\alpha_X$ and $\beta_A\beta_X$ states regain their thermal equilibrium populations. However, the populations of the $\alpha_A\beta_X$ and $\beta_A\alpha_X$ levels remain unchanged at the values characteristic of saturation. As we see from Fig. 15.44, the population difference between the states joined by transitions of A is now greater than at equilibrium, so the resonance absorption is enhanced. Another possibility is for the dipolar interaction between the two spins to cause α to flip to β and β to flop to α . This transition equilibrates the populations of $\alpha_A\beta_X$ and $\beta_A\alpha_X$ but leaves the $\alpha_A\alpha_X$ and $\beta_A\beta_X$ populations unchanged. Now we see from the illustration that the population differences in the states involved in the A transitions are decreased, so the resonance absorption is diminished.

Which effect wins? Does the NOE enhance the A absorption or does it diminish it? As in the discussion of relaxation times in Section 15.9, the efficiency of the intensity-enhancing $\beta_A\beta_X \leftrightarrow \alpha_A\alpha_X$ relaxation is high if the dipole field oscillates at a frequency close to the transition frequency, which in this case is about 2ν ; likewise, the efficiency

Fig. 15.44 (a) When the X transition is saturated, the populations of its two states are equalized and the population excess and deficit become as shown (using the same symbols as in Fig. 15.43). (b) Dipole–dipole relaxation relaxes the populations of the highest and lowest states, and they regain their original populations. (c) The A transitions reflect the difference in populations resulting from the preceding changes, and are enhanced compared with those shown in Fig. 15.43.

Fig. 15.45 (a) When the X transition is saturated, just as in Fig. 15.44 the populations of its two states are equalized and the population excess and deficit become as shown. (b) Dipole–dipole relaxation relaxes the populations of the two intermediate states, and they regain their original populations. (c) The A transitions reflect the difference in populations resulting from the preceding changes, and are diminished compared with those shown in Fig. 15.41.

of the intensity-diminishing $\alpha_A\beta_X \leftrightarrow \beta_A\alpha_X$ relaxation is high if the dipole field is stationary (as there is no frequency difference between the initial and final states). A large molecule rotates so slowly that there is very little motion at 2ν , so we expect an intensity decrease (Fig. 15.45). A small molecule rotating rapidly can be expected to have substantial motion at 2ν , and a consequent enhancement of the signal. In practice, the enhancement lies somewhere between the two extremes and is reported in terms of the parameter η (eta), where

$$\eta = \frac{I_A - I_A^\circ}{I_A^\circ} \quad [15.36]$$

Here I_A° and I_A are the intensities of the NMR signals due to nucleus A before and after application of the long ($> T_1$) radiofrequency pulse that saturates transitions due to the X nucleus. When A and X are nuclei of the same species, such as protons, η lies between -1 (diminution) and $+\frac{1}{2}$ (enhancement). However, η also depends on the values of the magnetogyric ratios of A and X. In the case of maximal enhancement it is possible to show that

$$\eta = \frac{\gamma_X}{2\gamma_A} \quad (15.37)$$

where γ_A and γ_X are the magnetogyric ratios of nuclei A and X, respectively. For ^{13}C close to a saturated proton, the ratio evaluates to 1.99, which shows that an enhancement of about a factor of 2 can be achieved.

The NOE is also used to determine interproton distances. The Overhauser enhancement of a proton A generated by saturating a spin X depends on the fraction of A's spin–lattice relaxation that is caused by its dipolar interaction with X. Because the dipolar field is proportional to r^{-3} , where r is the internuclear distance, and the relaxation effect is proportional to the square of the field, and therefore to r^{-6} , the NOE may be used to determine the geometries of molecules in solution. The determination of the structure of a small protein in solution involves the use of several hundred NOE measurements, effectively casting a net over the protons present. The enormous importance of this procedure is that we can determine the conformation of biological macromolecules in an aqueous environment and do not need to try to make the single crystals that are essential for an X-ray diffraction investigation (Chapter 20).

15.12 Two-dimensional NMR

An NMR spectrum contains a great deal of information and, if many protons are present, is very complex. Even a first-order spectrum is complex, for the fine structure of different groups of lines can overlap. The complexity would be reduced if we could use two axes to display the data, with resonances belonging to different groups lying at different locations on the second axis. This separation is essentially what is achieved in **two-dimensional NMR**.

All two-dimensional NMR experiments use the **PEMD pulse structure**, which consists of:

Fig. 15.46 The pulse sequence used in correlation spectroscopy (COSY). The preparation period is much longer than either T_1 or T_2 , so the spins have time to relax before the next cycle of pulses begins. Acquisitions of free-induction decays are taken during t_2 for a set of different evolution times t_1 . Fourier transformation on both variables t_1 and t_2 results in a two-dimensional spectrum, such as that shown in Fig 15.52.

Comment 15.8

A vector, v , of length v , in the xy -plane and its two components, v_x and v_y , can be thought of as forming a right-angled triangle, with v the length of the hypotenuse (see the illustration). If θ is the angle that v_y makes with v , then it follows that $v_x = v \sin \theta$ and $v_y = v \cos \theta$.

P: a *preparation period*, in which the spins first return to thermal equilibrium and then are excited by one or more radiofrequency pulses

E: an *evolution period* of duration t_1 , during which the spins precess under the influence of their chemical shifts and spin–spin couplings

M: a *mixing period*, in which pulses may be used to transfer information between spins

D: a *detection period* of duration t_2 , during which the FID is recorded.

Now we shall see how the PEMD pulse structure can be used to devise experiments that reveal spin–spin couplings and internuclear distances in small and large molecules.

(a) Correlation spectroscopy

Much modern NMR work makes use of techniques such as **correlation spectroscopy** (COSY) in which a clever choice of pulses and Fourier transformation techniques makes it possible to determine all spin–spin couplings in a molecule. The basic COSY experiment uses the simplest of all two-dimensional pulse sequences, consisting of two consecutive 90° pulses (Fig. 15.46).

To see how we can obtain a two-dimensional spectrum from a COSY experiment, we consider a trivial but illustrative example: the spectrum of a compound containing one proton, such as trichloromethane (chloroform, CHCl_3). Figure 15.47 shows the effect of the pulse sequence on the magnetization of the sample, which is aligned initially along the z -axis with a magnitude M_0 . A 90° pulse applied in the x -direction (in the stationary frame) tilts the magnetization vector toward the y -axis. Then, during the evolution period, the magnetization vector rotates in the xy -plane with a frequency ν . At a time t_1 the vector will have swept through an angle $2\pi\nu t_1$ and the magnitude of the magnetization will have decayed by spin–spin relaxation to $M = M_0 e^{-t_1/T_2}$. By trigonometry, the magnitudes of the components of the magnetization vector are:

$$M_x = M \sin 2\pi\nu t_1 \quad M_y = M \cos 2\pi\nu t_1 \quad M_z = 0 \quad (15.38a)$$

Application of the second 90° pulse parallel to the x -axis tilts the magnetization again and the resulting vector has components with magnitudes (once again, in the stationary frame)

$$M_x = M \sin 2\pi\nu t_1 \quad M_y = 0 \quad M_z = M \cos 2\pi\nu t_1 \quad (15.38b)$$

The FID is detected over a period t_2 and Fourier transformation yields a signal over a frequency range ν_2 with a peak at ν , the resonance frequency of the proton. The signal intensity is related to M_x , the magnitude of the magnetization that is rotating around the xy -plane at the time of application of the detection pulse, so it follows that the signal strength varies sinusoidally with the duration of the evolution period. That is, if we were to acquire a series of spectra at different evolution times t_1 , then we would obtain data as shown in Fig. 15.48a.

Fig. 15.48 (a) Spectra acquired for different evolution times t_1 between two 90° pulses. (b) A plot of the maximum intensity of each absorption line against t_1 . Fourier transformation of this plot leads to a spectrum centred at ν , the resonance frequency of the protons in the sample.

Fig. 15.49 (a) The two-dimensional NMR spectrum of the sample discussed in Figs. 15.47 and 15.48. See the text for an explanation of how the spectrum is obtained from a series of Fourier transformations of the data. (b) The contour plot of the spectrum in (a).

A plot of the maximum intensity of each absorption band in Fig. 15.48a against t_1 has the form shown in Fig. 15.48b. The plot resembles an FID curve with the oscillating component having a frequency ν , so Fourier transformation yields a signal over a frequency range ν_1 with a peak at ν . If we continue the process by first plotting signal intensity against t_1 for several frequencies along the ν_2 axis and then carrying out Fourier transformations, we generate a family of curves that can be pooled together into a three-dimensional plot of $I(\nu_1, \nu_2)$, the signal intensity as a function of the frequencies ν_1 and ν_2 (Fig. 15.49a). This plot is referred to as a *two-dimensional NMR spectrum* because Fourier transformations were performed in two variables. The most common representation of the data is as a contour plot, such as the one shown in Fig. 15.49b.

The experiment described above is not necessary for as simple a system as chloroform because the information contained in the two-dimensional spectrum could have been obtained much more quickly through the conventional, one-dimensional approach. However, when the one-dimensional spectrum is complex, the COSY experiment shows which spins are related by spin–spin coupling. To justify this statement, we now examine a spin-coupled AX system.

From our discussion so far, we know that the key to the COSY technique is the effect of the second 90° pulse. In this more complex example we consider its role for the four energy levels of an AX system (as shown in Fig. 15.12). At thermal equilibrium, the population of the $\alpha_A\alpha_X$ level is the greatest, and that of the $\beta_A\beta_X$ level is the least; the other two levels have the same energy and an intermediate population. After the first 90° pulse, the spins are no longer at thermal equilibrium. If a second 90° pulse

Fig. 15.47 (a) The effect of the pulse sequence shown in Fig. 15.46 on the magnetization M_0 of a sample of a compound with only one proton. (b) A 90° pulse applied in the x -direction tilts the magnetization vector toward the y -axis. (c) After a time t_1 has elapsed, the vector will have swept through an angle $2\pi\nu t_1$ and the magnitude of the magnetization will have decayed to M . The magnitudes of the components of M are $M_x = M \sin 2\pi\nu t_1$, $M_y = M \cos 2\pi\nu t_1$, and $M_z = 0$. (d) Application of the second 90° pulse parallel to the x -axis tilts the magnetization again and the resulting vector has components with magnitude $M_x = M \sin 2\pi\nu t_1$, $M_y = 0$, and $M_z = M \cos 2\pi\nu t_1$. The FID is detected at this stage of the experiment.

Fig. 15.50 An example of the change in the population of energy levels of an AX spin system that results from the second 90° pulse of a COSY experiment. Each square represents the same large number of spins. In this example, we imagine that the pulse affects the X spins first, and then the A spins. Excitation of the X spins inverts the populations of the $\beta_A\beta_X$ and $\beta_A\alpha_X$ levels and does not affect the populations of the $\alpha_A\alpha_X$ and $\alpha_A\beta_X$ levels. As a result, excitation of the A spins by the pulse generates an FID in which one of the two A transitions has increased in intensity and the other has decreased. That is, magnetization has been transferred from the X spins to the A spins. Similar schemes can be written to show that magnetization can be transferred from the A spins to the X spins.

is applied at a time t_1 that is short compared to the spin–lattice relaxation time T_1 , the extra input of energy causes further changes in the populations of the four states. The changes in populations of the four states of the AX system will depend on how far the individual magnetizations have precessed during the evolution period. It is difficult to visualize these changes because the A spins are affecting the X spins and vice-versa.

For simplicity, we imagine that the second pulse induces X and A transitions sequentially. Depending on the evolution time t_1 , the 90° pulse may leave the population differences across each of the two X transitions unchanged, inverted, or somewhere in between. Consider the extreme case in which one population difference is inverted and the other unchanged (Fig. 15.50). Excitation of the A transitions will now generate an FID in which one of the two A transitions has increased in intensity (because the population difference is now greater), and the other has decreased (because the population difference is now smaller). The overall effect is that precession of the X spins during the evolution period determines the amplitudes of the signals from the A spins obtained during the detection period. As the evolution time t_1 is increased, the intensities of the signals from A spins oscillate with frequencies determined by the frequencies of the two X transitions. Of course, it is just as easy to turn our scenario around and to conclude that the intensities of signals from X spins oscillate with frequencies determined by the frequencies of the A transitions.

This transfer of information between spins is at the heart of two-dimensional NMR spectroscopy: it leads to the *correlation* between different signals in a spectrum. In this case, information transfer tells us that there is spin–spin coupling between A and X. So, just as before, if we conduct a series of experiments in which t_1 is incremented, Fourier transformation of the FIDs on t_2 yields a set of spectra $I(t_1, F_2)$ in which the signal amplitudes oscillate as a function of t_1 . A second Fourier transformation, now on t_1 , converts these oscillations into a two-dimensional spectrum $I(F_1, F_2)$. The signals are spread out in F_1 according to their precession frequencies during the detection period. Thus, if we apply the COSY pulse sequence (Fig. 15.46) to the AX spin system, the result is a two-dimensional spectrum that contains four groups of signals in F_1 and F_2 centred on the two chemical shifts (Fig. 15.51). Each group consists of a block of four signals separated by J . The **diagonal peaks** are signals centred on (δ_A, δ_A) and (δ_X, δ_X) and lie along the diagonal $F_1 = F_2$. That is, the spectrum along the diagonal is equivalent to the one-dimensional spectrum obtained with the conventional NMR technique (Fig. 15.13). The **cross-peaks** (or *off-diagonal peaks*) are signals centred on (δ_A, δ_X) and (δ_X, δ_A) and owe their existence to the coupling between A and X.

Although information from two-dimensional NMR spectroscopy is trivial in an AX system, it can be of enormous help in the interpretation of more complex spectra, leading to a map of the couplings between spins and to the determination of the bonding network in complex molecules. Indeed, the spectrum of a synthetic or biological polymer that would be impossible to interpret in one-dimensional NMR but can often be interpreted reasonably rapidly by two-dimensional NMR. Below we illustrate the procedure by assigning the resonances in the COSY spectrum of an amino acid.

Fig. 15.51 A representation of the two-dimensional NMR spectrum obtained by application of the COSY pulse sequence to an AX spin system.

Fig. 15.52 Proton COSY spectrum of isoleucine. (Adapted from K.E. van Holde, W.C. Johnson, and P.S. Ho, *Principles of physical biochemistry*, p. 508, Prentice Hall, Upper Saddle River (1998).)

Illustration 15.3 The COSY spectrum of isoleucine

Figure 15.52 is a portion of the COSY spectrum of the amino acid isoleucine (7), showing the resonances associated with the protons bound to the carbon atoms. We begin the assignment process by considering which protons should be interacting by spin–spin coupling. From the known molecular structure, we conclude that:

1. The C_a –H proton is coupled only to the C_b –H proton.
2. The C_b –H protons are coupled to the C_a –H, C_c –H, and C_d –H protons.
3. The inequivalent C_d –H protons are coupled to the C_b –H and C_e –H protons.

We now note that:

- The resonance with $\delta = 3.6$ shares a cross-peak with only one other resonance at $\delta = 1.9$, which in turn shares cross-peaks with resonances at $\delta = 1.4$, 1.2 , and 0.9 . This identification is consistent with the resonances at $\delta = 3.6$ and 1.9 corresponding to the C_a –H and C_b –H protons, respectively.
- The proton with resonance at $\delta = 0.8$ is not coupled to the C_b –H protons, so we assign the resonance at $\delta = 0.8$ to the C_e –H protons.
- The resonances at $\delta = 1.4$ and 1.2 do not share cross-peaks with the resonance at $\delta = 0.9$.

In the light of the expected couplings, we assign the resonance at $\delta = 0.9$ to the C_c –H protons and the resonances at $\delta = 1.4$ and 1.2 to the inequivalent C_d –H protons.

7 Isoleucine

Our simplified description of the COSY experiment does not reveal some important details. For example, the second 90° pulse actually mixes the spin state transitions caused by the first 90° pulse (hence the term ‘mixing period’). Each of the four transitions (two for A and two for X) generated by the first pulse can be converted into any of the other three, or into formally forbidden **multiple quantum transitions**, which have $|\Delta m| > 1$. The latter transitions cannot generate any signal in the receiver coil of the spectrometer, but their existence can be demonstrated by applying a third pulse to mix them back into the four observable single quantum transitions. Many modern NMR experiments exploit multiple quantum transitions to filter out unwanted signals and to simplify spectra for interpretation.

(b) Nuclear Overhauser effect spectroscopy

Many different two-dimensional NMR experiments are based on the PEMD pulse structure. We have seen that the steady-state nuclear Overhauser effect can provide information about internuclear distances through analysis of enhancement patterns in the NMR spectrum before and after saturation of selected resonances. In its dynamic analogue, **nuclear Overhauser effect spectroscopy** (NOESY), the second 90° pulse of the COSY experiment is replaced by two 90° pulses separated by a time delay during which dipole–dipole interactions cause magnetization to be exchanged between neighbouring spins (Fig. 15.50). The results of double Fourier transformation is a spectrum in which the cross-peaks form a map of all the NOE interactions in a molecule. Because the nuclear Overhauser effect depends on the inverse sixth power of the separation between nuclei (see Section 15.11), NOESY data reveal internuclear distances up to about 0.5 nm.

15.13 Solid-state NMR

The principal difficulty with the application of NMR to solids is the low resolution characteristic of solid samples. Nevertheless, there are good reasons for seeking to overcome these difficulties. They include the possibility that a compound of interest is unstable in solution or that it is insoluble, so conventional solution NMR cannot be employed. Moreover, many species are intrinsically interesting as solids, and it is important to determine their structures and dynamics. Synthetic polymers are particularly interesting in this regard, and information can be obtained about the arrangement of molecules, their conformations, and the motion of different parts of the chain. This kind of information is crucial to an interpretation of the bulk properties of the polymer in terms of its molecular characteristics. Similarly, inorganic substances, such as the zeolites that are used as molecular sieves and shape-selective catalysts, can be studied using solid-state NMR, and structural problems can be resolved that cannot be tackled by X-ray diffraction.

Problems of resolution and linewidth are not the only features that plague NMR studies of solids, but the rewards are so great that considerable efforts have been made to overcome them and have achieved notable success. Because molecular rotation has almost ceased (except in special cases, including ‘plastic crystals’ in which the molecules continue to tumble), spin–lattice relaxation times are very long but spin–spin relaxation times are very short. Hence, in a pulse experiment, there is a need for lengthy delays—of several seconds—between successive pulses so that the spin system has time to revert to equilibrium. Even gathering the murky information may therefore be a lengthy process. Moreover, because lines are so broad, very high powers of radio-frequency radiation may be required to achieve saturation. Whereas solution pulse NMR uses transmitters of a few tens of watts, solid-state NMR may require transmitters rated at several hundreds of watts.

(a) The origins of linewidths in solids

There are two principal contributions to the linewidths of solids. One is the direct magnetic dipolar interaction between nuclear spins. As we saw in the discussion of spin–spin coupling, a nuclear magnetic moment will give rise to a local magnetic field, which points in different directions at different locations around the nucleus. If we are interested only in the component parallel to the direction of the applied magnetic field (because only this component has a significant effect), then we can use a classical expression to write the magnitude of the local magnetic field as

$$\mathcal{B}_{\text{loc}} = -\frac{\gamma \hbar \mu_0 m_I}{4\pi R^3} (1 - 3 \cos^2 \theta) \quad (15.39)$$

Unlike in solution, this field is not motionally averaged to zero. Many nuclei may contribute to the total local field experienced by a nucleus of interest, and different nuclei in a sample may experience a wide range of fields. Typical dipole fields are of the order of 10^{-3} T, which corresponds to splittings and linewidths of the order of 10^4 Hz.

A second source of linewidth is the anisotropy of the chemical shift. We have seen that chemical shifts arise from the ability of the applied field to generate electron currents in molecules. In general, this ability depends on the orientation of the molecule relative to the applied field. In solution, when the molecule is tumbling rapidly, only the average value of the chemical shift is relevant. However, the anisotropy is not averaged to zero for stationary molecules in a solid, and molecules in different orientations have resonances at different frequencies. The chemical shift anisotropy also varies with the angle between the applied field and the principal axis of the molecule as $1 - 3 \cos^2 \theta$.

(b) The reduction of linewidths

Fortunately, there are techniques available for reducing the linewidths of solid samples. One technique, **magic-angle spinning** (MAS), takes note of the $1 - 3 \cos^2 \theta$ dependence of both the dipole–dipole interaction and the chemical shift anisotropy. The ‘magic angle’ is the angle at which $1 - 3 \cos^2 \theta = 0$, and corresponds to 54.74° . In the technique, the sample is spun at high speed at the magic angle to the applied field (Fig. 15.53). All the dipolar interactions and the anisotropies average to the value they would have at the magic angle, but at that angle they are zero. The difficulty with MAS is that the spinning frequency must not be less than the width of the spectrum, which is of the order of kilohertz. However, gas-driven sample spinners that can be rotated at up to 25 kHz are now routinely available, and a considerable body of work has been done.

Pulsed techniques similar to those described in the previous section may also be used to reduce linewidths. The dipolar field of protons, for instance, may be reduced by a decoupling procedure. However, because the range of coupling strengths is so large, radiofrequency power of the order of 1 kW is required. Elaborate pulse sequences have also been devised that reduce linewidths by averaging procedures that make use of twisting the magnetization vector through an elaborate series of angles.

Electron paramagnetic resonance

Electron paramagnetic resonance (EPR) is less widely applicable than NMR because it cannot be detected in normal, spin-paired molecules and the sample must possess unpaired electron spins. It is used to study radicals formed during chemical reactions or by radiation, radicals that act as probes of biological structure, many *d*-metal complexes, and molecules in triplet states (such as those involved in phosphorescence, Section 14.3b). The sample may be a gas, a liquid, or a solid, but the free rotation of molecules in the gas phase gives rise to complications.

15.14 The EPR spectrometer

Both Fourier-transform (FT) and continuous wave (CW) EPR spectrometers are available. The FT-EPR instrument is based on the concepts developed in Section 15.8, except that pulses of microwaves are used to excite electron spins in the sample. The layout of the more common CW-EPR spectrometer is shown in Fig. 15.54. It consists

Fig. 15.53 In magic angle spinning, the sample spins at 54.74° (that is, $\arccos(1/3)^{1/2}$) to the applied magnetic field. Rapid motion at this angle averages dipole–dipole interactions and chemical shift anisotropies to zero.

Fig. 15.54 The layout of a continuous-wave EPR spectrometer. A typical magnetic field is 0.3 T, which requires 9 GHz (3 cm) microwaves for resonance.

Fig. 15.55 The EPR spectrum of the benzene radical anion, C_6H_6^- , in fluid solution. a is the hyperfine splitting of the spectrum; the centre of the spectrum is determined by the g -value of the radical.

Fig. 15.56 When phase-sensitive detection is used, the signal is the first derivative of the absorption intensity. Note that the peak of the absorption corresponds to the point where the derivative passes through zero.

Fig. 15.57 An applied magnetic field can induce circulation of electrons that makes use of excited state orbitals (shown as a green outline).

of a microwave source (a klystron or a Gunn oscillator), a cavity in which the sample is inserted in a glass or quartz container, a microwave detector, and an electromagnet with a field that can be varied in the region of 0.3 T. The EPR spectrum is obtained by monitoring the microwave absorption as the field is changed, and a typical spectrum (of the benzene radical anion, C_6H_6^-) is shown in Fig. 15.55. The peculiar appearance of the spectrum, which is in fact the first-derivative of the absorption, arises from the detection technique, which is sensitive to the slope of the absorption curve (Fig. 15.56).

15.15 The g -value

Equation 15.13b gives the resonance frequency for a transition between the $m_s = -\frac{1}{2}$ and the $m_s = +\frac{1}{2}$ levels of a ‘free’ electron in terms of the g -value $g_e \approx 2.0023$. The magnetic moment of an unpaired electron in a radical also interacts with an external field, but the g -value is different from that for a free electron because of local magnetic fields induced by the molecular framework of the radical. Consequently, the resonance condition is normally written as

$$h\nu = g\mu_B B_0 \quad (15.40)$$

where g is the **g -value** of the radical.

Illustration 15.4 Calculating the g -value of an organic radical

The centre of the EPR spectrum of the methyl radical occurred at 329.40 mT in a spectrometer operating at 9.2330 GHz (radiation belonging to the X band of the microwave region). Its g -value is therefore

$$g = \frac{h\nu}{\mu_B B} = \frac{(6.626\,08 \times 10^{-34} \text{ J s}) \times (9.2330 \times 10^9 \text{ s}^{-1})}{(9.2740 \times 10^{-24} \text{ J T}^{-1}) \times (0.329\,40 \text{ T})} = 2.0027$$

Self-test 15.4 At what magnetic field would the methyl radical come into resonance in a spectrometer operating at 34.000 GHz (radiation belonging to the Q band of the microwave region)? [1.213 T]

The g -value in a molecular environment (a radical or a d -metal complex) is related to the ease with which the applied field can stir up currents through the molecular framework and the strength of the magnetic field the currents generate. Therefore, the g -value gives some information about electronic structure and plays a similar role in EPR to that played by shielding constants in NMR.

Electrons can migrate through the molecular framework by making use of excited states (Fig. 15.57). This additional path for circulation of electrons gives rise to a local magnetic field that adds to the applied field. Therefore, we expect that the ease of stirring up currents to be inversely proportional to the separation of energy levels, ΔE , in the molecule. As we saw in Section 10.8, the strength of the field generated by electronic currents in atoms (and analogously in molecules) is related to the extent of coupling between spin and orbital angular momenta. That is, the local field strength is proportional to the molecular spin–orbit coupling constant, ξ .

We can conclude from the discussion above that the g -value of a radical or d -metal complex differs from g_e , the ‘free-electron’ g -value, by an amount that is proportional to $\xi/\Delta E$. This proportionality is widely observed. Many organic radicals have g -values close to 2.0027 and inorganic radicals have g -values typically in the range 1.9 to 2.1. The g -values of paramagnetic d -metal complexes often differ considerably from g_e ,

varying from 0 to 6, because in them ΔE is small (on account of the splitting of d -orbitals brought about by interactions with ligands, as we saw in Section 14.2).

Just as in the case of the chemical shift in NMR spectroscopy, the g -value is anisotropic: that is, its magnitude depends on the orientation of the radical with respect to the applied field. In solution, when the molecule is tumbling rapidly, only the average value of the g -value is observed. Therefore, anisotropy of the g -value is observed only for radicals trapped in solids.

15.16 Hyperfine structure

The most important feature of EPR spectra is their **hyperfine structure**, the splitting of individual resonance lines into components. In general in spectroscopy, the term ‘hyperfine structure’ means the structure of a spectrum that can be traced to interactions of the electrons with nuclei other than as a result of the latter’s point electric charge. The source of the hyperfine structure in EPR is the magnetic interaction between the electron spin and the magnetic dipole moments of the nuclei present in the radical.

(a) The effects of nuclear spin

Consider the effect on the EPR spectrum of a single H nucleus located somewhere in a radical. The proton spin is a source of magnetic field, and depending on the orientation of the nuclear spin, the field it generates adds to or subtracts from the applied field. The total local field is therefore

$$\mathcal{B}_{\text{loc}} = \mathcal{B} + am_I \quad m_I = \pm \frac{1}{2} \quad (15.41)$$

where a is the **hyperfine coupling constant**. Half the radicals in a sample have $m_I = +\frac{1}{2}$, so half resonate when the applied field satisfies the condition

$$h\nu = g\mu_B(\mathcal{B} + \tfrac{1}{2}a), \quad \text{or} \quad \mathcal{B} = \frac{h\nu}{g\mu_B} - \tfrac{1}{2}a \quad (15.42a)$$

The other half (which have $m_I = -\frac{1}{2}$) resonate when

$$h\nu = g\mu_B(\mathcal{B} - \tfrac{1}{2}a), \quad \text{or} \quad \mathcal{B} = \frac{h\nu}{g\mu_B} + \tfrac{1}{2}a \quad (15.42b)$$

Therefore, instead of a single line, the spectrum shows two lines of half the original intensity separated by a and centred on the field determined by g (Fig. 15.58).

If the radical contains an ^{14}N atom ($I = 1$), its EPR spectrum consists of three lines of equal intensity, because the ^{14}N nucleus has three possible spin orientations, and each spin orientation is possessed by one-third of all the radicals in the sample. In general, a spin- I nucleus splits the spectrum into $2I + 1$ hyperfine lines of equal intensity.

When there are several magnetic nuclei present in the radical, each one contributes to the hyperfine structure. In the case of equivalent protons (for example, the two CH_2 protons in the radical $\text{CH}_3\text{CH}_2\cdot$) some of the hyperfine lines are coincident. It is not hard to show that, if the radical contains N equivalent protons, then there are $N + 1$ hyperfine lines with a binomial intensity distribution (the intensity distribution given by Pascal’s triangle). The spectrum of the benzene radical anion in Fig. 15.55, which has seven lines with intensity ratio 1:6:15:20:15:6:1, is consistent with a radical containing six equivalent protons. More generally, if the radical contains N equivalent nuclei with spin quantum number I , then there are $2NI + 1$ hyperfine lines with an intensity distribution based on a modified version of Pascal’s triangle as shown in the following *Example*.

Fig. 15.58 The hyperfine interaction between an electron and a spin- $\frac{1}{2}$ nucleus results in four energy levels in place of the original two. As a result, the spectrum consists of two lines (of equal intensity) instead of one. The intensity distribution can be summarized by a simple stick diagram. The diagonal lines show the energies of the states as the applied field is increased, and resonance occurs when the separation of states matches the fixed energy of the microwave photon.

Fig. 15.59 The analysis of the hyperfine structure of radicals containing one ^{14}N nucleus ($I = 1$) and two equivalent protons.

Fig. 15.60 The analysis of the hyperfine structure of radicals containing three equivalent ^{14}N nuclei.

Example 15.3 Predicting the hyperfine structure of an EPR spectrum

A radical contains one ^{14}N nucleus ($I = 1$) with hyperfine constant 1.61 mT and two equivalent protons ($I = \frac{1}{2}$) with hyperfine constant 0.35 mT. Predict the form of the EPR spectrum.

Method We should consider the hyperfine structure that arises from each type of nucleus or group of equivalent nuclei in succession. So, split a line with one nucleus, then each of those lines is split by a second nucleus (or group of nuclei), and so on. It is best to start with the nucleus with the largest hyperfine splitting; however, any choice could be made, and the order in which nuclei are considered does not affect the conclusion.

Answer The ^{14}N nucleus gives three hyperfine lines of equal intensity separated by 1.61 mT. Each line is split into doublets of spacing 0.35 mT by the first proton, and each line of these doublets is split into doublets with the same 0.35 mT splitting (Fig. 15.59). The central lines of each split doublet coincide, so the proton splitting gives 1:2:1 triplets of internal splitting 0.35 mT. Therefore, the spectrum consists of three equivalent 1:2:1 triplets.

Self-test 15.5 Predict the form of the EPR spectrum of a radical containing three equivalent ^{14}N nuclei. [Fig. 15.60]

The hyperfine structure of an EPR spectrum is a kind of fingerprint that helps to identify the radicals present in a sample. Moreover, because the magnitude of the splitting depends on the distribution of the unpaired electron near the magnetic nuclei present, the spectrum can be used to map the molecular orbital occupied by the unpaired electron. For example, because the hyperfine splitting in C_6H_6^- is 0.375 mT, and one proton is close to a C atom with one-sixth the unpaired electron spin density (because the electron is spread uniformly around the ring), the hyperfine splitting caused by a proton in the electron spin entirely confined to a single adjacent C atom should be $6 \times 0.375 \text{ mT} = 2.25 \text{ mT}$. If in another aromatic radical we find a hyperfine splitting constant a , then the **spin density**, ρ , the probability that an unpaired electron is on the atom, can be calculated from the **McConnell equation**:

$$a = Q\rho \quad (15.43)$$

with $Q = 2.25 \text{ mT}$. In this equation, ρ is the spin density on a C atom and a is the hyperfine splitting observed for the H atom to which it is attached.

Illustration 15.5 Using the McConnell equation

The hyperfine structure of the EPR spectrum of the radical anion (naphthalene) $^-$ can be interpreted as arising from two groups of four equivalent protons. Those at the 1, 4, 5, and 8 positions in the ring have $a = 0.490 \text{ mT}$ and for those in the 2, 3, 6, and 7 positions have $a = 0.183 \text{ mT}$. The densities obtained by using the McConnell equation are 0.22 and 0.08, respectively (8).

Self-test 15.6 The spin density in (anthracene) $^-$ is shown in (9). Predict the form of its EPR spectrum.

[A 1:2:1 triplet of splitting 0.43 mT split into a 1:4:6:4:1 quintet of splitting 0.22 mT, split into a 1:4:6:4:1 quintet of splitting 0.11 mT, $3 \times 5 \times 5 = 75$ lines in all]

(b) The origin of the hyperfine interaction

The hyperfine interaction is an interaction between the magnetic moments of the unpaired electron and the nuclei. There are two contributions to the interaction.

An electron in a p orbital does not approach the nucleus very closely, so it experiences a field that appears to arise from a point magnetic dipole. The resulting interaction is called the **dipole–dipole interaction**. The contribution of a magnetic nucleus to the local field experienced by the unpaired electron is given by an expression like that in eqn 15.28. A characteristic of this type of interaction is that it is anisotropic. Furthermore, just as in the case of NMR, the dipole–dipole interaction averages to zero when the radical is free to tumble. Therefore, hyperfine structure due to the dipole–dipole interaction is observed only for radicals trapped in solids.

An s electron is spherically distributed around a nucleus and so has zero average dipole–dipole interaction with the nucleus even in a solid sample. However, because an s electron has a nonzero probability of being at the nucleus, it is incorrect to treat the interaction as one between two point dipoles. An s electron has a Fermi contact interaction with the nucleus, which as we saw in Section 15.6d is a magnetic interaction that occurs when the point dipole approximation fails. The contact interaction is isotropic (that is, independent of the radical's orientation), and consequently is shown even by rapidly tumbling molecules in fluids (provided the spin density has some s character).

The dipole–dipole interactions of p electrons and the Fermi contact interaction of s electrons can be quite large. For example, a $2p$ electron in a nitrogen atom experiences an average field of about 3.4 mT from the ^{14}N nucleus. A $1s$ electron in a hydrogen atom experiences a field of about 50 mT as a result of its Fermi contact interaction with the central proton. More values are listed in Table 15.3. The magnitudes of the contact interactions in radicals can be interpreted in terms of the s orbital character of the molecular orbital occupied by the unpaired electron, and the dipole–dipole interaction can be interpreted in terms of the p character. The analysis of hyperfine structure therefore gives information about the composition of the orbital, and especially the hybridization of the atomic orbitals (see Problem 15.11).

We still have the source of the hyperfine structure of the C_6H_6^- anion and other aromatic radical anions to explain. The sample is fluid, and as the radicals are tumbling the hyperfine structure cannot be due to the dipole–dipole interaction. Moreover, the protons lie in the nodal plane of the π orbital occupied by the unpaired electron, so the structure cannot be due to a Fermi contact interaction. The explanation lies in a **polarization mechanism** similar to the one responsible for spin–spin coupling in NMR. There is a magnetic interaction between a proton and the α electrons ($m_s = +\frac{1}{2}$) which results in one of the electrons tending to be found with a greater probability nearby (Fig. 15.61). The electron with opposite spin is therefore more likely to be close to the C atom at the other end of the bond. The unpaired electron on the C atom has a lower energy if it is parallel to that electron (Hund's rule favours parallel electrons on atoms), so the unpaired electron can detect the spin of the proton indirectly. Calculation using this model leads to a hyperfine interaction in agreement with the observed value of 2.25 mT.

Synoptic table 15.3* Hyperfine coupling constants for atoms, a/mT

Nuclide	Isotropic coupling	Anisotropic coupling
^1H	50.8 (1s)	
^2H	7.8 (1s)	
^{14}N	55.2 (2s)	3.4 (2p)
^{19}F	1720 (2s)	108.4 (2p)

* More values are given in the Data section.

(a) Low energy

(b) High energy

Fig. 15.61 The polarization mechanism for the hyperfine interaction in π -electron radicals. The arrangement in (a) is lower in energy than that in (b), so there is an effective coupling between the unpaired electron and the proton.

Fig. 15.62 ESR spectra of the di-*tert*-butyl nitroxide radical at 292 K (top) and 77 K (bottom). Adapted from J.R. Bolton, in *Biological applications of electron spin resonance*, H.M. Swartz, J.R. Bolton, and D.C. Borg (ed.), Wiley, New York (1972).

IMPACT ON BIOCHEMISTRY I15.2 Spin probes

We saw in Sections 15.14 and 15.15 that anisotropy of the g -value and of the nuclear hyperfine interactions can be observed when a radical is immobilized in a solid. Figure 15.62 shows the variation of the lineshape of the EPR spectrum of the di-*tert*-butyl nitroxide radical (**10**) with temperature. At 292 K, the radical tumbles freely and isotropic hyperfine coupling to the ^{14}N nucleus gives rise to three sharp peaks. At 77 K,

10

11

motion of the radical is restricted. Both isotropic and anisotropic hyperfine couplings determine the appearance of the spectrum, which now consists of three broad peaks.

A *spin probe* (or *spin label*) is a radical that interacts with a biopolymer and with an EPR spectrum that reports on the dynamical properties of the biopolymer. The ideal spin probe is one with a spectrum that broadens significantly as its motion is restricted to a relatively small extent. Nitroxide spin probes have been used to show that the hydrophobic interiors of biological membranes, once thought to be rigid, are in fact very fluid and individual lipid molecules move laterally through the sheet-like structure of the membrane.

Just as chemical exchange can broaden proton NMR spectra (Section 15.7), electron exchange between two radicals can broaden EPR spectra. Therefore, the distance between two spin probe molecules may be measured from the linewidths of their EPR spectra. The effect can be used in a number of biochemical studies. For example, the kinetics of association of two polypeptides labelled with the synthetic amino acid 2,2,6,6-tetramethylpiperidine-1-oxyl-4-amino-4-carboxylic acid (11) may be studied by measuring the change in linewidth of the label with time. Alternatively, the thermodynamics of association may be studied by examining the temperature dependence of the linewidth.

Checklist of key ideas

- ☐ 1. The energy of an electron in a magnetic field $\mathcal{B}_0$ is $E_m = -g_e \gamma_e \hbar \mathcal{B}_0 m_s$, where γ_e is the magnetogyric ratio of the electron. The energy of a nucleus in a magnetic field $\mathcal{B}_0$ is $E_{m_I} = -\gamma \hbar \mathcal{B}_0 m_I$, where γ is the nuclear magnetogyric ratio.
- ☐ 2. The resonance condition for an electron in a magnetic field is $h\nu = g_e \mu_B \mathcal{B}_0$. The resonance condition for a nucleus in a magnetic field is $h\nu = \gamma \hbar \mathcal{B}_0$.
- ☐ 3. Nuclear magnetic resonance (NMR) is the observation of the frequency at which magnetic nuclei in molecules come into resonance with an electromagnetic field when the molecule is exposed to a strong magnetic field; NMR is a radiofrequency technique.
- ☐ 4. Electron paramagnetic resonance (EPR) is the observation of the frequency at which an electron spin comes into resonance with an electromagnetic field when the molecule is exposed to a strong magnetic field; EPR is a microwave technique.
- ☐ 5. The intensity of an NMR or EPR transition increases with the difference in population of α and β states and the strength of the applied magnetic field (as $\mathcal{B}_0^2$).
- ☐ 6. The chemical shift of a nucleus is the difference between its resonance frequency and that of a reference standard; chemical shifts are reported on the δ scale, in which $\delta = (\nu - \nu^\circ) \times 10^6 / \nu^\circ$.
- ☐ 7. The observed shielding constant is the sum of a local contribution, a neighbouring group contribution, and a solvent contribution.
- ☐ 8. The fine structure of an NMR spectrum is the splitting of the groups of resonances into individual lines; the strength of the interaction is expressed in terms of the spin–spin coupling constant, J .
- ☐ 9. N equivalent spin- $\frac{1}{2}$ nuclei split the resonance of a nearby spin or group of equivalent spins into $N + 1$ lines with an intensity distribution given by Pascal's triangle.
- ☐ 10. Spin–spin coupling in molecules in solution can be explained in terms of the polarization mechanism, in which the interaction is transmitted through the bonds.
- ☐ 11. The Fermi contact interaction is a magnetic interaction that depends on the very close approach of an electron to the nucleus and can occur only if the electron occupies an s orbital.
- ☐ 12. Coalescence of the two lines occurs in conformational interchange or chemical exchange when the lifetime, τ , of the states is related to their resonance frequency difference, $\delta\nu$, by $\tau = 2^{1/2} / \pi \delta\nu$.
- ☐ 13. In Fourier-transform NMR, the spectrum is obtained by mathematical analysis of the free-induction decay of magnetization, the response of nuclear spins in a sample to the application of one or more pulses of radiofrequency radiation.
- ☐ 14. Spin relaxation is the nonradiative return of a spin system to an equilibrium distribution of populations in which the transverse spin orientations are random; the system returns exponentially to the equilibrium population distribution with a time constant called the spin–lattice relaxation time, T_1 .
- ☐ 15. The spin–spin relaxation time, T_2 , is the time constant for the exponential return of the system to random transverse spin orientations.
- ☐ 16. In proton decoupling of ^{13}C -NMR spectra, protons are made to undergo rapid spin reorientations and the ^{13}C nucleus

senses an average orientation. As a result, its resonance is a single line and not a group of lines.

- 17. The nuclear Overhauser effect (NOE) is the modification of one resonance by the saturation of another.
- 18. In two-dimensional NMR, spectra are displayed in two axes, with resonances belonging to different groups lying at different locations on the second axis. An example of a two-dimensional NMR technique is correlation spectroscopy (COSY), in which all spin–spin couplings in a molecule are determined. Another example is nuclear Overhauser effect spectroscopy (NOESY), in which internuclear distances up to about 0.5 nm are determined.
- 19. Magic-angle spinning (MAS) is technique in which the NMR linewidths in a solid sample are reduced by spinning at an angle of 54.74° to the applied magnetic field.
- 20. The EPR resonance condition is written $h\nu = g\mu_B\mathcal{B}$, where g is the g -value of the radical; the deviation of g from $g_e = 2.0023$ depends on the ability of the applied field to induce local electron currents in the radical.
- 21. The hyperfine structure of an EPR spectrum is its splitting of individual resonance lines into components by the magnetic interaction between the electron and nuclei with spin.
- 22. If a radical contains N equivalent nuclei with spin quantum number I , then there are $2NI + 1$ hyperfine lines with an intensity distribution given by a modified version of Pascal's triangle.
- 23. The hyperfine structure due to a hydrogen attached to an aromatic ring is converted to spin density, ρ , on the neighbouring carbon atom by using the McConnell equation: $a = Q\rho$ with $Q = 2.25$ mT.

Further information

Further information 15.1 *Fourier transformation of the FID curve*

The analysis of the FID curve is achieved by the standard mathematical technique of Fourier transformation, which we explored in the context of FT infrared spectroscopy (*Further information* 13.2). We start by noting that the signal $S(t)$ in the time domain, the total FID curve, is the sum (more precisely, the integral) over all the contributing frequencies

$$S(t) = \int_{-\infty}^{\infty} I(\nu) e^{-2\pi i \nu t} d\nu \quad (15.44)$$

Because $e^{2\pi i \nu t} = \cos(2\pi \nu t) + i \sin(2\pi \nu t)$, the expression above is a sum over harmonically oscillating functions, with each one weighted by the intensity $I(\nu)$.

We need $I(\nu)$, the spectrum in the frequency domain; it is obtained by evaluating the integral

$$I(\nu) = 2 \operatorname{Re} \int_0^{\infty} S(t) e^{2\pi i \nu t} dt \quad (15.45)$$

where Re means take the real part of the following expression. This integral is very much like an overlap integral: it gives a nonzero value if $S(t)$ contains a component that matches the oscillating function $e^{2\pi i \nu t}$. The integration is carried out at a series of frequencies ν on a computer that is built into the spectrometer.

Discussion questions

15.1 Discuss in detail the origins of the local, neighbouring group, and solvent contributions to the shielding constant.

15.2 Discuss in detail the effects of a 90° pulse and of a 180° pulse on a system of spin- $\frac{1}{2}$ nuclei in a static magnetic field.

15.3 Suggest a reason why the relaxation times of ^{13}C nuclei are typically much longer than those of ^1H nuclei.

15.4 Discuss the origins of diagonal and cross peaks in the COSY spectrum of an AX system.

15.5 Discuss how the Fermi contact interaction and the polarization mechanism contribute to spin–spin couplings in NMR and hyperfine interactions in EPR.

15.6 Suggest how spin probes could be used to estimate the depth of a crevice in a biopolymer, such as the active site of an enzyme.

Exercises

15.1a What is the resonance frequency of a proton in a magnetic field of 14.1 T?

15.1b What is the resonance frequency of a ^{19}F nucleus in a magnetic field of 16.2 T?

15.2a ^{33}S has a nuclear spin of $\frac{3}{2}$ and a nuclear g-factor of 0.4289. Calculate the energies of the nuclear spin states in a magnetic field of 7.500 T.

15.2b ^{14}N has a nuclear spin of 1 and a nuclear g-factor of 0.404. Calculate the energies of the nuclear spin states in a magnetic field of 11.50 T.

15.3a Calculate the frequency separation of the nuclear spin levels of a ^{13}C nucleus in a magnetic field of 14.4 T given that the magnetogyric ratio is $6.73 \times 10^7 \text{ T}^{-1} \text{ s}^{-1}$.

15.3b Calculate the frequency separation of the nuclear spin levels of a ^{14}N nucleus in a magnetic field of 15.4 T given that the magnetogyric ratio is $1.93 \times 10^7 \text{ T}^{-1} \text{ s}^{-1}$.

15.4a In which of the following systems is the energy level separation the largest? (a) A proton in a 600 MHz NMR spectrometer, (b) a deuteron in the same spectrometer.

15.4b In which of the following systems is the energy level separation the largest? (a) A ^{14}N nucleus in (for protons) a 600 MHz NMR spectrometer, (b) an electron in a radical in a field of 0.300 T.

15.5a Calculate the energy difference between the lowest and highest nuclear spin states of a ^{14}N nucleus in a 15.00 T magnetic field.

15.5b Calculate the magnetic field needed to satisfy the resonance condition for unshielded protons in a 150.0 MHz radiofrequency field.

15.6a Use Table 15.2 to predict the magnetic fields at which (a) ^1H , (b) ^2H , (c) ^{13}C come into resonance at (i) 250 MHz, (ii) 500 MHz.

15.6b Use Table 15.2 to predict the magnetic fields at which (a) ^{14}N , (b) ^{19}F , and (c) ^{31}P come into resonance at (i) 300 MHz, (ii) 750 MHz.

15.7a Calculate the relative population differences ($\delta N/N$) for protons in fields of (a) 0.30 T, (b) 1.5 T, and (c) 10 T at 25°C .

15.7b Calculate the relative population differences ($\delta N/N$) for ^{13}C nuclei in fields of (a) 0.50 T, (b) 2.5 T, and (c) 15.5 T at 25°C .

15.8a The first generally available NMR spectrometers operated at a frequency of 60 MHz; today it is not uncommon to use a spectrometer that operates at 800 MHz. What are the relative population differences of ^{13}C spin states in these two spectrometers at 25°C ?

15.8b What are the relative values of the chemical shifts observed for nuclei in the spectrometers mentioned in Exercise 15.8a in terms of (a) δ values, (b) frequencies?

15.9a The chemical shift of the CH_3 protons in acetaldehyde (ethanal) is $\delta = 2.20$ and that of the CHO proton is 9.80. What is the difference in local magnetic field between the two regions of the molecule when the applied field is (a) 1.5 T, (b) 15 T?

15.9b The chemical shift of the CH_3 protons in diethyl ether is $\delta = 1.16$ and that of the CH_2 protons is 3.36. What is the difference in local magnetic field between the two regions of the molecule when the applied field is (a) 1.9 T, (b) 16.5 T?

15.10a Sketch the appearance of the ^1H -NMR spectrum of acetaldehyde (ethanal) using $J = 2.90$ Hz and the data in Exercise 15.9a in a spectrometer operating at (a) 250 MHz, (b) 500 MHz.

15.10b Sketch the appearance of the ^1H -NMR spectrum of diethyl ether using $J = 6.97$ Hz and the data in Exercise 15.9b in a spectrometer operating at (a) 350 MHz, (b) 650 MHz.

15.11a Two groups of protons are made equivalent by the isomerization of a fluxional molecule. At low temperatures, where the interconversion is slow, one group has $\delta = 4.0$ and the other has $\delta = 5.2$. At what rate of interconversion will the two signals merge in a spectrometer operating at 250 MHz?

15.11b Two groups of protons are made equivalent by the isomerization of a fluxional molecule. At low temperatures, where the interconversion is slow, one group has $\delta = 5.5$ and the other has $\delta = 6.8$. At what rate of interconversion will the two signals merge in a spectrometer operating at 350 MHz?

15.12a Sketch the form of the ^{19}F -NMR spectra of a natural sample of tetrafluoroborate ions, BF_4^- , allowing for the relative abundances of $^{10}\text{BF}_4^-$ and $^{11}\text{BF}_4^-$.

15.12b From the data in Table 15.2, predict the frequency needed for ^{31}P -NMR in an NMR spectrometer designed to observe proton resonance at 500 MHz. Sketch the proton and ^{31}P resonances in the NMR spectrum of PH_4^+ .

15.13a Sketch the form of an $\text{A}_3\text{M}_2\text{X}_4$ spectrum, where A, M, and X are protons with distinctly different chemical shifts and $J_{\text{AM}} > J_{\text{AX}} > J_{\text{MX}}$.

15.13b Sketch the form of an $\text{A}_2\text{M}_2\text{X}_5$ spectrum, where A, M, and X are protons with distinctly different chemical shifts and $J_{\text{AM}} > J_{\text{AX}} > J_{\text{MX}}$.

15.14a Which of the following molecules have sets of nuclei that are chemically but not magnetically equivalent? (a) CH_3CH_3 , (b) $\text{CH}_2=\text{CH}_2$.

15.14b Which of the following molecules have sets of nuclei that are chemically but not magnetically equivalent? (a) $\text{CH}_2=\text{CF}_2$, (b) *cis*- and *trans*- $[\text{Mo}(\text{CO})_4(\text{PH}_3)_2]$.

15.15a The duration of a 90° or 180° pulse depends on the strength of the $\mathcal{B}_1$ field. If a 90° pulse requires $10\ \mu\text{s}$, what is the strength of the $\mathcal{B}_1$ field? How long would the corresponding 180° pulse require?

15.15b The duration of a 90° or 180° pulse depends on the strength of the $\mathcal{B}_1$ field. If a 180° pulse requires $12.5\ \mu\text{s}$, what is the strength of the $\mathcal{B}_1$ field? How long would the corresponding 90° pulse require?

15.16a What magnetic field would be required in order to use an EPR X-band spectrometer (9 GHz) to observe ^1H -NMR and a 300 MHz spectrometer to observe EPR?

15.16b Some commercial EPR spectrometers use 8 mm microwave radiation (the Q band). What magnetic field is needed to satisfy the resonance condition?

15.17a The centre of the EPR spectrum of atomic hydrogen lies at 329.12 mT in a spectrometer operating at 9.2231 GHz. What is the g -value of the electron in the atom?

15.17b The centre of the EPR spectrum of atomic deuterium lies at 330.02 mT in a spectrometer operating at 9.2482 GHz. What is the g -value of the electron in the atom?

15.18a A radical containing two equivalent protons shows a three-line spectrum with an intensity distribution 1:2:1. The lines occur at 330.2 mT, 332.5 mT, and 334.8 mT. What is the hyperfine coupling constant for each proton? What is the g -value of the radical given that the spectrometer is operating at 9.319 GHz?

15.18b A radical containing three equivalent protons shows a four-line spectrum with an intensity distribution 1:3:3:1. The lines occur at 331.4 mT, 333.6 mT, 335.8 mT, and 338.0 mT. What is the hyperfine coupling constant

for each proton? What is the g -value of the radical given that the spectrometer is operating at 9.332 GHz?

15.19a A radical containing two inequivalent protons with hyperfine constants 2.0 mT and 2.6 mT gives a spectrum centred on 332.5 mT. At what fields do the hyperfine lines occur and what are their relative intensities?

15.19b A radical containing three inequivalent protons with hyperfine constants 2.11 mT, 2.87 mT, and 2.89 mT gives a spectrum centred on 332.8 mT. At what fields do the hyperfine lines occur and what are their relative intensities?

15.20a Predict the intensity distribution in the hyperfine lines of the EPR spectra of (a) $\cdot\text{CH}_3$, (b) $\cdot\text{CD}_3$.

15.20b Predict the intensity distribution in the hyperfine lines of the EPR spectra of (a) $\cdot\text{CH}_2\text{H}_3$, (b) $\cdot\text{CD}_2\text{CD}_3$.

15.21a The benzene radical anion has $g = 2.0025$. At what field should you search for resonance in a spectrometer operating at (a) 9.302 GHz, (b) 33.67 GHz?

15.21b The naphthalene radical anion has $g = 2.0024$. At what field should you search for resonance in a spectrometer operating at (a) 9.312 GHz, (b) 33.88 GHz?

15.22a The EPR spectrum of a radical with a single magnetic nucleus is split into four lines of equal intensity. What is the nuclear spin of the nucleus?

15.22b The EPR spectrum of a radical with two equivalent nuclei of a particular kind is split into five lines of intensity ratio 1:2:3:2:1. What is the spin of the nuclei?

15.23a Sketch the form of the hyperfine structures of radicals XH_2 and XD_2 , where the nucleus X has $I = \frac{5}{2}$.

15.23b Sketch the form of the hyperfine structures of radicals XH_3 and XD_3 , where the nucleus X has $I = \frac{3}{2}$.

Problems*

Numerical problems

15.1 A scientist investigates the possibility of neutron spin resonance, and has available a commercial NMR spectrometer operating at 300 MHz. What field is required for resonance? What is the relative population difference at room temperature? Which is the lower energy spin state of the neutron?

15.2 Two groups of protons have $\delta = 4.0$ and $\delta = 5.2$ and are interconverted by a conformational change of a fluxional molecule. In a 60 MHz spectrometer the spectrum collapsed into a single line at 280 K but at 300 MHz the collapse did not occur until the temperature had been raised to 300 K. What is the activation energy of the interconversion?

15.3† Suppose that the FID in Fig. 15.31 was recorded in a 300 MHz spectrometer, and that the interval between maxima in the oscillations in the FID is 0.10 s. What is the Larmor frequency of the nuclei and the spin-spin relaxation time?

15.4† In a classic study of the application of NMR to the measurement of rotational barriers in molecules, P.M. Nair and J.D. Roberts (*J. Am. Chem. Soc.* **79**, 4565 (1957)) obtained the 40 MHz ^{19}F -NMR spectrum of $\text{F}_2\text{BrCCBrCl}_2$. Their spectra are reproduced in Fig. 15.63. At 193 K the

spectrum shows five resonance peaks. Peaks I and III are separated by 160 Hz, as are IV and V. The ratio of the integrated intensities of peak II to peaks I, III, IV, and V is approximately 10 to 1. At 273 K, the five peaks have collapsed into

Fig. 15.63

* Problems denoted with the symbol † were supplied by Charles Trapp and Carmen Giunta.

one. Explain the spectrum and its change with temperature. At what rate of interconversion will the spectrum collapse to a single line? Calculate the rotational energy barrier between the rotational isomers on the assumption that it is related to the rate of interconversion between the isomers.

15.5† Various versions of the Karplus equation (eqn 15.27) have been used to correlate data on vicinal proton coupling constants in systems of the type $R_1R_2CHCHR_3R_4$. The original version, (M. Karplus, *J. Am. Chem. Soc.* **85**, 2870 (1963)), is $^3J_{HH} = A \cos^2 \phi_{HH} + B$. When $R_3 = R_4 = H$, $^3J_{HH} = 7.3$ Hz; when $R_3 = CH_3$ and $R_4 = H$, $^3J_{HH} = 8.0$ Hz; when $R_3 = R_4 = CH_3$, $^3J_{HH} = 11.2$ Hz. Assume that only staggered conformations are important and determine which version of the Karplus equation fits the data better.

15.6† It might be unexpected that the Karplus equation, which was first derived for $^3J_{HH}$ coupling constants, should also apply to vicinal coupling between the nuclei of metals such as tin. T.N. Mitchell and B. Kowall (*Magn. Reson. Chem.* **33**, 325 (1995)) have studied the relation between $^3J_{HH}$ and $^3J_{SnSn}$ in compounds of the type $Me_3SnCH_2CHRSnMe_3$ and find that $^3J_{SnSn} = 78.86^3J_{HH} + 27.84$ Hz. (a) Does this result support a Karplus type equation for tin? Explain your reasoning. (b) Obtain the Karplus equation for $^3J_{SnSn}$ and plot it as a function of the dihedral angle. (c) Draw the preferred conformation.

15.7 Figure 15.64 shows the proton COSY spectrum of 1-nitropropane. Account for the appearance of off-diagonal peaks in the spectrum.

Fig. 15.64 The COSY spectrum of 1-nitropropane ($NO_2CH_2CH_2CH_3$). The circles show enhanced views of the spectral features. (Spectrum provided by Prof. G. Morris.)

15.8 The angular NO_2 molecule has a single unpaired electron and can be trapped in a solid matrix or prepared inside a nitrite crystal by radiation damage of NO_2^- ions. When the applied field is parallel to the OO direction the centre of the spectrum lies at 333.64 mT in a spectrometer operating at 9.302 GHz. When the field lies along the bisector of the ONO angle, the resonance lies at 331.94 mT. What are the g-values in the two orientations?

15.9 The hyperfine coupling constant in $\cdot CH_3$ is 2.3 mT. Use the information in Table 15.3 to predict the splitting between the hyperfine lines of the spectrum of $\cdot CD_3$. What are the overall widths of the hyperfine spectra in each case?

15.10 The *p*-dinitrobenzene radical anion can be prepared by reduction of *p*-dinitrobenzene. The radical anion has two equivalent N nuclei ($I = 1$) and

four equivalent protons. Predict the form of the EPR spectrum using $a(N) = 0.148$ mT and $a(H) = 0.112$ mT.

15.11 When an electron occupies a 2s orbital on an N atom it has a hyperfine interaction of 55.2 mT with the nucleus. The spectrum of NO_2 shows an isotropic hyperfine interaction of 5.7 mT. For what proportion of its time is the unpaired electron of NO_2 occupying a 2s orbital? The hyperfine coupling constant for an electron in a 2p orbital of an N atom is 3.4 mT. In NO_2 the anisotropic part of the hyperfine coupling is 1.3 mT. What proportion of its time does the unpaired electron spend in the 2p orbital of the N atom in NO_2 ? What is the total probability that the electron will be found on (a) the N atoms, (b) the O atoms? What is the hybridization ratio of the N atom? Does the hybridization support the view that NO_2 is angular?

15.12 The hyperfine coupling constants observed in the radical anions (12), (13), and (14) are shown (in millitesla, mT). Use the value for the benzene radical anion to map the probability of finding the unpaired electron in the π orbital on each C atom.

Theoretical problems

15.13 Calculate σ_d for a hydrogenic atom with atomic number Z .

15.14 In this problem you will use the molecular electronic structure methods described in Chapter 11 to investigate the hypothesis that the magnitude of the ^{13}C chemical shift correlates with the net charge on a ^{13}C atom. (a) Using molecular modelling software³ and the computational method of your choice, calculate the net charge at the C atom *para* to the substituents in this series of molecules: benzene, phenol, toluene, trifluorotoluene, benzonitrile, and nitrobenzene. (b) The ^{13}C chemical shifts of the *para* C atoms in each of the molecules that you examined in part (a) are given below:

Substituent	OH	CH ₃	H	CF ₃	CN	NO ₂
δ	130.1	128.4	128.5	128.9	129.1	129.4

Is there a linear correlation between net charge and ^{13}C chemical shift of the *para* C atom in this series of molecules? (c) If you did find a correlation in part (b), use the concepts developed in this chapter to explain the physical origins of the correlation.

³ The web site contains links to molecular modelling freeware and to other sites where you may perform molecular orbital calculations directly from your web browser.

15.15 The z -component of the magnetic field at a distance R from a magnetic moment parallel to the z -axis is given by eqn 15.28. In a solid, a proton at a distance R from another can experience such a field and the measurement of the splitting it causes in the spectrum can be used to calculate R . In gypsum, for instance, the splitting in the H_2O resonance can be interpreted in terms of a magnetic field of 0.715 mT generated by one proton and experienced by the other. What is the separation of the protons in the H_2O molecule?

15.16 In a liquid, the dipolar magnetic field averages to zero: show this result by evaluating the average of the field given in eqn 15.28. *Hint.* The volume element is $\sin \theta \, d\theta \, d\phi$ in polar coordinates.

15.17 The shape of a spectral line, $I(\omega)$, is related to the free induction decay signal $G(t)$ by

$$I(\omega) = a \operatorname{Re} \int_0^\infty G(t) e^{i\omega t} dt$$

where a is a constant and 'Re' means take the real part of what follows. Calculate the lineshape corresponding to an oscillating, decaying function $G(t) = \cos \omega_0 t \, e^{-t/\tau}$.

15.18 In the language of Problem 15.17, show that, if $G(t) = (a \cos \omega_1 t + b \cos \omega_2 t) e^{-t/\tau}$, then the spectrum consists of two lines with intensities proportional to a and b and located at $\omega = \omega_1$ and ω_2 , respectively.

15.19 EPR spectra are commonly discussed in terms of the parameters that occur in the *spin-hamiltonian*, a hamiltonian operator that incorporates various effects involving spatial operators (like the orbital angular momentum) into operators that depend on the spin alone. Show that, if you use $H = -g_e \gamma_e \mathcal{B}_0 s_z - \gamma_e \mathcal{B}_0 l_z$ as the true hamiltonian, then from second-order perturbation theory (and specifically eqn 9.65), the eigenvalues of the spin are the same as those of the spin-hamiltonian $H_{\text{spin}} = -g \gamma_e \mathcal{B}_0 s_z$ (note the g in place of g_e) and find an expression for g .

Applications: to biochemistry and medicine

15.20 Interpret the following features of the NMR spectra of hen lysozyme: (a) saturation of a proton resonance assigned to the side chain of methionine-105 changes the intensities of proton resonances assigned to the side chains of tryptophan-28 and tyrosine-23; (b) saturation of proton resonances assigned to tryptophan-28 did not affect the spectrum of tyrosine-23.

15.21 When interacting with a large biopolymer or even larger organelle, a small molecule might not rotate freely in all directions and the dipolar interaction might not average to zero. Suppose a molecule is bound so that, although the vector separating two protons may rotate freely around the z -axis, the colatitude may vary only between 0 and θ' . Average the dipolar field over this restricted range of orientations and confirm that the average vanishes when $\theta' = \pi$ (corresponding to rotation over an entire sphere). What is the average value of the local dipolar field for the H_2O molecule in Problem 15.15 if it is bound to a biopolymer that enables it to rotate up to $\theta' = 30^\circ$?

15.22 Suggest a reason why the spin-lattice relaxation time of benzene (a small molecule) in a mobile, deuterated hydrocarbon solvent increases with temperature whereas that of an oligonucleotide (a large molecule) decreases.

15.23 NMR spectroscopy may be used to determine the equilibrium constant for dissociation of a complex between a small molecule, such as an enzyme inhibitor I , and a protein, such as an enzyme E :

In the limit of slow chemical exchange, the NMR spectrum of a proton in I would consist of two resonances: one at ν_I for free I and another at ν_{EI} for bound I . When chemical exchange is fast, the NMR spectrum of the same proton in I consists of a single peak with a resonance frequency ν given by $\nu = f_I \nu_I + f_{EI} \nu_{EI}$, where $f_I = [I]/([I] + [EI])$ and $f_{EI} = [EI]/([I] + [EI])$ are, respectively, the fractions of free I and bound I . For the purposes of analysing the data, it is also useful to define the frequency differences $\delta\nu = \nu - \nu_I$ and $\Delta\nu = \nu_{EI} - \nu_I$. Show that, when the initial concentration of I , $[I]_0$, is much greater than the initial concentration of E , $[E]_0$, a plot of $[I]_0$ against $\delta\nu^{-1}$ is a straight line with slope $[E]_0 \Delta\nu$ and y -intercept $-K_I$.

15.24 The molecular electronic structure methods described in Chapter 11 may be used to predict the spin density distribution in a radical. Recent EPR studies have shown that the amino acid tyrosine participates in a number of biological electron transfer reactions, including the processes of water oxidation to O_2 in plant photosystem II and of O_2 reduction to water in cytochrome c oxidase (Impact I17.2). During the course of these electron transfer reactions, a tyrosine radical forms, with spin density delocalized over the side chain of the amino acid. (a) The phenoxy radical shown in (15) is a suitable model of the tyrosine radical. Using molecular modelling software and the computational method of your choice (semi-empirical or *ab initio* methods), calculate the spin densities at the O atom and at all of the C atoms in (15). (b) Predict the form of the EPR spectrum of (15).

15.25 Sketch the EPR spectra of the di-*tert*-butyl nitroxide radical (10) at 292 K in the limits of very low concentration (at which electron exchange is negligible), moderate concentration (at which electron exchange effects begin to be observed), and high concentration (at which electron exchange effects predominate). Discuss how the observation of electron exchange between nitroxide spin probes can inform the study of lateral mobility of lipids in a biological membrane.

15.26 You are designing an MRI spectrometer. What field gradient (in microtesla per metre, $\mu\text{T m}^{-1}$) is required to produce a separation of 100 Hz between two protons separated by the long diameter of a human kidney (taken as 8 cm) given that they are in environments with $\delta = 3.4$? The radiofrequency field of the spectrometer is at 400 MHz and the applied field is 9.4 T.

15.27 Suppose a uniform disk-shaped organ is in a linear field gradient, and that the MRI signal is proportional to the number of protons in a slice of width δx at each horizontal distance x from the centre of the disk. Sketch the shape of the absorption intensity for the MRI image of the disk before any computer manipulation has been carried out.

Problems

Statistical thermodynamics provides the link between the microscopic properties of matter and its bulk properties. Two key ideas are introduced in this chapter. The first is the Boltzmann distribution, which is used to predict the populations of states in systems at thermal equilibrium. In this chapter we see its derivation in terms of the distribution of particles over available states. The derivation leads naturally to the introduction of the partition function, which is the central mathematical concept of this and the next chapter. We see how to interpret the partition function and how to calculate it in a number of simple cases. We then see how to extract thermodynamic information from the partition function. In the final part of the chapter, we generalize the discussion to include systems that are composed of assemblies of interacting particles. Very similar equations are developed to those in the first part of the chapter, but they are much more widely applicable.

The preceding chapters of this part of the text have shown how the energy levels of molecules can be calculated, determined spectroscopically, and related to their structures. The next major step is to see how a knowledge of these energy levels can be used to account for the properties of matter in bulk. To do so, we now introduce the concepts of **statistical thermodynamics**, the link between individual molecular properties and bulk thermodynamic properties.

The crucial step in going from the quantum mechanics of individual molecules to the thermodynamics of bulk samples is to recognize that the latter deals with the *average* behaviour of large numbers of molecules. For example, the pressure of a gas depends on the average force exerted by its molecules, and there is no need to specify which molecules happen to be striking the wall at any instant. Nor is it necessary to consider the fluctuations in the pressure as different numbers of molecules collide with the wall at different moments. The fluctuations in pressure are very small compared with the steady pressure: it is highly improbable that there will be a sudden lull in the number of collisions, or a sudden surge. Fluctuations in other thermodynamic properties also occur, but for large numbers of particles they are negligible compared to the mean values.

This chapter introduces statistical thermodynamics in two stages. The first, the derivation of the Boltzmann distribution for individual particles, is of restricted applicability, but it has the advantage of taking us directly to a result of central importance in a straightforward and elementary way. We can *use* statistical thermodynamics once we have deduced the Boltzmann distribution. Then (in Section 16.5) we extend the arguments to systems composed of interacting particles.

The distribution of molecular states

We consider a closed system composed of N molecules. Although the total energy is constant at E , it is not possible to be definite about how that energy is shared between the molecules. Collisions result in the ceaseless redistribution of energy not only between the molecules but also among their different modes of motion. The closest we can come to a description of the distribution of energy is to report the **population** of a state, the average number of molecules that occupy it, and to say that on average there are n_i molecules in a state of energy ε_i . The populations of the states remain almost constant, but the precise identities of the molecules in each state may change at every collision.

The problem we address in this section is the calculation of the populations of states for any type of molecule in any mode of motion at any temperature. The only restriction is that the molecules should be independent, in the sense that the total energy of the system is a sum of their individual energies. We are discounting (at this stage) the possibility that in a real system a contribution to the total energy may arise from interactions between molecules. We also adopt the **principle of equal *a priori* probabilities**, the assumption that all possibilities for the distribution of energy are equally probable. *A priori* means in this context loosely ‘as far as one knows’. We have no reason to presume otherwise than that, for a collection of molecules at thermal equilibrium, vibrational states of a certain energy, for instance, are as likely to be populated as rotational states of the same energy.

One very important conclusion that will emerge from the following analysis is that the populations of states depend on a single parameter, the ‘temperature’. That is, statistical thermodynamics provides a molecular justification for the concept of temperature and some insight into this crucially important quantity.

16.1 Configurations and weights

Any individual molecule may exist in states with energies $\varepsilon_0, \varepsilon_1, \dots$. We shall always take ε_0 the lowest state, as the zero of energy ($\varepsilon_0 = 0$), and measure all other energies relative to that state. To obtain the actual internal energy, U , we may have to add a constant to the calculated energy of the system. For example, if we are considering the vibrational contribution to the internal energy, then we must add the total zero-point energy of any oscillators in the sample.

(a) Instantaneous configurations

At any instant there will be n_0 molecules in the state with energy ε_0 , n_1 with ε_1 , and so on. The specification of the set of populations $n_0, n_1, \dots$ in the form $\{n_0, n_1, \dots\}$ is a statement of the instantaneous **configuration** of the system. The instantaneous configuration fluctuates with time because the populations change. We can picture a large number of different instantaneous configurations. One, for example, might be $\{N, 0, 0, \dots\}$, corresponding to every molecule being in its ground state. Another might be $\{N - 2, 2, 0, 0, \dots\}$, in which two molecules are in the first excited state. The latter configuration is intrinsically more likely to be found than the former because it can be achieved in more ways: $\{N, 0, 0, \dots\}$ can be achieved in only one way, but $\{N - 2, 2, 0, \dots\}$ can be achieved in $\frac{1}{2}N(N - 1)$ different ways (Fig. 16.1; see *Justification 16.1*). At this stage in the argument, we are ignoring the requirement that the total energy of the system should be constant (the second configuration has a higher energy than the first). The constraint of total energy is imposed later in this section.

Fig. 16.1 Whereas a configuration $\{5, 0, 0, \dots\}$ can be achieved in only one way, a configuration $\{3, 2, 0, \dots\}$ can be achieved in the ten different ways shown here, where the tinted blocks represent different molecules.

Fig. 16.2 The 18 molecules shown here can be distributed into four receptacles (distinguished by the three vertical lines) in $18!$ different ways. However, $3!$ of the selections that put three molecules in the first receptacle are equivalent, $6!$ that put six molecules into the second receptacle are equivalent, and so on. Hence the number of distinguishable arrangements is $18!/3!6!5!4!$.

If, as a result of collisions, the system were to fluctuate between the configurations $\{N, 0, 0, \dots\}$ and $\{N - 2, 2, 0, \dots\}$, it would almost always be found in the second, more likely state (especially if N were large). In other words, a system free to switch between the two configurations would show properties characteristic almost exclusively of the second configuration. A general configuration $\{n_0, n_1, \dots\}$ can be achieved in W different ways, where W is called the **weight** of the configuration. The weight of the configuration $\{n_0, n_1, \dots\}$ is given by the expression

$$W = \frac{N!}{n_0! n_1! n_2! \dots} \quad (16.1)$$

Equation 16.1 is a generalization of the formula $W = \frac{1}{2}N(N - 1)$, and reduces to it for the configuration $\{N - 2, 2, 0, \dots\}$.

Comment 16.1

More formally, W is called the **multinomial coefficient** (see Appendix 2). In eqn 16.1, $x!$, x factorial, denotes $x(x - 1)(x - 2) \dots 1$, and by definition $0! = 1$.

Justification 16.1 The weight of a configuration

First, consider the weight of the configuration $\{N - 2, 2, 0, \dots\}$. One candidate for promotion to an upper state can be selected in N ways. There are $N - 1$ candidates for the second choice, so the total number of choices is $N(N - 1)$. However, we should not distinguish the choice (Jack, Jill) from the choice (Jill, Jack) because they lead to the same configurations. Therefore, only half the choices lead to distinguishable configurations, and the total number of distinguishable choices is $\frac{1}{2}N(N - 1)$.

Now we generalize this remark. Consider the number of ways of distributing N balls into bins. The first ball can be selected in N different ways, the next ball in $N - 1$ different ways for the balls remaining, and so on. Therefore, there are $N(N - 1) \dots 1 = N!$ ways of selecting the balls for distribution over the bins. However, if there are n_0 balls in the bin labelled ϵ_0 , there would be $n_0!$ different ways in which the same balls could have been chosen (Fig. 16.2). Similarly, there are $n_1!$ ways in which the n_1 balls in the bin labelled ϵ_1 can be chosen, and so on. Therefore, the total number of distinguishable ways of distributing the balls so that there are n_0 in bin ϵ_0 , n_1 in bin ϵ_1 , etc. regardless of the order in which the balls were chosen is $N!/n_0!n_1! \dots$, which is the content of eqn 16.1.

Illustration 16.1 Calculating the weight of a distribution

To calculate the number of ways of distributing 20 identical objects with the arrangement 1, 0, 3, 5, 10, 1, we note that the configuration is $\{1, 0, 3, 5, 10, 1\}$ with $N = 20$; therefore the weight is

$$W = \frac{20!}{1!0!3!5!10!1!} = 9.31 \times 10^8$$

Self-test 16.1 Calculate the weight of the configuration in which 20 objects are distributed in the arrangement 0, 1, 5, 0, 8, 0, 3, 2, 0, 1. $[4.19 \times 10^{10}]$

It will turn out to be more convenient to deal with the natural logarithm of the weight, $\ln W$, rather than with the weight itself. We shall therefore need the expression

$$\begin{aligned}\ln W &= \ln \frac{N!}{n_0!n_1!n_2!\dots} = \ln N! - \ln(n_0!n_1!n_2!\dots) \\ &= \ln N! - (\ln n_0! + \ln n_1! + \ln n_2! + \dots) \\ &= \ln N! - \sum_i \ln n_i!\end{aligned}$$

where in the first line we have used $\ln(x/y) = \ln x - \ln y$ and in the second $\ln xy = \ln x + \ln y$. One reason for introducing $\ln W$ is that it is easier to make approximations. In particular, we can simplify the factorials by using **Stirling's approximation** in the form

$$\ln x! \approx x \ln x - x \quad (16.2)$$

Then the approximate expression for the weight is

$$\ln W = (N \ln N - N) - \sum_i (n_i \ln n_i - n_i) = N \ln N - \sum_i n_i \ln n_i \quad (16.3)$$

The final form of eqn 16.3 is derived by noting that the sum of n_i is equal to N , so the second and fourth terms in the second expression cancel.

(b) The Boltzmann distribution

We have seen that the configuration $\{N-2,2,0,\dots\}$ dominates $\{N,0,0,\dots\}$, and it should be easy to believe that there may be other configurations that have a much greater weight than both. We shall see, in fact, that there is a configuration with so great a weight that it overwhelms all the rest in importance to such an extent that the system will almost always be found in it. The properties of the system will therefore be characteristic of that particular dominating configuration. This dominating configuration can be found by looking for the values of n_i that lead to a maximum value of W . Because W is a function of all the n_i , we can do this search by varying the n_i and looking for the values that correspond to $dW=0$ (just as in the search for the maximum of any function), or equivalently a maximum value of $\ln W$. However, there are two difficulties with this procedure.

The first difficulty is that the only permitted configurations are those corresponding to the specified, constant, total energy of the system. This requirement rules out many configurations; $\{N,0,0,\dots\}$ and $\{N-2,2,0,\dots\}$, for instance, have different energies, so both cannot occur in the same isolated system. It follows that, in looking for the configuration with the greatest weight, we must ensure that the configuration also satisfies the condition

$$\text{Constant total energy:} \quad \sum_i n_i \epsilon_i = E \quad (16.4)$$

where E is the total energy of the system.

The second constraint is that, because the total number of molecules present is also fixed (at N), we cannot arbitrarily vary all the populations simultaneously. Thus, increasing the population of one state by 1 demands that the population of another state must be reduced by 1. Therefore, the search for the maximum value of W is also subject to the condition

$$\text{Constant total number of molecules:} \quad \sum_i n_i = N \quad (16.5)$$

We show in *Further information 16.1* that the populations in the configuration of greatest weight, subject to the two constraints in eqns 16.4 and 16.5, depend on the energy of the state according to the **Boltzmann distribution**:

Comment 16.2

A more accurate form of Stirling's approximation is

$$x! \approx (2\pi)^{1/2} x^{x+1/2} e^{-x}$$

and is in error by less than 1 per cent when x is greater than about 10. We deal with far larger values of x , and the simplified version in eqn 16.2 is adequate.

$$\frac{n_i}{N} = \frac{e^{-\beta \epsilon_i}}{\sum_i e^{-\beta \epsilon_i}} \quad (16.6a)$$

where $\epsilon_0 \leq \epsilon_1 \leq \epsilon_2 \dots$. Equation 16.6a is the justification of the remark that a single parameter, here denoted β , determines the most probable populations of the states of the system. We shall see in Section 16.3b that

$$\beta = \frac{1}{kT} \quad (16.6b)$$

where T is the thermodynamic temperature and k is Boltzmann's constant. In other words, *the thermodynamic temperature is the unique parameter that governs the most probable populations of states of a system at thermal equilibrium*. In Further information 16.3, moreover, we see that β is a more natural measure of temperature than T itself.

16.2 The molecular partition function

From now on we write the Boltzmann distribution as

$$p_i = \frac{e^{-\beta \epsilon_i}}{q} \quad (16.7)$$

where p_i is the fraction of molecules in the state i , $p_i = n_i/N$, and q is the **molecular partition function**:

$$q = \sum_i e^{-\beta \epsilon_i} \quad [16.8]$$

The sum in q is sometimes expressed slightly differently. It may happen that several states have the same energy, and so give the same contribution to the sum. If, for example, g_i states have the same energy ϵ_i (so the level is g_i -fold degenerate), we could write

$$q = \sum_{\text{levels } i} g_i e^{-\beta \epsilon_i} \quad (16.9)$$

where the sum is now over energy levels (sets of states with the same energy), not individual states.

Example 16.1 Writing a partition function

Write an expression for the partition function of a linear molecule (such as HCl) treated as a rigid rotor.

Method To use eqn 16.9 we need to know (a) the energies of the levels, (b) the degeneracies, the number of states that belong to each level. Whenever calculating a partition function, the energies of the levels are expressed relative to 0 for the state of lowest energy. The energy levels of a rigid linear rotor were derived in Section 13.5c.

Answer From eqn 13.31, the energy levels of a linear rotor are $hcBJ(J+1)$, with $J = 0, 1, 2, \dots$. The state of lowest energy has zero energy, so no adjustment need be made to the energies given by this expression. Each level consists of $2J+1$ degenerate states. Therefore,

$$q = \sum_{J=0}^{\infty} \overbrace{(2J+1)}^{g_J} e^{-\beta \overbrace{hcBJ(J+1)}^{\epsilon_J}}$$

The sum can be evaluated numerically by supplying the value of B (from spectroscopy or calculation) and the temperature. For reasons explained in Section 17.2b,

this expression applies only to unsymmetrical linear rotors (for instance, HCl, not CO₂).

Self-test 16.2 Write the partition function for a two-level system, the lower state (at energy 0) being nondegenerate, and the upper state (at an energy ϵ) doubly degenerate. [$q = 1 + 2e^{-\beta\epsilon}$]

(a) An interpretation of the partition function

Some insight into the significance of a partition function can be obtained by considering how q depends on the temperature. When T is close to zero, the parameter $\beta = 1/kT$ is close to infinity. Then every term except one in the sum defining q is zero because each one has the form e^{-x} with $x \rightarrow \infty$. The exception is the term with $\epsilon_0 \equiv 0$ (or the g_0 terms at zero energy if the ground state is g_0 -fold degenerate), because then $\epsilon_0/kT \equiv 0$ whatever the temperature, including zero. As there is only one surviving term when $T = 0$, and its value is g_0 , it follows that

$$\lim_{T \rightarrow 0} q = g_0 \quad (16.10)$$

That is, at $T = 0$, the partition function is equal to the degeneracy of the ground state.

Now consider the case when T is so high that for each term in the sum $\epsilon_j/kT \approx 0$. Because $e^{-x} = 1$ when $x = 0$, each term in the sum now contributes 1. It follows that the sum is equal to the number of molecular states, which in general is infinite:

$$\lim_{T \rightarrow \infty} q = \infty \quad (16.11)$$

In some idealized cases, the molecule may have only a finite number of states; then the upper limit of q is equal to the number of states. For example, if we were considering only the spin energy levels of a radical in a magnetic field, then there would be only two states ($m_s = \pm \frac{1}{2}$). The partition function for such a system can therefore be expected to rise towards 2 as T is increased towards infinity.

We see that *the molecular partition function gives an indication of the number of states that are thermally accessible to a molecule at the temperature of the system*. At $T = 0$, only the ground level is accessible and $q = g_0$. At very high temperatures, virtually all states are accessible, and q is correspondingly large.

Example 16.2 Evaluating the partition function for a uniform ladder of energy levels

Evaluate the partition function for a molecule with an infinite number of equally spaced nondegenerate energy levels (Fig. 16.3). These levels can be thought of as the vibrational energy levels of a diatomic molecule in the harmonic approximation.

Method We expect the partition function to increase from 1 at $T = 0$ and approach infinity as $T \rightarrow \infty$. To evaluate eqn 16.8 explicitly, note that

$$1 + x + x^2 + \dots = \frac{1}{1 - x}$$

Answer If the separation of neighbouring levels is ϵ , the partition function is

$$q = 1 + e^{-\beta\epsilon} + e^{-2\beta\epsilon} + \dots = 1 + e^{-\beta\epsilon} + (e^{-\beta\epsilon})^2 + \dots = \frac{1}{1 - e^{-\beta\epsilon}}$$

This expression is plotted in Fig. 16.4: notice that, as anticipated, q rises from 1 to infinity as the temperature is raised.

Fig. 16.3 The equally spaced infinite array of energy levels used in the calculation of the partition function. A harmonic oscillator has the same spectrum of levels.

Comment 16.3

The sum of the infinite series $S = 1 + x + x^2 + \dots$ is obtained by multiplying both sides by x , which gives $xS = x + x^2 + x^3 + \dots = S - 1$ and hence $S = 1/(1 - x)$.

Fig. 16.4 The partition function for the system shown in Fig. 16.3 (a harmonic oscillator) as a function of temperature.

Exploration Plot the partition function of a harmonic oscillator against temperature for several values of the energy separation ϵ . How does q vary with temperature when T is high, in the sense that $kT \gg \epsilon$ (or $\beta\epsilon \ll 1$)?

Fig. 16.5 The partition function for a two-level system as a function of temperature. The two graphs differ in the scale of the temperature axis to show the approach to 1 as $T \rightarrow 0$ and the slow approach to 2 as $T \rightarrow \infty$.

Exploration Consider a three-level system with levels 0, ϵ , and 2ϵ . Plot the partition function against kT/ϵ .

Fig. 16.6 The populations of the energy levels of the system shown in Fig. 16.3 at different temperatures, and the corresponding values of the partition function calculated in Example 16.2. Note that $\beta = 1/kT$.

Exploration To visualize the content of Fig. 16.6 in a different way, plot the functions p_0 , p_1 , p_2 , and p_3 against kT/ϵ .

Self-test 16.3 Find and plot an expression for the partition function of a system with one state at zero energy and another state at the energy ϵ .
 $[q = 1 + e^{-\beta\epsilon}$, Fig. 16.5]

It follows from eqn 16.8 and the expression for q derived in Example 16.2 for a uniform ladder of states of spacing ϵ ,

$$q = \frac{1}{1 - e^{-\beta\epsilon}} \quad (16.12)$$

that the fraction of molecules in the state with energy ϵ_i is

$$p_i = \frac{e^{-\beta\epsilon_i}}{q} = (1 - e^{-\beta\epsilon})e^{-\beta\epsilon_i} \quad (16.13)$$

Figure 16.6 shows how p_i varies with temperature. At very low temperatures, where q is close to 1, only the lowest state is significantly populated. As the temperature is raised, the population breaks out of the lowest state, and the upper states become progressively more highly populated. At the same time, the partition function rises from 1 and its value gives an indication of the range of states populated. The name 'partition function' reflects the sense in which q measures how the total number of molecules is distributed—partitioned—over the available states.

The corresponding expressions for a two-level system derived in Self-test 16.3 are

$$p_0 = \frac{1}{1 + e^{-\beta\epsilon}} \quad p_1 = \frac{e^{-\beta\epsilon}}{1 + e^{-\beta\epsilon}} \quad (16.14)$$

These functions are plotted in Fig. 16.7. Notice how the populations tend towards equality ($p_0 = \frac{1}{2}$, $p_1 = \frac{1}{2}$) as $T \rightarrow \infty$. A common error is to suppose that all the molecules in the system will be found in the upper energy state when $T = \infty$; however, we see

Fig. 16.7 The fraction of populations of the two states of a two-level system as a function of temperature (eqn 16.14). Note that, as the temperature approaches infinity, the populations of the two states become equal (and the fractions both approach 0.5).

 **Exploration** Consider a three-level system with levels 0, ϵ , and 2ϵ . Plot the functions p_0 , p_1 , and p_2 against kT/ϵ .

from eqn 16.14 that, as $T \rightarrow \infty$, the populations of states become equal. The same conclusion is true of multi-level systems too: as $T \rightarrow \infty$, all states become equally populated.

Example 16.3 Using the partition function to calculate a population

Calculate the proportion of I_2 molecules in their ground, first excited, and second excited vibrational states at 25°C . The vibrational wavenumber is 214.6 cm^{-1} .

Method Vibrational energy levels have a constant separation (in the harmonic approximation, Section 13.9), so the partition function is given by eqn 16.12 and the populations by eqn 16.13. To use the latter equation, we identify the index i with the quantum number v , and calculate p_v for $v = 0, 1$, and 2 . At 298.15 K , $kT/hc = 207.226\text{ cm}^{-1}$.

Answer First, we note that

$$\beta\epsilon = \frac{hc\tilde{\nu}}{kT} = \frac{214.6\text{ cm}^{-1}}{207.226\text{ cm}^{-1}} = 1.036$$

Then it follows from eqn 16.13 that the populations are

$$p_v = (1 - e^{-\beta\epsilon})e^{-v\beta\epsilon} = 0.645e^{-1.036v}$$

Therefore, $p_0 = 0.645$, $p_1 = 0.229$, $p_2 = 0.081$. The I—I bond is not stiff and the atoms are heavy: as a result, the vibrational energy separations are small and at room temperature several vibrational levels are significantly populated. The value of the partition function, $q = 1.55$, reflects this small but significant spread of populations.

Self-test 16.4 At what temperature would the $v = 1$ level of I_2 have (a) half the population of the ground state, (b) the same population as the ground state?

[(a) 445 K, (b) infinite]

Fig. 16.8 The technique of adiabatic demagnetization is used to attain very low temperatures. The upper curve shows that variation of the entropy of a paramagnetic system in the absence of an applied field. The lower curve shows that variation in entropy when a field is applied and has made the electron magnets more orderly. The isothermal magnetization step is from A to B; the adiabatic demagnetization step (at constant entropy) is from B to C.

It follows from our discussion of the partition function that to reach low temperatures it is necessary to devise strategies that populate the low energy levels of a system at the expense of high energy levels. Common methods used to reach very low temperatures include **optical trapping** and **adiabatic demagnetization**. In optical trapping, atoms in the gas phase are cooled by inelastic collisions with photons from intense laser beams, which act as walls of a very small container. Adiabatic demagnetization is based on the fact that, in the absence of a magnetic field, the unpaired electrons of a paramagnetic material are orientated at random, but in the presence of a magnetic field there are more β spins ($m_s = -\frac{1}{2}$) than α spins ($m_s = +\frac{1}{2}$). In thermodynamic terms, the application of a magnetic field lowers the entropy of a sample and, at a given temperature, the entropy of a sample is lower when the field is on than when it is off. Even lower temperatures can be reached if nuclear spins (which also behave like small magnets) are used instead of electron spins in the technique of **adiabatic nuclear demagnetization**, which has been used to cool a sample of silver to about 280 pK. In certain circumstances it is possible to achieve negative temperatures, and the equations derived later in this chapter can be extended to $T < 0$ with interesting consequences (see *Further information 16.3*).

Illustration 16.2 Cooling a sample by adiabatic demagnetization

Consider the situation summarized by Fig. 16.8. A sample of paramagnetic material, such as a *d*- or *f*-metal complex with several unpaired electrons, is cooled to about 1 K by using helium. The sample is then exposed to a strong magnetic field while it is surrounded by helium, which provides thermal contact with the cold reservoir. This magnetization step is isothermal, and energy leaves the system as heat while the electron spins adopt the lower energy state (AB in the illustration). Thermal contact between the sample and the surroundings is now broken by pumping away the helium and the magnetic field is reduced to zero. This step is adiabatic and effectively reversible, so the state of the sample changes from B to C. At the end of this step the sample is the same as it was at A except that it now has a lower entropy. That lower entropy in the absence of a magnetic field corresponds to a lower temperature. That is, adiabatic demagnetization has cooled the sample.

(b) Approximations and factorizations

In general, exact analytical expressions for partition functions cannot be obtained. However, closed approximate expressions can often be found and prove to be very important in a number of chemical and biochemical applications (*Impact 16.1*). For instance, the expression for the partition function for a particle of mass m free to move in a one-dimensional container of length X can be evaluated by making use of the fact that the separation of energy levels is very small and that large numbers of states are accessible at normal temperatures. As shown in the *Justification* below, in this case

$$q_X = \left(\frac{2\pi m}{h^2 \beta} \right)^{1/2} X \quad (16.15)$$

This expression shows that the partition function for translational motion increases with the length of the box and the mass of the particle, for in each case the separation of the energy levels becomes smaller and more levels become thermally accessible. For a given mass and length of the box, the partition function also increases with increasing temperature (decreasing β), because more states become accessible.

Justification 16.2 *The partition function for a particle in a one-dimensional box*

The energy levels of a molecule of mass m in a container of length X are given by eqn 9.4a with $L = X$:

$$E_n = \frac{n^2 h^2}{8mX^2} \quad n = 1, 2, \dots$$

The lowest level ($n = 1$) has energy $h^2/8mX^2$, so the energies relative to that level are

$$\epsilon_n = (n^2 - 1)\epsilon \quad \epsilon = h^2/8mX^2$$

The sum to evaluate is therefore

$$q_X = \sum_{n=1}^{\infty} e^{-(n^2-1)\beta\epsilon}$$

The translational energy levels are very close together in a container the size of a typical laboratory vessel; therefore, the sum can be approximated by an integral:

$$q_X = \int_1^{\infty} e^{-(n^2-1)\beta\epsilon} dn \approx \int_0^{\infty} e^{-n^2\beta\epsilon} dn$$

The extension of the lower limit to $n = 0$ and the replacement of $n^2 - 1$ by n^2 introduces negligible error but turns the integral into standard form. We make the substitution $x^2 = n^2\beta\epsilon$, implying $dn = dx/(\beta\epsilon)^{1/2}$, and therefore that

$$q_X = \left(\frac{1}{\beta\epsilon}\right)^{1/2} \int_0^{\infty} e^{-x^2} dx = \left(\frac{1}{\beta\epsilon}\right)^{1/2} \left(\frac{\pi^{1/2}}{2}\right) = \left(\frac{2\pi m}{h^2\beta}\right)^{1/2} X$$

Another useful feature of partition functions is used to derive expressions when the energy of a molecule arises from several different, independent sources: if the energy is a sum of contributions from independent modes of motion, then the partition function is a product of partition functions for each mode of motion. For instance, suppose the molecule we are considering is free to move in three dimensions. We take the length of the container in the y -direction to be Y and that in the z -direction to be Z . The total energy of a molecule ϵ is the sum of its translational energies in all three directions:

$$\epsilon_{n_1 n_2 n_3} = \epsilon_{n_1}^{(X)} + \epsilon_{n_2}^{(Y)} + \epsilon_{n_3}^{(Z)} \quad (16.16)$$

where n_1 , n_2 , and n_3 are the quantum numbers for motion in the x -, y -, and z -directions, respectively. Therefore, because $e^{a+b+c} = e^a e^b e^c$, the partition function factorizes as follows:

$$\begin{aligned} q &= \sum_{\text{all } n} e^{-\beta\epsilon_{n_1}^{(X)} - \beta\epsilon_{n_2}^{(Y)} - \beta\epsilon_{n_3}^{(Z)}} = \sum_{\text{all } n} e^{-\beta\epsilon_{n_1}^{(X)}} e^{-\beta\epsilon_{n_2}^{(Y)}} e^{-\beta\epsilon_{n_3}^{(Z)}} \\ &= \left(\sum_{n_1} e^{-\beta\epsilon_{n_1}^{(X)}}\right) \left(\sum_{n_2} e^{-\beta\epsilon_{n_2}^{(Y)}}\right) \left(\sum_{n_3} e^{-\beta\epsilon_{n_3}^{(Z)}}\right) \\ &= q_X q_Y q_Z \end{aligned} \quad (16.17)$$

It is generally true that, if the energy of a molecule can be written as the sum of independent terms, then the partition function is the corresponding product of individual contributions.

Equation 16.15 gives the partition function for translational motion in the x -direction. The only change for the other two directions is to replace the length X by the lengths Y or Z . Hence the partition function for motion in three dimensions is

$$q = \left(\frac{2\pi m}{h^2 \beta} \right)^{3/2} XYZ \quad (16.18)$$

The product of lengths XYZ is the volume, V , of the container, so we can write

$$q = \frac{V}{\Lambda^3} \quad \Lambda = h \left(\frac{\beta}{2\pi m} \right)^{1/2} = \frac{h}{(2\pi m k T)^{1/2}} \quad (16.19)$$

The quantity Λ has the dimensions of length and is called the **thermal wavelength** (sometimes the *thermal de Broglie wavelength*) of the molecule. The thermal wavelength decreases with increasing mass and temperature. As in the one-dimensional case, the partition function increases with the mass of the particle (as $m^{3/2}$) and the volume of the container (as V); for a given mass and volume, the partition function increases with temperature (as $T^{3/2}$).

Illustration 16.3 Calculating the translational partition function

To calculate the translational partition function of an H_2 molecule confined to a 100 cm^3 vessel at 25°C we use $m = 2.016 \text{ u}$; then

$$\begin{aligned} \Lambda &= \frac{6.626 \times 10^{-34} \text{ J s}}{\{2\pi \times (2.016 \times 1.6605 \times 10^{-27} \text{ kg}) \times (1.38 \times 10^{-23} \text{ J K}^{-1}) \times (298 \text{ K})\}^{1/2}} \\ &= 7.12 \times 10^{-11} \text{ m} \end{aligned}$$

where we have used $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$. Therefore,

$$q = \frac{1.00 \times 10^{-4} \text{ m}^3}{(7.12 \times 10^{-11} \text{ m})^3} = 2.77 \times 10^{26}$$

About 10^{26} quantum states are thermally accessible, even at room temperature and for this light molecule. Many states are occupied if the thermal wavelength (which in this case is 71.2 pm) is small compared with the linear dimensions of the container.

Self-test 16.5 Calculate the translational partition function for a D_2 molecule under the same conditions. [$q = 7.8 \times 10^{26}$, $2^{3/2}$ times larger]

The validity of the approximations that led to eqn 16.19 can be expressed in terms of the average separation of the particles in the container, d . We do not have to worry about the role of the Pauli principle on the occupation of states if there are many states available for each molecule. Because q is the total number of accessible states, the average number of states per molecule is q/N . For this quantity to be large, we require $V/N\Lambda^3 \gg 1$. However, V/N is the volume occupied by a single particle, and therefore the average separation of the particles is $d = (V/N)^{1/3}$. The condition for there being many states available per molecule is therefore $d^3/\Lambda^3 \gg 1$, and therefore $d \gg \Lambda$. That is, for eqn 16.19 to be valid, *the average separation of the particles must be much greater than their thermal wavelength*. For H_2 molecules at 1 bar and 298 K, the average separation is 3 nm , which is significantly larger than their thermal wavelength (71.2 pm , *Illustration 16.3*).

IMPACT ON BIOCHEMISTRY

I16.1 The helix–coil transition in polypeptides

Proteins are polymers that attain well defined three-dimensional structures both in solution and in biological cells. They are *polypeptides* formed from different amino acids strung together by the *peptide link*, $-\text{CONH}-$. Hydrogen bonds between amino acids of a polypeptide give rise to stable helical or sheet structures, which may collapse into a random coil when certain conditions are changed. The unwinding of a helix into a random coil is a *cooperative transition*, in which the polymer becomes increasingly more susceptible to structural changes once the process has begun. We examine here a model grounded in the principles of statistical thermodynamics that accounts for the cooperativity of the helix–coil transition in polypeptides.

To calculate the fraction of polypeptide molecules present as helix or coil we need to set up the partition function for the various states of the molecule. To illustrate the approach, consider a short polypeptide with four amino acid residues, each labelled h if it contributes to a helical region and c if it contributes to a random coil region. We suppose that conformations $hhhh$ and $cccc$ contribute terms q_0 and q_4 , respectively, to the partition function q . Then we assume that each of the four conformations with one c amino acid (such as $hchh$) contributes q_1 . Similarly, each of the six states with two c amino acids contributes a term q_2 , and each of the four states with three c amino acids contributes a term q_3 . The partition function is then

$$q = q_0 + 4q_1 + 6q_2 + 4q_3 + q_4 = q_0 \left(1 + \frac{4q_1}{q_0} + \frac{6q_2}{q_0} + \frac{4q_3}{q_0} + \frac{q_4}{q_0} \right)$$

We shall now suppose that each partition function differs from q_0 only by the energy of each conformation relative to $hhhh$, and write

$$\frac{q_i}{q_0} = e^{-(\varepsilon_i - \varepsilon_0)/kT}$$

Next, we suppose that the conformational transformations are non-cooperative, in the sense that the energy associated with changing one h amino acid into one c amino acid has the same value regardless of how many h or c amino acid residues are in the reactant or product state and regardless of where in the chain the conversion occurs. That is, we suppose that the difference in energy between $c^i h^{4-i}$ and $c^{i+1} h^{3-i}$ has the same value γ for all i . This assumption implies that $\varepsilon_i - \varepsilon_0 = i\gamma$ and therefore that

$$q = q_0(1 + 4s + 6s^2 + 4s^3 + s^4) \quad s = e^{-\Gamma/RT} \quad (16.20)$$

where $\Gamma = N_A \gamma$ and s is called the *stability parameter*. The term in parentheses has the form of the binomial expansion of $(1 + s)^4$.

$$\frac{q}{q_0} = \sum_{i=0}^4 C(4, i) s^i \quad \text{with} \quad C(4, i) = \frac{4!}{(4-i)!i!} \quad (16.21)$$

which we interpret as the number of ways in which a state with i c amino acids can be formed.

The extension of this treatment to take into account a longer chain of residues is now straightforward: we simply replace the upper limit of 4 in the sum by n :

$$\frac{q}{q_0} = \sum_{i=0}^n C(n, i) s^i \quad (16.22)$$

A cooperative transformation is more difficult to accommodate, and depends on building a model of how neighbours facilitate each other's conformational change. In

Comment 16.4

The binomial expansion of $(1 + x)^n$ is

$$(1 + x)^n = \sum_{i=0}^n C(n, i) x^i,$$

$$\text{with } C(n, i) = \frac{n!}{(n-i)!i!}$$

Fig. 16.9 The distribution of p_i , the fraction of molecules that has a number i of c amino acids for $s = 0.8$ ($\langle i \rangle = 1.1$), 1.0 ($\langle i \rangle = 3.8$), and 1.5 ($\langle i \rangle = 15.9$), with $\sigma = 5.0 \times 10^{-3}$.

Fig. 16.10 Plots of the degree of conversion θ , against s for several values of σ . The curves show the sigmoidal shape characteristics of cooperative behaviour.

the simple *zipper model*, conversion from h to c is allowed only if a residue adjacent to the one undergoing the conversion is already a c residue. Thus, the zipper model allows a transition of the type $\dots hhhch. \dots \rightarrow \dots hhhcc. \dots$, but not a transition of the type $\dots hhhch. \dots \rightarrow \dots hchch. \dots$. The only exception to this rule is, of course, the very first conversion from h to c in a fully helical chain. Cooperativity is included in the zipper model by assuming that the first conversion from h to c , called the *nucleation step*, is less favourable than the remaining conversions and replacing s for that step by σs , where $\sigma \ll 1$. Each subsequent step is called a *propagation step* and has a stability parameter s . In Problem 16.24, you are invited to show that the partition function is:

$$q = 1 + \sum_{i=1}^n Z(n, i) \sigma s^i \quad (16.23)$$

where $Z(n, i)$ is the number of ways in which a state with a number i of c amino acids can be formed under the strictures of the zipper model. Because $Z(n, i) = n - i + 1$ (see Problem 16.24),

$$q = 1 + \sigma(n+1) \sum_{i=1}^n s^i - \sigma \sum_{i=1}^n i s^i \quad (16.24)$$

After evaluating both geometric series by using the two relations

$$\sum_{i=1}^n x^i = \frac{x^{n+1} - x}{x - 1} \quad \sum_{i=1}^n i x^i = \frac{x}{(x-1)^2} [n x^{n+1} - (n+1)x^n + 1]$$

we find

$$q = 1 + \frac{\sigma s [s^{n+1} - (n+1)s^n + 1]}{(s-1)^2}$$

The fraction $p_i = q_i/q$ of molecules that has a number i of c amino acids is $p_i = [(n-i+1)\sigma s^i]/q$ and the mean value of i is then $\langle i \rangle = \sum_i i p_i$. Figure 16.9 shows the distribution of p_i for various values of s with $\sigma = 5.0 \times 10^{-3}$. We see that most of the polypeptide chains remain largely helical when $s < 1$ and that most of the chains exist largely as random coils when $s > 1$. When $s = 1$, there is a more widespread distribution of length of random coil segments. Because the *degree of conversion*, θ , of a polypeptide with n amino acids to a random coil is defined as $\theta = \langle i \rangle/n$, it is possible to show (see Problem 16.24) that

$$\theta = \frac{1}{n} \frac{d}{d(\ln s)} \ln q \quad (16.25)$$

This is a general result that applies to any model of the helix-coil transition in which the partition function q is expressed as a function of the stability parameter s .

A more sophisticated model for the helix-coil transition must allow for helical segments to form in different regions of a long polypeptide chain, with the nascent helices being separated by shrinking coil segments. Calculations based on this more complete *Zimm-Bragg model* give

$$\theta = \frac{1}{2} \left(1 + \frac{(s-1) + 2\sigma}{[(s-1)^2 + 4s\sigma]^{1/2}} \right) \quad (16.26)$$

Figure 16.10 shows plots of θ against s for several values of σ . The curves show the sigmoidal shape characteristic of cooperative behaviour. There is a sudden surge of transition to a random coil as s passes through 1 and, the smaller the parameter σ , the greater the sharpness and hence the greater the cooperativity of the transition. That is, the harder it is to get coil formation started, the sharper the transition from helix to coil.

The internal energy and the entropy

The importance of the molecular partition function is that it contains all the information needed to calculate the thermodynamic properties of a system of independent particles. In this respect, q plays a role in statistical thermodynamics very similar to that played by the wavefunction in quantum mechanics: q is a kind of thermal wavefunction.

16.3 The internal energy

We shall begin to unfold the importance of q by showing how to derive an expression for the internal energy of the system.

(a) The relation between U and q

The total energy of the system relative to the energy of the lowest state is

$$E = \sum_i n_i \varepsilon_i \quad (16.27)$$

Because the most probable configuration is so strongly dominating, we can use the Boltzmann distribution for the populations and write

$$E = \frac{N}{q} \sum_i \varepsilon_i e^{-\beta \varepsilon_i} \quad (16.28)$$

To manipulate this expression into a form involving only q we note that

$$\varepsilon_i e^{-\beta \varepsilon_i} = - \frac{d}{d\beta} e^{-\beta \varepsilon_i}$$

It follows that

$$E = - \frac{N}{q} \sum_i \frac{d}{d\beta} e^{-\beta \varepsilon_i} = - \frac{N}{q} \frac{d}{d\beta} \sum_i e^{-\beta \varepsilon_i} = - \frac{N}{q} \frac{dq}{d\beta} \quad (16.29)$$

Fig. 16.11 The total energy of a two-level system (expressed as a multiple of $N\varepsilon$) as a function of temperature, on two temperature scales. The graph at the top shows the slow rise away from zero energy at low temperatures; the slope of the graph at $T=0$ is 0 (that is, the heat capacity is zero at $T=0$). The graph below shows the slow rise to 0.5 as $T \rightarrow \infty$ as both states become equally populated (see Fig. 16.7).

Exploration Draw graphs similar to those in Fig. 16.11 for a three-level system with levels 0, ε , and 2ε .

Illustration 16.4 The energy of a two-level system

From the two-level partition function $q = 1 + e^{-\beta \varepsilon}$, we can deduce that the total energy of N two-level systems is

$$E = - \left(\frac{N}{1 + e^{-\beta \varepsilon}} \right) \frac{d}{d\beta} (1 + e^{-\beta \varepsilon}) = \frac{N \varepsilon e^{-\beta \varepsilon}}{1 + e^{-\beta \varepsilon}} = \frac{N \varepsilon}{1 + e^{\beta \varepsilon}}$$

This function is plotted in Fig. 16.11. Notice how the energy is zero at $T=0$, when only the lower state (at the zero of energy) is occupied, and rises to $\frac{1}{2}N\varepsilon$ as $T \rightarrow \infty$, when the two levels become equally populated.

There are several points in relation to eqn 16.29 that need to be made. Because $\varepsilon_0 = 0$ (remember that we measure all energies from the lowest available level), E should be interpreted as the value of the internal energy relative to its value at $T=0$, $U(0)$. Therefore, to obtain the conventional internal energy U , we must add the internal energy at $T=0$:

$$U = U(0) + E \quad (16.30)$$

Secondly, because the partition function may depend on variables other than the temperature (for example, the volume), the derivative with respect to β in eqn 16.29 is actually a *partial* derivative with these other variables held constant. The complete expression relating the molecular partition function to the thermodynamic internal energy of a system of independent molecules is therefore

$$U = U(0) - \frac{N}{q} \left(\frac{\partial q}{\partial \beta} \right)_V \quad (16.31a)$$

An equivalent form is obtained by noting that $dx/x = d \ln x$:

$$U = U(0) - N \left(\frac{\partial \ln q}{\partial \beta} \right)_V \quad (16.31b)$$

These two equations confirm that we need know only the partition function (as a function of temperature) to calculate the internal energy relative to its value at $T = 0$.

(b) The value of β

We now confirm that the parameter β , which we have anticipated is equal to $1/kT$, does indeed have that value. To do so, we compare the equipartition expression for the internal energy of a monatomic perfect gas, which from *Molecular interpretation* 2.2 we know to be

$$U = U(0) + \frac{3}{2}nRT \quad (16.32a)$$

with the value calculated from the translational partition function (see the following *Justification*), which is

$$U = U(0) + \frac{3N}{2\beta} \quad (16.32b)$$

It follows by comparing these two expressions that

$$\beta = \frac{N}{nRT} = \frac{nN_A}{nN_A kT} = \frac{1}{kT} \quad (16.33)$$

(We have used $N = nN_A$, where n is the amount of gas molecules, N_A is Avogadro's constant, and $R = N_A k$.) Although we have proved that $\beta = 1/kT$ by examining a very specific example, the translational motion of a perfect monatomic gas, the result is general (see *Example 17.1* and *Further reading*).

Justification 16.3 *The internal energy of a perfect gas*

To use eqn 16.31, we introduce the translational partition function from eqn 16.19:

$$\left(\frac{\partial q}{\partial \beta} \right)_V = \left(\frac{\partial}{\partial \beta} \frac{V}{\Lambda^3} \right)_V = V \frac{d}{d\beta} \frac{1}{\Lambda^3} = -3 \frac{V}{\Lambda^4} \frac{d\Lambda}{d\beta}$$

Then we note from the formula for Λ in eqn 16.19 that

$$\frac{d\Lambda}{d\beta} = \frac{d}{d\beta} \left\{ \frac{h\beta^{1/2}}{(2\pi m)^{1/2}} \right\} = \frac{1}{2\beta^{1/2}} \times \frac{h}{(2\pi m)^{1/2}} = \frac{\Lambda}{2\beta}$$

and so obtain

$$\left(\frac{\partial q}{\partial \beta} \right)_V = -\frac{3V}{2\beta\Lambda^3}$$

Then, by eqn 16.31a,

$$U = U(0) - N \left(\frac{\Lambda^3}{V} \right) \left(-\frac{3V}{2\beta\Lambda^3} \right) = U(0) + \frac{3N}{2\beta}$$

as in eqn 16.32b.

16.4 The statistical entropy

If it is true that the partition function contains all thermodynamic information, then it must be possible to use it to calculate the entropy as well as the internal energy. Because we know (from Section 3.2) that entropy is related to the dispersal of energy and that the partition function is a measure of the number of thermally accessible states, we can be confident that the two are indeed related.

We shall develop the relation between the entropy and the partition function in two stages. In *Further information* 16.2, we justify one of the most celebrated equations in statistical thermodynamics, the **Boltzmann formula** for the entropy:

$$S = k \ln W \quad [16.34]$$

In this expression, W is the weight of the most probable configuration of the system. In the second stage, we express W in terms of the partition function.

The statistical entropy behaves in exactly the same way as the thermodynamic entropy. Thus, as the temperature is lowered, the value of W , and hence of S , decreases because fewer configurations are compatible with the total energy. In the limit $T \rightarrow 0$, $W = 1$, so $\ln W = 0$, because only one configuration (every molecule in the lowest level) is compatible with $E = 0$. It follows that $S \rightarrow 0$ as $T \rightarrow 0$, which is compatible with the Third Law of thermodynamics, that the entropies of all perfect crystals approach the same value as $T \rightarrow 0$ (Section 3.4).

Now we relate the Boltzmann formula for the entropy to the partition function. To do so, we substitute the expression for $\ln W$ given in eqn 16.3 into eqn 16.34 and, as shown in the *Justification* below, obtain

$$S = \frac{U - U(0)}{T} + Nk \ln q \quad (16.35)$$

Justification 16.4 The statistical entropy

The first stage is to use eqn 16.3 ($\ln W = N \ln N - \sum_i n_i \ln n_i$) and $N = \sum_i n_i$ to write

$$S = k \sum_i (n_i \ln N - n_i \ln n_i) = -k \sum_i n_i \ln \frac{n_i}{N} = -Nk \sum_i p_i \ln p_i$$

where $p_i = n_i/N$, the fraction of molecules in state i . It follows from eqn 16.7 that

$$\ln p_i = -\beta \epsilon_i - \ln q$$

and therefore that

$$S = -Nk(-\beta \sum_i p_i \epsilon_i - \sum_i p_i \ln q) = k\beta \{U - U(0)\} + Nk \ln q$$

We have used the fact that the sum over the p_i is equal to 1 and that (from eqns 16.27 and 16.30)

$$N \sum_i p_i \epsilon_i = \sum_i N p_i \epsilon_i = \sum_i n_i \epsilon_i = E = U - U(0)$$

We have already established that $\beta = 1/kT$, so eqn 16.35 immediately follows.

Fig. 16.12 The temperature variation of the entropy of the system shown in Fig. 16.3 (expressed here as a multiple of Nk). The entropy approaches zero as $T \rightarrow 0$, and increases without limit as $T \rightarrow \infty$.

 **Exploration** Plot the function dS/dT , the temperature coefficient of the entropy, against kT/ϵ . Is there a temperature at which this coefficient passes through a maximum? If you find a maximum, explain its physical origins.

Example 16.4 Calculating the entropy of a collection of oscillators

Calculate the entropy of a collection of N independent harmonic oscillators, and evaluate it using vibrational data for I_2 vapour at 25°C (Example 16.3).

Method To use eqn 16.35, we use the partition function for a molecule with evenly spaced vibrational energy levels, eqn 16.12. With the partition function available, the internal energy can be found by differentiation (as in eqn 16.31a), and the two expressions then combined to give S .

Answer The molecular partition function as given in eqn 16.12 is

$$q = \frac{1}{1 - e^{-\beta\epsilon}}$$

The internal energy is obtained by using eqn 16.31a:

$$U - U(0) = -\frac{N}{q} \left(\frac{\partial q}{\partial \beta} \right)_V = \frac{N\epsilon e^{-\beta\epsilon}}{1 - e^{-\beta\epsilon}} = \frac{N\epsilon}{e^{\beta\epsilon} - 1}$$

The entropy is therefore

$$S = Nk \left\{ \frac{\beta\epsilon}{e^{\beta\epsilon} - 1} - \ln(1 - e^{-\beta\epsilon}) \right\}$$

This function is plotted in Fig. 16.12. For I_2 at 25°C , $\beta\epsilon = 1.036$ (Example 16.3), so $S_m = 8.38 \text{ J K}^{-1} \text{ mol}^{-1}$.

Self-test 16.6 Evaluate the molar entropy of N two-level systems and plot the resulting expression. What is the entropy when the two states are equally thermally accessible?

$$[S/Nk = \beta\epsilon/(1 + e^{\beta\epsilon}) + \ln(1 + e^{-\beta\epsilon}); \text{ see Fig. 16.13; } S = Nk \ln 2]$$

Fig. 16.13 The temperature variation of the entropy of a two-level system (expressed as a multiple of Nk). As $T \rightarrow \infty$, the two states become equally populated and S approaches $Nk \ln 2$.

 **Exploration** Draw graphs similar to those in Fig. 16.13 for a three-level system with levels 0, ϵ , and 2ϵ .

The canonical partition function

In this section we see how to generalize our conclusions to include systems composed of interacting molecules. We shall also see how to obtain the molecular partition function from the more general form of the partition function developed here.

16.5 The canonical ensemble

The crucial new concept we need when treating systems of interacting particles is the ‘ensemble’. Like so many scientific terms, the term has basically its normal meaning of ‘collection’, but it has been sharpened and refined into a precise significance.

(a) The concept of ensemble

To set up an ensemble, we take a closed system of specified volume, composition, and temperature, and think of it as replicated $\tilde{N}$ times (Fig. 16.14). All the identical closed systems are regarded as being in thermal contact with one another, so they can exchange energy. The total energy of all the systems is $\tilde{E}$ and, because they are in thermal equilibrium with one another, they all have the same temperature, T . This imaginary collection of replications of the actual system with a common temperature is called the **canonical ensemble**.

The word ‘canon’ means ‘according to a rule’. There are two other important ensembles. In the **microcanonical ensemble** the condition of constant temperature is replaced by the requirement that all the systems should have exactly the same energy: each system is individually isolated. In the **grand canonical ensemble** the volume and temperature of each system is the same, but they are open, which means that matter can be imagined as able to pass between the systems; the composition of each one may fluctuate, but now the chemical potential is the same in each system:

Microcanonical ensemble: N, V, E common

Canonical ensemble: N, V, T common

Grand canonical ensemble: μ, V, T common

The important point about an ensemble is that it is a collection of *imaginary* replications of the system, so we are free to let the number of members be as large as we like; when appropriate, we can let $\tilde{N}$ become infinite. The number of members of the ensemble in a state with energy E_i is denoted $\tilde{n}_i$, and we can speak of the configuration of the ensemble (by analogy with the configuration of the system used in Section 16.1) and its weight, $\tilde{W}$. Note that $\tilde{N}$ is unrelated to N , the number of molecules in the actual system; $\tilde{N}$ is the number of imaginary replications of that system.

(b) Dominating configurations

Just as in Section 16.1, some of the configurations of the ensemble will be very much more probable than others. For instance, it is very unlikely that the whole of the total energy, $\tilde{E}$, will accumulate in one system. By analogy with the earlier discussion, we can anticipate that there will be a dominating configuration, and that we can evaluate the thermodynamic properties by taking the average over the ensemble using that single, most probable, configuration. In the **thermodynamic limit** of $\tilde{N} \rightarrow \infty$, this dominating configuration is overwhelmingly the most probable, and it dominates the properties of the system virtually completely.

The quantitative discussion follows the argument in Section 16.1 with the modification that N and n_i are replaced by $\tilde{N}$ and $\tilde{n}_i$. The weight of a configuration $\{\tilde{n}_0, \tilde{n}_1, \dots\}$ is

Fig. 16.14 A representation of the canonical ensemble, in this case for $\tilde{N} = 20$. The individual replications of the actual system all have the same composition and volume. They are all in mutual thermal contact, and so all have the same temperature. Energy may be transferred between them as heat, and so they do not all have the same energy. The total energy $\tilde{E}$ of all 20 replications is a constant because the ensemble is isolated overall.

Fig. 16.15 The energy density of states is the number of states in an energy range divided by the width of the range.

Fig. 16.16 To construct the form of the distribution of members of the canonical ensemble in terms of their energies, we multiply the probability that any one is in a state of given energy, eqn 16.39, by the number of states corresponding to that energy (a steeply rising function). The product is a sharply peaked function at the mean energy, which shows that almost all the members of the ensemble have that energy.

$$\tilde{W} = \frac{\tilde{N}!}{\tilde{n}_0! \tilde{n}_1! \dots} \quad (16.36)$$

The configuration of greatest weight, subject to the constraints that the total energy of the ensemble is constant at $\tilde{E}$ and that the total number of members is fixed at $\tilde{N}$, is given by the **canonical distribution**:

$$\frac{\tilde{n}_i}{\tilde{N}} = \frac{e^{-\beta E_i}}{Q} \quad Q = \sum_i e^{-\beta E_i} \quad (16.37)$$

The quantity Q , which is a function of the temperature, is called the **canonical partition function**.

(c) Fluctuations from the most probable distribution

The canonical distribution in eqn 16.37 is only apparently an exponentially decreasing function of the energy of the system. We must appreciate that eqn 16.37 gives the probability of occurrence of members in a single state i of the entire system of energy E_i . There may in fact be numerous states with almost identical energies. For example, in a gas the identities of the molecules moving slowly or quickly can change without necessarily affecting the total energy. The density of states, the number of states in an energy range divided by the width of the range (Fig. 16.15), is a very sharply increasing function of energy. It follows that the probability of a member of an ensemble having a specified energy (as distinct from being in a specified state) is given by eqn 16.37, a sharply decreasing function, multiplied by a sharply increasing function (Fig. 16.16). Therefore, the overall distribution is a sharply peaked function. We conclude that most members of the ensemble have an energy very close to the mean value.

16.6 The thermodynamic information in the partition function

Like the molecular partition function, the canonical partition function carries all the thermodynamic information about a system. However, Q is more general than q because it does not assume that the molecules are independent. We can therefore use Q to discuss the properties of condensed phases and real gases where molecular interactions are important.

(a) The internal energy

If the total energy of the ensemble is $\tilde{E}$, and there are $\tilde{N}$ members, the average energy of a member is $E = \tilde{E}/\tilde{N}$. We use this quantity to calculate the internal energy of the system in the limit of $\tilde{N}$ (and $\tilde{E}$) approaching infinity:

$$U = U(0) + E = U(0) + \tilde{E}/\tilde{N} \quad \text{as} \quad \tilde{N} \rightarrow \infty \quad (16.38)$$

The fraction, $\tilde{p}_i$, of members of the ensemble in a state i with energy E_i is given by the analogue of eqn 16.7 as

$$\tilde{p}_i = \frac{e^{-\beta E_i}}{Q} \quad (16.39)$$

It follows that the internal energy is given by

$$U = U(0) + \sum_i \tilde{p}_i E_i = U(0) + \frac{1}{Q} \sum_i E_i e^{-\beta E_i} \quad (16.40)$$

By the same argument that led to eqn 16.31,

$$U = U(0) - \frac{1}{Q} \left(\frac{\partial Q}{\partial \beta} \right)_V = U(0) - \left(\frac{\partial \ln Q}{\partial \beta} \right)_V \quad (16.41)$$

(b) The entropy

The total weight, $\tilde{W}$, of a configuration of the ensemble is the product of the average weight W of each member of the ensemble, $\tilde{W} = W^N$. Hence, we can calculate S from

$$S = k \ln W = k \ln \tilde{W}^{1/N} = \frac{k}{N} \ln \tilde{W} \quad (16.42)$$

It follows, by the same argument used in Section 16.4, that

$$S = \frac{U - U(0)}{T} + k \ln Q \quad (16.43)$$

16.7 Independent molecules

We shall now see how to recover the molecular partition function from the more general canonical partition function when the molecules are independent. When the molecules are independent and distinguishable (in the sense to be described), the relation between Q and q is

$$Q = q^N \quad (16.44)$$

Justification 16.5 The relation between Q and q

The total energy of a collection of N independent molecules is the sum of the energies of the molecules. Therefore, we can write the total energy of a state i of the system as

$$E_i = \varepsilon_i(1) + \varepsilon_i(2) + \cdots + \varepsilon_i(N)$$

In this expression, $\varepsilon_i(1)$ is the energy of molecule 1 when the system is in the state i , $\varepsilon_i(2)$ the energy of molecule 2 when the system is in the same state i , and so on. The canonical partition function is then

$$Q = \sum_i e^{-\beta \varepsilon_i(1) - \beta \varepsilon_i(2) - \cdots - \beta \varepsilon_i(N)}$$

The sum over the states of the system can be reproduced by letting each molecule enter all its own individual states (although we meet an important proviso shortly). Therefore, instead of summing over the states i of the system, we can sum over all the individual states i of molecule 1, all the states i of molecule 2, and so on. This rewriting of the original expression leads to

$$Q = \left(\sum_i e^{-\beta \varepsilon_i} \right) \left(\sum_i e^{-\beta \varepsilon_i} \right) \cdots \left(\sum_i e^{-\beta \varepsilon_i} \right) = \left(\sum_i e^{-\beta \varepsilon_i} \right)^N = q^N$$

(a) Distinguishable and indistinguishable molecules

If all the molecules are identical and free to move through space, we cannot distinguish them and the relation $Q = q^N$ is not valid. Suppose that molecule 1 is in some state a , molecule 2 is in b , and molecule 3 is in c , then one member of the ensemble has an energy $E = \varepsilon_a + \varepsilon_b + \varepsilon_c$. This member, however, is indistinguishable from one formed by putting molecule 1 in state b , molecule 2 in state c , and molecule 3 in state a , or some other permutation. There are six such permutations in all, and $N!$ in

general. In the case of indistinguishable molecules, it follows that we have counted too many states in going from the sum over system states to the sum over molecular states, so writing $Q = q^N$ overestimates the value of Q . The detailed argument is quite involved, but at all except very low temperatures it turns out that the correction factor is $1/N!$. Therefore:

- For distinguishable independent molecules: $Q = q^N$ (16.45a)

- For indistinguishable independent molecules: $Q = q^N/N!$ (16.45b)

For molecules to be indistinguishable, they must be of the same kind: an Ar atom is never indistinguishable from a Ne atom. Their identity, however, is not the only criterion. Each identical molecule in a crystal lattice, for instance, can be ‘named’ with a set of coordinates. Identical molecules in a lattice can therefore be treated as distinguishable because their sites are distinguishable, and we use eqn 16.45a. On the other hand, identical molecules in a gas are free to move to different locations, and there is no way of keeping track of the identity of a given molecule; we therefore use eqn 16.45b.

(b) The entropy of a monatomic gas

An important application of the previous material is the derivation (as shown in the *Justification* below) of the **Sackur–Tetrode equation** for the entropy of a monatomic gas:

$$S = nR \ln \left(\frac{e^{5/2} V}{n N_A \Lambda^3} \right) \quad \Lambda = \frac{h}{(2\pi m k T)^{1/2}} \quad (16.46a)$$

This equation implies that the molar entropy of a perfect gas of high molar mass is greater than one of low molar mass under the same conditions (because the former has more thermally accessible translational states). Because the gas is perfect, we can use the relation $V = nRT/p$ to express the entropy in terms of the pressure as

$$S = nR \ln \left(\frac{e^{5/2} k T}{p \Lambda^3} \right) \quad (16.46b)$$

Justification 16.6 The Sackur–Tetrode equation

For a gas of independent molecules, Q may be replaced by $q^N/N!$, with the result that eqn 16.43 becomes

$$S = \frac{U - U(0)}{T} + Nk \ln q - k \ln N!$$

Because the number of molecules ($N = nN_A$) in a typical sample is large, we can use Stirling’s approximation (eqn 16.2) to write

$$S = \frac{U - U(0)}{T} + nR \ln q - nR \ln N + nR$$

The only mode of motion for a gas of atoms is translation, and the partition function is $q = V/\Lambda^3$ (eqn 16.19), where Λ is the thermal wavelength. The internal energy is given by eqn 16.32, so the entropy is

$$S = \frac{3}{2} nR + nR \left(\ln \frac{V}{\Lambda^3} - \ln nN_A + 1 \right) = nR \left(\ln e^{3/2} + \ln \frac{V}{\Lambda^3} - \ln nN_A + \ln e \right)$$

which rearranges into eqn 16.46.

Example 16.5 Using the Sackur–Tetrode equation

Calculate the standard molar entropy of gaseous argon at 25°C.

Method To calculate the molar entropy, S_m , from eqn 16.46b, divide both sides by n . To calculate the standard molar entropy, $S_m^\ominus$, set $p = p^\ominus$ in the expression for S_m :

$$S_m^\ominus = R \ln \left(\frac{e^{5/2} kT}{p^\ominus \Lambda^3} \right)$$

Answer The mass of an Ar atom is $m = 39.95$ u. At 25°C, its thermal wavelength is 16.0 pm (by the same kind of calculation as in *Illustration 16.3*). Therefore,

$$S_m^\ominus = R \ln \left\{ \frac{e^{5/2} \times (4.12 \times 10^{-21} \text{ J})}{(10^5 \text{ N m}^{-2}) \times (1.60 \times 10^{-11} \text{ m})^3} \right\} = 18.6R = 155 \text{ J K}^{-1} \text{ mol}^{-1}$$

We can anticipate, on the basis of the number of accessible states for a lighter molecule, that the standard molar entropy of Ne is likely to be smaller than for Ar; its actual value is $17.60R$ at 298 K.

Self-test 16.7 Calculate the translational contribution to the standard molar entropy of H_2 at 25°C. [14.2R]

The Sackur–Tetrode equation implies that, when a monatomic perfect gas expands isothermally from V_i to V_f , its entropy changes by

$$\Delta S = nR \ln(aV_f) - nR \ln(aV_i) = nR \ln \frac{V_f}{V_i} \quad (16.47)$$

where aV is the collection of quantities inside the logarithm of eqn 16.46a. This is exactly the expression we obtained by using classical thermodynamics (Example 3.1). Now, though, we see that that classical expression is in fact a consequence of the increase in the number of accessible translational states when the volume of the container is increased (Fig. 16.17).

Fig. 16.17 As the width of a container is increased (going from (a) to (b)), the energy levels become closer together (as $1/L^2$), and as a result more are thermally accessible at a given temperature. Consequently, the entropy of the system rises as the container expands.

Checklist of key ideas

- ☐ 1. The instantaneous configuration of a system of N molecules is the specification of the set of populations $n_0, n_1, \dots$ of the energy levels $\epsilon_0, \epsilon_1, \dots$. The weight W of a configuration is given by $W = N! / n_0! n_1! \dots$.
- ☐ 2. The Boltzmann distribution gives the numbers of molecules in each state of a system at any temperature: $N_i = N e^{-\beta \epsilon_i} / q$, $\beta = 1/kT$.
- ☐ 3. The partition function is defined as $q = \sum_j e^{-\beta \epsilon_j}$ and is an indication of the number of thermally accessible states at the temperature of interest.
- ☐ 4. The internal energy is $U(T) = U(0) + E$, with $E = -(N/q)(\partial q / \partial \beta)_V = -N(\partial \ln q / \partial \beta)_V$.
- ☐ 5. The Boltzmann formula for the entropy is $S = k \ln W$, where W is the number of different ways in which the molecules of a system can be arranged while keeping the same total energy.
- ☐ 6. The entropy in terms of the partition function is $S = \{U - U(0)\} / T + Nk \ln q$ (distinguishable molecules) or $S = \{U - U(0)\} / T + Nk \ln q - Nk(\ln N - 1)$ (indistinguishable molecules).
- ☐ 7. The canonical ensemble is an imaginary collection of replications of the actual system with a common temperature.
- ☐ 8. The canonical distribution is given by $\tilde{n}_i / \tilde{N} = e^{-\beta \epsilon_i} / \sum_j e^{-\beta \epsilon_j}$. The canonical partition function, $Q = \sum_i e^{-\beta \epsilon_i}$.
- ☐ 9. The internal energy and entropy of an ensemble are, respectively, $U = U(0) - (\partial \ln Q / \partial \beta)_V$ and $S = \{U - U(0)\} / T + k \ln Q$.
- ☐ 10. For distinguishable independent molecules we write $Q = q^N$. For indistinguishable independent molecules we write $Q = q^N / N!$.
- ☐ 11. The Sackur–Tetrode equation, eqn 16.46, is an expression for the entropy of a monatomic gas.

Further information

Further information 16.1 The Boltzmann distribution

We remarked in Section 16.1 that $\ln W$ is easier to handle than W . Therefore, to find the form of the Boltzmann distribution, we look for the condition for $\ln W$ being a maximum rather than dealing directly with W . Because $\ln W$ depends on all the n_i , when a configuration changes and the n_i change to $n_i + dn_i$, the function $\ln W$ changes to $\ln W + d \ln W$, where

$$d \ln W = \sum_i \left(\frac{\partial \ln W}{\partial n_i} \right) dn_i$$

All this expression states is that a change in $\ln W$ is the sum of contributions arising from changes in each value of n_i . At a maximum, $d \ln W = 0$. However, when the n_i change, they do so subject to the two constraints

$$\sum_i \varepsilon_i dn_i = 0 \quad \sum_i dn_i = 0 \quad (16.48)$$

The first constraint recognizes that the total energy must not change, and the second recognizes that the total number of molecules must not change. These two constraints prevent us from solving $d \ln W = 0$ simply by setting all $(\partial \ln W / \partial n_i) = 0$ because the dn_i are not all independent.

The way to take constraints into account was devised by the French mathematician Lagrange, and is called the **method of undetermined multipliers**. The technique is described in *Appendix 2*. All we need here is the rule that a constraint should be multiplied by a constant and then added to the main variation equation. The variables are then treated as though they were all independent, and the constants are evaluated at the end of the calculation.

We employ the technique as follows. The two constraints in eqn 16.48 are multiplied by the constants $-\beta$ and α , respectively (the minus sign in $-\beta$ has been included for future convenience), and then added to the expression for $d \ln W$:

$$\begin{aligned} d \ln W &= \sum_i \left(\frac{\partial \ln W}{\partial n_i} \right) dn_i + \alpha \sum_i dn_i - \beta \sum_i \varepsilon_i dn_i \\ &= \sum_i \left\{ \left(\frac{\partial \ln W}{\partial n_i} \right) + \alpha - \beta \varepsilon_i \right\} dn_i \end{aligned}$$

All the dn_i are now treated as independent. Hence the only way of satisfying $d \ln W = 0$ is to require that, for each i ,

$$\frac{\partial \ln W}{\partial n_i} + \alpha - \beta \varepsilon_i = 0 \quad (16.49)$$

when the n_i have their most probable values.

Differentiation of $\ln W$ as given in eqn 16.3 with respect to n_i gives

$$\frac{\partial \ln W}{\partial n_i} = \frac{\partial(N \ln N)}{\partial n_i} - \sum_j \frac{\partial(n_j \ln n_j)}{\partial n_i}$$

The derivative of the first term is obtained as follows:

$$\begin{aligned} \frac{\partial(N \ln N)}{\partial n_i} &= \left(\frac{\partial N}{\partial n_i} \right) \ln N + N \left(\frac{\partial \ln N}{\partial n_i} \right) \\ &= \ln N + \frac{\partial N}{\partial n_i} = \ln N + 1 \end{aligned}$$

The $\ln N$ in the first term on the right in the second line arises because $N = n_1 + n_2 + \dots$ and so the derivative of N with respect to any of the n_i is 1: that is, $\partial N / \partial n_i = 1$. The second term on the right in the second line arises because $\partial(\ln N) / \partial n_i = (1/N) \partial N / \partial n_i$. The final 1 is then obtained in the same way as in the preceding remark, by using $\partial N / \partial n_i = 1$.

For the derivative of the second term we first note that

$$\frac{\partial \ln n_j}{\partial n_i} = \frac{1}{n_j} \left(\frac{\partial n_j}{\partial n_i} \right)$$

Moreover, if $i \neq j$, n_j is independent of n_i , so $\partial n_j / \partial n_i = 0$. However, if $i = j$,

$$\frac{\partial n_j}{\partial n_i} = \frac{\partial n_j}{\partial n_j} = 1$$

Therefore,

$$\frac{\partial \ln n_j}{\partial n_i} = \delta_{ij}$$

with δ_{ij} the Kronecker delta ($\delta_{ij} = 1$ if $i = j$, $\delta_{ij} = 0$ otherwise). Then

$$\begin{aligned}\sum_j \frac{\partial(n_j \ln n_j)}{\partial n_i} &= \sum_j \left\{ \left(\frac{\partial n_j}{\partial n_i} \right) \ln n_j + n_j \left(\frac{\partial \ln n_j}{\partial n_i} \right) \right\} \\ &= \sum_j \left\{ \left(\frac{\partial n_j}{\partial n_i} \right) \ln n_j + \left(\frac{\partial n_j}{\partial n_i} \right) \right\} \\ &= \sum_j \left(\frac{\partial n_j}{\partial n_i} \right) (\ln n_j + 1) \\ &= \sum_j \delta_{ij} (\ln n_j + 1) = \ln n_i + 1\end{aligned}$$

and therefore

$$\frac{\partial \ln W}{\partial n_i} = -(\ln n_i + 1) + (\ln N + 1) = -\ln \frac{n_i}{N}$$

It follows from eqn 16.49 that

$$-\ln \frac{n_i}{N} + \alpha - \beta \epsilon_i = 0$$

and therefore that

$$\frac{n_i}{N} = e^{\alpha - \beta \epsilon_i}$$

At this stage we note that

$$N = \sum_i n_i = \sum_i N e^{\alpha - \beta \epsilon_i} = N e^{\alpha} \sum_i e^{-\beta \epsilon_i}$$

Because the N cancels on each side of this equality, it follows that

$$e^{\alpha} = \frac{1}{\sum_j e^{-\beta \epsilon_j}} \quad (16.50)$$

and

$$\frac{n_i}{N} = e^{\alpha - \beta \epsilon_i} = e^{\alpha} e^{-\beta \epsilon_i} = \frac{1}{\sum_j e^{-\beta \epsilon_j}} e^{-\beta \epsilon_i}$$

which is eqn 16.6a.

Further information 16.2 The Boltzmann formula

A change in the internal energy

$$U = U(0) + \sum_i n_i \epsilon_i \quad (16.51)$$

may arise from either a modification of the energy levels of a system (when ϵ_i changes to $\epsilon_i + d\epsilon_i$) or from a modification of the populations (when n_i changes to $n_i + dn_i$). The most general change is therefore

$$dU = dU(0) + \sum_i n_i d\epsilon_i + \sum_i \epsilon_i dn_i \quad (16.52)$$

Because the energy levels do not change when a system is heated at constant volume (Fig. 16.18), in the absence of all changes other than heating

$$dU = \sum_i \epsilon_i dn_i$$

Fig. 16.18 (a) When a system is heated, the energy levels are unchanged but their populations are changed. (b) When work is done on a system, the energy levels themselves are changed. The levels in this case are the one-dimensional particle-in-a-box energy levels of Chapter 9: they depend on the size of the container and move apart as its length is decreased.

We know from thermodynamics (and specifically from eqn 3.43) that under the same conditions

$$dU = dq_{\text{rev}} = TdS$$

Therefore,

$$dS = \frac{dU}{T} = k\beta \sum_i \epsilon_i dn_i \quad (16.53)$$

For changes in the most probable configuration (the only one we need consider), we rearrange eqn 16.49 to

$$\beta \epsilon_i = \frac{\partial \ln W}{\partial n_i} + \alpha$$

and find that

$$dS = k \sum_i \left(\frac{\partial \ln W}{\partial n_i} \right) dn_i + k\alpha \sum_i dn_i$$

But because the number of molecules is constant, the sum over the dn_i is zero. Hence

$$dS = k \sum_i \left(\frac{\partial \ln W}{\partial n_i} \right) dn_i = k(d \ln W)$$

This relation strongly suggests the definition $S = k \ln W$, as in eqn 16.34.

Further information 16.3 Temperatures below zero

The Boltzmann distribution tells us that the ratio of populations in a two-level system at a temperature T is

$$\frac{N_+}{N_-} = e^{-\epsilon/kT} \quad (16.54)$$

where ϵ is the separation of the upper state N_+ and the lower state N_- . It follows that, if we can contrive the population of the upper state to exceed that of the lower state, then the temperature must have a negative value. Indeed, for a general population,

$$T = \frac{\epsilon/k}{\ln(N_-/N_+)} \quad (16.55)$$

and the temperature is formally negative for all $N_+ > N_-$.

All the statistical thermodynamic expressions we have derived apply to $T < 0$ as well as to $T > 0$, the difference being that states with $T < 0$ are not in thermal equilibrium and therefore have to be achieved by techniques that do not rely on the equalization of temperatures of the system and its surroundings. The Third Law of thermodynamics prohibits the achievement of absolute zero in a finite number of steps. However, it is possible to circumvent this restriction in systems that have a finite number of levels or in systems that are effectively finite because they have such weak coupling to their surroundings. The practical realization of such a system is a group of spin- $\frac{1}{2}$ nuclei that have very long relaxation times, such as the ^{19}F nuclei in cold solid LiF. Pulse techniques in NMR can achieve non-equilibrium populations (Section 15.8) as can pumping procedures in laser technologies (Section 14.5). From now on, we shall suppose that these non-equilibrium distributions have been achieved, and will concentrate on the consequences.

The expressions for q , U , and S that we have derived in this chapter are applicable to $T < 0$ as well as to $T > 0$, and are shown in Fig. 16.19. We see that q and U show sharp discontinuities on passing through zero, and $T = +0$ (corresponding to all population in the lower state) is quite distinct from $T = -0$, where all the population is in the upper state. The entropy S is continuous at $T = 0$. But all these functions are continuous if we use $\beta = 1/kT$ as the dependent variable (Fig. 16.20), which shows that β is a more natural, if less familiar, variable than T . Note that $U \rightarrow 0$ as $\beta \rightarrow \infty$ (that is, as $T \rightarrow 0$, when only the lower state is occupied) and $U \rightarrow N\epsilon$ as $\beta \rightarrow -\infty$ (that is, as $T \rightarrow -0$);

Fig. 16.19 The partition function, internal energy, and entropy of a two-level system extended to negative temperatures.

we see that a state with $T = -0$ is 'hotter' than one with $T = +0$. The entropy of the system is zero on either side of $T = 0$, and rises to $Nk \ln 2$ as $T \rightarrow \pm\infty$. At $T = +0$ only one state is accessible (the lower state), only the upper state is accessible, so the entropy is zero in each case.

We get more insight into the dependence of thermodynamic properties on temperature by noting the thermodynamic result (Section 3.8) that $T = (\partial S / \partial U)_T$. When S is plotted against U for a two-level system (Fig. 6.21), we see that the entropy rises as energy is supplied to the system (as we would expect) provided that $T > 0$ (the thermal equilibrium regime). However, the entropy decreases as energy is supplied when $T < 0$. This conclusion is consistent with the thermodynamic definition of entropy, $dS = dq_{\text{rev}}/T$ (where, of course, q denotes heat and not the partition function). Physically, the increase in entropy for $T > 0$ corresponds to the increasing accessibility of the upper state, and the decrease for $T < 0$ corresponds

Fig. 16.20 The partition function, internal energy, and entropy of a two-level system extended to negative temperatures but plotted against $\beta = 1/kT$ (modified here to the dimensionless quantity ε/kT).

Fig. 16.21 The variation of the entropy with internal energy for a two-level system extended to negative temperatures.

to the shift towards population of the upper state alone as more energy is packed into the system.

The phenomenological laws of thermodynamics survive largely intact at negative temperatures. The First Law (in essence, the conservation of energy) is robust, and independent of how populations are distributed over states. The Second Law survives because the definition of entropy survives (as we have seen above). The efficiency of heat engines (Section 3.2), which is a direct consequence of the Second Law, is still given by $1 - T_{\text{cold}}/T_{\text{hot}}$. However, if the temperature of the cold reservoir is negative, then the efficiency of the engine may be greater than 1. This condition corresponds to the amplification of signals achieved in lasers. Alternatively, an efficiency greater than 1 implies that heat *can* be converted completely into work provided the heat is withdrawn from a reservoir at $T < 0$. If both reservoirs are at negative temperatures, then the efficiency is less than 1, as in the thermal equilibrium case treated in Chapter 3. The Third Law requires a slight amendment on account of the discontinuity of the populations across $T = 0$: it is impossible in a finite number of steps to cool any system down to $+0$ or to heat any system above -0 .

Discussion questions

16.1 Describe the physical significance of the partition function.

16.2 Explain how the internal energy and entropy of a system composed of two levels vary with temperature.

16.3 Enumerate the ways by which the parameter β may be identified with $1/kT$.

16.4 Distinguish between the zipper and Zimm–Bragg models of the helix–coil transition.

16.5 Explain what is meant by an *ensemble* and why it is useful in statistical thermodynamics.

16.6 Under what circumstances may identical particles be regarded as distinguishable?

Exercises

16.1a What are the relative populations of the states of a two-level system when the temperature is infinite?

16.1b What is the temperature of a two-level system of energy separation equivalent to 300 cm^{-1} when the population of the upper state is one-half that of the lower state?

16.2a Calculate the translational partition function at (a) 300 K and (b) 600 K of a molecule of molar mass 120 g mol^{-1} in a container of volume 2.00 cm^3 .

16.2b Calculate (a) the thermal wavelength, (b) the translational partition function of an Ar atom in a cubic box of side 1.00 cm at (i) 300 K and (ii) 3000 K.

16.3a Calculate the ratio of the translational partition functions of D_2 and H_2 at the same temperature and volume.

16.3b Calculate the ratio of the translational partition functions of xenon and helium at the same temperature and volume.

16.4a A certain atom has a threefold degenerate ground level, a non-degenerate electronically excited level at 3500 cm^{-1} , and a threefold degenerate level at 4700 cm^{-1} . Calculate the partition function of these electronic states at 1900 K.

16.4b A certain atom has a doubly degenerate ground level, a triply degenerate electronically excited level at 1250 cm^{-1} , and a doubly degenerate level at 1300 cm^{-1} . Calculate the partition function of these electronic states at 2000 K.

16.5a Calculate the electronic contribution to the molar internal energy at 1900 K for a sample composed of the atoms specified in Exercise 16.4a.

16.5b Calculate the electronic contribution to the molar internal energy at 2000 K for a sample composed of the atoms specified in Exercise 16.4b.

16.6a A certain molecule has a non-degenerate excited state lying at 540 cm^{-1} above the non-degenerate ground state. At what temperature will 10 per cent of the molecules be in the upper state?

16.6b A certain molecule has a doubly degenerate excited state lying at 360 cm^{-1} above the non-degenerate ground state. At what temperature will 15 per cent of the molecules be in the upper state?

16.7a An electron spin can adopt either of two orientations in a magnetic field, and its energies are $\pm\mu_B\mathcal{B}$, where μ_B is the Bohr magneton. Deduce an expression for the partition function and mean energy of the electron and sketch the variation of the functions with $\mathcal{B}$. Calculate the relative populations of the spin states at (a) 4.0 K, (b) 298 K when $\mathcal{B} = 1.0\text{ T}$.

16.7b A nitrogen nucleus spin can adopt any of three orientations in a magnetic field, and its energies are $0, \pm\gamma_N\hbar\mathcal{B}$, where γ_N is the magnetogyric ratio of the nucleus. Deduce an expression for the partition function and mean energy of the nucleus and sketch the variation of the functions with $\mathcal{B}$. Calculate the relative populations of the spin states at (a) 1.0 K, (b) 298 K when $\mathcal{B} = 20.0\text{ T}$.

16.8a Consider a system of distinguishable particles having only two non-degenerate energy levels separated by an energy that is equal to the value of kT at 10 K. Calculate (a) the ratio of populations in the two states at (1) 1.0 K, (2) 10 K, and (3) 100 K, (b) the molecular partition function at 10 K, (c) the molar energy at 10 K, (d) the molar heat capacity at 10 K, (e) the molar entropy at 10 K.

16.8b Consider a system of distinguishable particles having only three non-degenerate energy levels separated by an energy which is equal to the value of kT at 25.0 K. Calculate (a) the ratio of populations in the states at (1) 1.00 K, (2) 25.0 K, and (3) 100 K, (b) the molecular partition function at 25.0 K, (c) the molar energy at 25.0 K, (d) the molar heat capacity at 25.0 K, (e) the molar entropy at 25.0 K.

16.9a At what temperature would the population of the first excited vibrational state of HCl be $1/e$ times its population of the ground state?

16.9b At what temperature would the population of the first excited rotational level of HCl be $1/e$ times its population of the ground state?

16.10a Calculate the standard molar entropy of neon gas at (a) 200 K, (b) 298.15 K.

16.10b Calculate the standard molar entropy of xenon gas at (a) 100 K, (b) 298.15 K.

16.11a Calculate the vibrational contribution to the entropy of Cl_2 at 500 K given that the wavenumber of the vibration is 560 cm^{-1} .

16.11b Calculate the vibrational contribution to the entropy of Br_2 at 600 K given that the wavenumber of the vibration is 321 cm^{-1} .

16.12a Identify the systems for which it is essential to include a factor of $1/N!$ on going from Q to q : (a) a sample of helium gas, (b) a sample of carbon monoxide gas, (c) a solid sample of carbon monoxide, (d) water vapour.

16.12b Identify the systems for which it is essential to include a factor of $1/N!$ on going from Q to q : (a) a sample of carbon dioxide gas, (b) a sample of graphite, (c) a sample of diamond, (d) ice.

Problems*

Numerical problems

16.1‡ Consider a system A consisting of subsystems A_1 and A_2 , for which $W_1 = 1 \times 10^{20}$ and $W_2 = 2 \times 10^{20}$. What is the number of configurations available to the combined system? Also, compute the entropies S_1 , and S_2 . What is the significance of this result?

16.2‡ Consider 1.00×10^{22} ^4He atoms in a box of dimensions $1.0\text{ cm} \times 1.0\text{ cm} \times 1.0\text{ cm}$. Calculate the occupancy of the first excited level at 1.0 mK, 2.0 K, and 4.0 K. Do the same for ^3He . What conclusions might you draw from the results of your calculations?

* Problems denoted with the symbol ‡ were supplied by Charles Trapp and Carmen Giunta.

16.3‡ By what factor does the number of available configurations increase when 100 J of energy is added to a system containing 1.00 mol of particles at constant volume at 298 K?

16.4‡ By what factor does the number of available configurations increase when 20 m³ of air at 1.00 atm and 300 K is allowed to expand by 0.0010 per cent at constant temperature?

16.5 Explore the conditions under which the ‘integral’ approximation for the translational partition function is not valid by considering the translational partition function of an Ar atom in a cubic box of side 1.00 cm. Estimate the temperature at which, according to the integral approximation, $q = 10$ and evaluate the exact partition function at that temperature.

16.6 A certain atom has a doubly degenerate ground level pair and an upper level of four degenerate states at 450 cm⁻¹ above the ground level. In an atomic beam study of the atoms it was observed that 30 per cent of the atoms were in the upper level, and the translational temperature of the beam was 300 K. Are the electronic states of the atoms in thermal equilibrium with the translational states?

16.7 (a) Calculate the electronic partition function of a tellurium atom at (i) 298 K, (ii) 5000 K by direct summation using the following data:

Term	Degeneracy	Wavenumber/cm ⁻¹
Ground	5	0
1	1	4 707
2	3	4 751
3	5	10 559

(b) What proportion of the Te atoms are in the ground term and in the term labelled 2 at the two temperatures? (c) Calculate the electronic contribution to the standard molar entropy of gaseous Te atoms.

16.8 The four lowest electronic levels of a Ti atom are: ³F₂, ³F₃, ³F₄, and ⁵F₁, at 0, 170, 387, and 6557 cm⁻¹, respectively. There are many other electronic states at higher energies. The boiling point of titanium is 3287°C. What are the relative populations of these levels at the boiling point? *Hint.* The degeneracies of the levels are $2J + 1$.

16.9 The NO molecule has a doubly degenerate excited electronic level 121.1 cm⁻¹ above the doubly degenerate electronic ground term. Calculate and plot the electronic partition function of NO from $T = 0$ to 1000 K. Evaluate (a) the term populations and (b) the electronic contribution to the molar internal energy at 300 K. Calculate the electronic contribution to the molar entropy of the NO molecule at 300 K and 500 K.

16.10‡ J. Sugar and A. Musgrove (*J. Phys. Chem. Ref. Data* **22**, 1213 (1993)) have published tables of energy levels for germanium atoms and cations from Ge⁺ to Ge⁺³¹. The lowest-lying energy levels in neutral Ge are as follows:

	³ P ₀	³ P ₁	³ P ₂	¹ D ₂	¹ S ₀
E/cm ⁻¹	0	557.1	1410.0	7125.3	16 367.3

Calculate the electronic partition function at 298 K and 1000 K by direct summation. *Hint.* The degeneracy of a level is $2J + 1$.

16.11 Calculate, by explicit summation, the vibrational partition function and the vibrational contribution to the molar internal energy of I₂ molecules at (a) 100 K, (b) 298 K given that its vibrational energy levels lie at the following wavenumbers above the zero-point energy level: 0, 213.30, 425.39, 636.27, 845.93 cm⁻¹. What proportion of I₂ molecules are in the ground and first two excited levels at the two temperatures? Calculate the vibrational contribution to the molar entropy of I₂ at the two temperatures.

16.12‡ (a) The standard molar entropy of graphite at 298, 410, and 498 K is 5.69, 9.03, and 11.63 J K⁻¹ mol⁻¹, respectively. If 1.00 mol C(graphite) at 298 K is surrounded by thermal insulation and placed next to 1.00 mol C(graphite)

at 498 K, also insulated, how many configurations are there altogether for the combined but independent systems? (b) If the same two samples are now placed in thermal contact and brought to thermal equilibrium, the final temperature will be 410 K. (Why might the final temperature not be the average?) How many configurations are there now in the combined system? Neglect any volume changes. (c) Demonstrate that this process is spontaneous.

Theoretical problems

16.13 A sample consisting of five molecules has a total energy 5ϵ . Each molecule is able to occupy states of energy $j\epsilon$, with $j = 0, 1, 2, \dots$ (a) Calculate the weight of the configuration in which the molecules are distributed evenly over the available states. (b) Draw up a table with columns headed by the energy of the states and write beneath them all configurations that are consistent with the total energy. Calculate the weights of each configuration and identify the most probable configurations.

16.14 A sample of nine molecules is numerically tractable but on the verge of being thermodynamically significant. Draw up a table of configurations for $N = 9$, total energy 9ϵ in a system with energy levels $j\epsilon$ (as in Problem 16.13). Before evaluating the weights of the configurations, guess (by looking for the most ‘exponential’ distribution of populations) which of the configurations will turn out to be the most probable. Go on to calculate the weights and identify the most probable configuration.

16.15 The most probable configuration is characterized by a parameter we know as the ‘temperature’. The temperatures of the system specified in Problems 16.13 and 16.14 must be such as to give a mean value of ϵ for the energy of each molecule and a total energy $N\epsilon$ for the system. (a) Show that the temperature can be obtained by plotting p_j against j , where p_j is the (most probable) fraction of molecules in the state with energy $j\epsilon$. Apply the procedure to the system in Problem 16.14. What is the temperature of the system when ϵ corresponds to 50 cm⁻¹? (b) Choose configurations other than the most probable, and show that the same procedure gives a worse straight line, indicating that a temperature is not well-defined for them.

16.16 A certain molecule can exist in either a non-degenerate singlet state or a triplet state (with degeneracy 3). The energy of the triplet exceeds that of the singlet by ϵ . Assuming that the molecules are distinguishable (localized) and independent, (a) obtain the expression for the molecular partition function. (b) Find expressions in terms of ϵ for the molar energy, molar heat capacity, and molar entropy of such molecules and calculate their values at $T = \epsilon/k$.

16.17 Consider a system with energy levels $\epsilon_j = j\epsilon$ and N molecules. (a) Show that if the mean energy per molecule is $a\epsilon$, then the temperature is given by

$$\beta = \frac{1}{\epsilon} \ln \left(1 + \frac{1}{a} \right)$$

Evaluate the temperature for a system in which the mean energy is ϵ , taking ϵ equivalent to 50 cm⁻¹. (b) Calculate the molecular partition function q for the system when its mean energy is $a\epsilon$. (c) Show that the entropy of the system is

$$S/k = (1 + a) \ln(1 + a) - a \ln a$$

and evaluate this expression for a mean energy ϵ .

16.18 Consider Stirling’s approximation for $\ln N!$ in the derivation of the Boltzmann distribution. What difference would it make if (a) a cruder approximation, $N! = N^N$, (b) the better approximation in *Comment* 16.2 were used instead?

16.19‡ For gases, the canonical partition function, Q , is related to the molecular partition function q by $Q = q^N/N!$. Use the expression for q and general thermodynamic relations to derive the perfect gas law $pV = nRT$.

Applications: to atmospheric science, astrophysics, and biochemistry

16.20† Obtain the barometric formula (Problem 1.27) from the Boltzmann distribution. Recall that the potential energy of a particle at height h above the surface of the Earth is mgh . Convert the barometric formula from pressure to number density, $\mathcal{N}$. Compare the relative number densities, $\mathcal{N}(h)/\mathcal{N}(0)$, for O_2 and H_2O at $h = 8.0$ km, a typical cruising altitude for commercial aircraft.

16.21† Planets lose their atmospheres over time unless they are replenished. A complete analysis of the overall process is very complicated and depends upon the radius of the planet, temperature, atmospheric composition, and other factors. Prove that the atmosphere of planets cannot be in an equilibrium state by demonstrating that the Boltzmann distribution leads to a uniform finite number density as $r \rightarrow \infty$. *Hint.* Recall that in a gravitational field the potential energy is $V(r) = -GMm/r$, where G is the gravitational constant, M is the mass of the planet, and m the mass of the particle.

16.22† Consider the electronic partition function of a perfect atomic hydrogen gas at a density of $1.99 \times 10^{-4} \text{ kg m}^{-3}$ and 5780 K. These are the mean conditions within the Sun's photosphere, the surface layer of the Sun that is about 190 km thick. (a) Show that this partition function, which involves a sum over an infinite number of quantum states that are solutions to the Schrödinger equation for an isolated atomic hydrogen atom, is infinite. (b) Develop a theoretical argument for truncating the sum and estimate the maximum number of quantum states that contribute to the sum. (c) Calculate the equilibrium probability that an atomic hydrogen electron is in each

quantum state. Are there any general implications concerning electronic states that will be observed for other atoms and molecules? Is it wise to apply these calculations in the study of the Sun's photosphere?

16.23 Consider a protein P with four distinct sites, with each site capable of binding one ligand L. Show that the possible varieties (configurations) of the species PL_i (with PL_0 denoting P) are given by the binomial coefficients $C(4, i)$.

16.24 Complete some of the derivations in the discussion of the helix-coil transition in polypeptides (*Impact* I16.1). (a) Show that, within the tenets of the zipper model,

$$q = 1 + \sum_{i=1}^n Z(n, i) \sigma^i$$

and that $Z(n, i) = n - i + 1$ is the number of ways in which an allowed state with a number i of c amino acids can be formed. (b) Using the zipper model, show that $\theta = (1/n) d(\ln q)/d(\ln s)$. *Hint.* As a first step, show that $\sum_i i(n - i + 1) \sigma^i = s(dq/ds)$.

16.25 Here you will use the zipper model discussed in *Impact* I16.1 to explore the helix-coil transition in polypeptides. (a) Investigate the effect of the parameter s on the distribution of random coil segments in a polypeptide with $n = 20$ by plotting p_i , the fraction of molecules with a number i of amino acids in a coil region, against i for $s = 0.8, 1.0$, and 1.5 , with $\sigma = 5.0 \times 10^{-2}$. Discuss the significance of any effects you discover. (b) The average value of i given by $\langle i \rangle = \sum_i i p_i$. Use the results of the zipper model to calculate $\langle i \rangle$ for all the combinations of s and σ used in Fig. 16.10 and part (a).

Statistical thermodynamics 2: applications

17

In this chapter we apply the concepts of statistical thermodynamics to the calculation of chemically significant quantities. First, we establish the relations between thermodynamic functions and partition functions. Next, we show that the molecular partition function can be factorized into contributions from each mode of motion and establish the formulas for the partition functions for translational, rotational, and vibrational modes of motion and the contribution of electronic excitation. These contributions can be calculated from spectroscopic data. Finally, we turn to specific applications, which include the mean energies of modes of motion, the heat capacities of substances, and residual entropies. In the final section, we see how to calculate the equilibrium constant of a reaction and through that calculation understand some of the molecular features that determine the magnitudes of equilibrium constants and their variation with temperature.

A partition function is the bridge between thermodynamics, spectroscopy, and quantum mechanics. Once it is known, a partition function can be used to calculate thermodynamic functions, heat capacities, entropies, and equilibrium constants. It also sheds light on the significance of these properties.

Fundamental relations

In this section we see how to obtain any thermodynamic function once we know the partition function. Then we see how to calculate the molecular partition function, and through that the thermodynamic functions, from spectroscopic data.

17.1 The thermodynamic functions

We have already derived (in Chapter 16) the two expressions for calculating the internal energy and the entropy of a system from its canonical partition function, Q :

$$U - U(0) = - \left(\frac{\partial \ln Q}{\partial \beta} \right)_V \quad S = \frac{U - U(0)}{T} + k \ln Q \quad (17.1)$$

where $\beta = 1/kT$. If the molecules are independent, we can go on to make the substitutions $Q = q^N$ (for distinguishable molecules, as in a solid) or $Q = q^N/N!$ (for indistinguishable molecules, as in a gas). All the thermodynamic functions introduced in Part 1 are related to U and S , so we have a route to their calculation from Q .

Discussion questions

Exercises

Problems

(a) The Helmholtz energy

The Helmholtz energy, A , is defined as $A = U - TS$. This relation implies that $A(0) = U(0)$, so substitution for U and S by using eqn 17.1 leads to the very simple expression

$$A - A(0) = -kT \ln Q \quad (17.2)$$

(b) The pressure

By an argument like that leading to eqn 3.31, it follows from $A = U - TS$ that $dA = -pdV - SdT$. Therefore, on imposing constant temperature, the pressure and the Helmholtz energy are related by $p = -(\partial A / \partial V)_T$. It then follows from eqn 17.2 that

$$p = kT \left(\frac{\partial \ln Q}{\partial V} \right)_T \quad (17.3)$$

This relation is entirely general, and may be used for any type of substance, including perfect gases, real gases, and liquids. Because Q is in general a function of the volume, temperature, and amount of substance, eqn 17.3 is an equation of state.

Example 17.1 *Deriving an equation of state*

Derive an expression for the pressure of a gas of independent particles.

Method We should suspect that the pressure is that given by the perfect gas law. To proceed systematically, substitute the explicit formula for Q for a gas of independent, indistinguishable molecules (see eqn 16.45 and Table 17.3 at the end of the chapter) into eqn 17.3.

Answer For a gas of independent molecules, $Q = q^N / N!$ with $q = V/\Lambda^3$:

$$\begin{aligned} p &= kT \left(\frac{\partial \ln Q}{\partial V} \right)_T = \frac{kT}{Q} \left(\frac{\partial Q}{\partial V} \right)_T = \frac{NkT}{q} \left(\frac{\partial q}{\partial V} \right)_T \\ &= \frac{NkT\Lambda^3}{V} \times \frac{1}{\Lambda^3} = \frac{NkT}{V} = \frac{nRT}{V} \end{aligned}$$

To derive this relation, we have used

$$\left(\frac{\partial q}{\partial V} \right)_T = \left(\frac{\partial (V/\Lambda^3)}{\partial V} \right)_T = \frac{1}{\Lambda^3}$$

and $NkT = nN_A kT = nRT$. The calculation shows that the equation of state of a gas of independent particles is indeed the perfect gas law.

Self-test 17.1 Derive the equation of state of a sample for which $Q = q^N f / N!$, with $q = V/\Lambda^3$, where f depends on the volume. $[p = nRT/V + kT(\partial \ln f / \partial V)_T]$

(c) The enthalpy

At this stage we can use the expressions for U and p in the definition $H = U + pV$ to obtain an expression for the enthalpy, H , of any substance:

$$H - H(0) = - \left(\frac{\partial \ln Q}{\partial \beta} \right)_V + kTV \left(\frac{\partial \ln Q}{\partial V} \right)_T \quad (17.4)$$

We have already seen that $U - U(0) = \frac{3}{2}nRT$ for a gas of independent particles (eqn 16.32a), and have just shown that $pV = nRT$. Therefore, for such a gas,

$$H - H(0) = \frac{5}{2}nRT \quad (17.5)^\circ$$

(d) The Gibbs energy

One of the most important thermodynamic functions for chemistry is the Gibbs energy, $G = H - TS = A + pV$. We can now express this function in terms of the partition function by combining the expressions for A and p :

$$G - G(0) = -kT \ln Q + kTV \left(\frac{\partial \ln Q}{\partial V} \right)_T \quad (17.6)$$

This expression takes a simple form for a gas of independent molecules because pV in the expression $G = A + pV$ can be replaced by nRT :

$$G - G(0) = -kT \ln Q + nRT \quad (17.7)^\circ$$

Furthermore, because $Q = q^N/N!$, and therefore $\ln Q = N \ln q - \ln N!$, it follows by using Stirling's approximation ($\ln N! \approx N \ln N - N$) that we can write

$$\begin{aligned} G - G(0) &= -NkT \ln q + kT \ln N! + nRT \\ &= -nRT \ln q + kT(N \ln N - N) + nRT \\ &= -nRT \ln \frac{q}{N} \end{aligned} \quad (17.8)^\circ$$

with $N = nN_A$. Now we see another interpretation of the Gibbs energy: it is proportional to the logarithm of the average number of thermally accessible states per molecule.

It will turn out to be convenient to define the **molar partition function**, $q_m = q/n$ (with units mol^{-1}), for then

$$G - G(0) = -nRT \ln \frac{q_m}{N_A} \quad (17.9)^\circ$$

17.2 The molecular partition function

The energy of a molecule is the sum of contributions from its different modes of motion:

$$\varepsilon_i = \varepsilon_i^T + \varepsilon_i^R + \varepsilon_i^V + \varepsilon_i^E \quad (17.10)$$

where T denotes translation, R rotation, V vibration, and E the electronic contribution. The electronic contribution is not actually a 'mode of motion', but it is convenient to include it here. The separation of terms in eqn 17.10 is only approximate (except for translation) because the modes are not completely independent, but in most cases it is satisfactory. The separation of the electronic and vibrational motions is justified provided only the ground electronic state is occupied (for otherwise the vibrational characteristics depend on the electronic state) and, for the electronic ground state, that the Born–Oppenheimer approximation is valid (Chapter 11). The separation of the vibrational and rotational modes is justified to the extent that the rotational constant is independent of the vibrational state.

Given that the energy is a sum of independent contributions, the partition function factorizes into a product of contributions (recall Section 16.2b):

$$\begin{aligned}
q &= \sum_i e^{-\beta \epsilon_i} = \sum_{i \text{ (all states)}} e^{-\beta \epsilon_i^T - \beta \epsilon_i^R - \beta \epsilon_i^V - \beta \epsilon_i^E} \\
&= \sum_{i \text{ (translational)}} \sum_{i \text{ (rotational)}} \sum_{i \text{ (vibrational)}} \sum_{i \text{ (electronic)}} e^{-\beta \epsilon_i^T - \beta \epsilon_i^R - \beta \epsilon_i^V - \beta \epsilon_i^E} \\
&= \left(\sum_{i \text{ (translational)}} e^{-\beta \epsilon_i^T} \right) \left(\sum_{i \text{ (rotational)}} e^{-\beta \epsilon_i^R} \right) \left(\sum_{i \text{ (vibrational)}} e^{-\beta \epsilon_i^V} \right) \left(\sum_{i \text{ (electronic)}} e^{-\beta \epsilon_i^E} \right) \\
&= q^T q^R q^V q^E
\end{aligned} \tag{17.11}$$

This factorization means that we can investigate each contribution separately.

(a) The translational contribution

The translational partition function of a molecule of mass m in a container of volume V was derived in Section 16.2:

$$q^T = \frac{V}{\Lambda^3} \quad \Lambda = h \left(\frac{\beta}{2\pi m} \right)^{1/2} = \frac{h}{(2\pi m k T)^{1/2}} \tag{17.12}$$

Notice that $q^T \rightarrow \infty$ as $T \rightarrow \infty$ because an infinite number of states becomes accessible as the temperature is raised. Even at room temperature $q^T \approx 2 \times 10^{28}$ for an O_2 molecule in a vessel of volume 100 cm^3 .

The thermal wavelength, Λ , lets us judge whether the approximations that led to the expression for q^T are valid. The approximations are valid if many states are occupied, which requires V/Λ^3 to be large. That will be so if Λ is small compared with the linear dimensions of the container. For H_2 at 25°C , $\Lambda = 71 \text{ pm}$, which is far smaller than any conventional container is likely to be (but comparable to pores in zeolites or cavities in clathrates). For O_2 , a heavier molecule, $\Lambda = 18 \text{ pm}$. We saw in Section 16.2 that an equivalent criterion of validity is that Λ should be much less than the average separation of the molecules in the sample.

(b) The rotational contribution

As demonstrated in Example 16.1, the partition function of a nonsymmetrical (AB) linear rotor is

$$q^R = \sum_J (2J+1) e^{-\beta h c B J(J+1)} \tag{17.13}$$

The direct method of calculating q^R is to substitute the experimental values of the rotational energy levels into this expression and to sum the series numerically.

Fig. 17.1 The contributions to the rotational partition function of an HCl molecule at 25°C . The vertical axis is the value of $(2J+1)e^{-\beta h c B J(J+1)}$. Successive terms (which are proportional to the populations of the levels) pass through a maximum because the population of individual states decreases exponentially, but the degeneracy of the levels increases with J .

Example 17.2 Evaluating the rotational partition function explicitly

Evaluate the rotational partition function of $^1\text{H}^{35}\text{Cl}$ at 25°C , given that $B = 10.591 \text{ cm}^{-1}$.

Method We use eqn 17.13 and evaluate it term by term. A useful relation is $kT/hc = 207.22 \text{ cm}^{-1}$ at 298.15 K . The sum is readily evaluated by using mathematical software.

Answer To show how successive terms contribute, we draw up the following table by using $kT/hcB = 0.05111$ (Fig. 17.1):

J	0	1	2	3	4	...	10
$(2J+1)e^{-0.05111J(J+1)}$	1	2.71	3.68	3.79	3.24	...	0.08

The sum required by eqn 17.13 (the sum of the numbers in the second row of the table) is 19.9, hence $q^R = 19.9$ at this temperature. Taking J up to 50 gives $q^R = 19.902$. Notice that about ten J -levels are significantly populated but the number of populated *states* is larger on account of the $(2J + 1)$ -fold degeneracy of each level. We shall shortly encounter the approximation that $q^R \approx kT/hcB$, which in the present case gives $q^R = 19.6$, in good agreement with the exact value and with much less work.

Self-test 17.2 Evaluate the rotational partition function for HCl at 0°C. [18.26]

At room temperature $kT/hc \approx 200 \text{ cm}^{-1}$. The rotational constants of many molecules are close to 1 cm^{-1} (Table 13.2) and often smaller (though the very light H_2 molecule, for which $B = 60.9 \text{ cm}^{-1}$, is one exception). It follows that many rotational levels are populated at normal temperatures. When this is the case, the partition function may be approximated by

$$\text{Linear rotors:} \quad q^R = \frac{kT}{hcB} \quad (17.14a)$$

$$\text{Nonlinear rotors:} \quad q^R = \left(\frac{kT}{hc} \right)^{3/2} \left(\frac{\pi}{ABC} \right)^{1/2} \quad (17.14b)$$

where A , B , and C are the rotational constants of the molecule. However, before using these expressions, read on (to eqns 17.15 and 17.16).

Justification 17.1 *The rotational contribution to the molecular partition function*

When many rotational states are occupied and kT is much larger than the separation between neighbouring states, the sum in the partition function can be approximated by an integral, much as we did for translational motion in *Justification 16.2*:

$$q^R = \int_0^\infty (2J + 1) e^{-\beta hc B J(J+1)} dJ$$

Although this integral looks complicated, it can be evaluated without much effort by noticing that because

$$\frac{d}{dJ} e^{aJ(J+1)} = \left\{ \frac{d}{dJ} aJ(J+1) \right\} e^{aJ(J+1)} = a(2J+1) e^{aJ(J+1)}$$

it can also be written as

$$q^R = \frac{1}{\beta hc B} \int_0^\infty \left(\frac{d}{dJ} e^{-\beta hc B J(J+1)} \right) dJ$$

Then, because the integral of a derivative of a function is the function itself, we obtain

$$q^R = -\frac{1}{\beta hc B} e^{-\beta hc B J(J+1)} \Big|_0^\infty = \frac{1}{\beta hc B}$$

which (because $\beta = 1/kT$) is eqn 17.14a.

The calculation for a nonlinear molecule is along the same lines, but slightly trickier. First, we note that the energies of a symmetric rotor are

$$E_{J,K,M_J} = hc B J(J+1) + hc(A-B)K^2$$

Fig. 17.2 (a) The sum over $J = 0, 1, 2, \dots$ and $K = J, J-1, \dots, -J$ (depicted by the circles) can be covered (b) by allowing K to range from $-\infty$ to ∞ , with J confined to $|K|, |K|+1, \dots, \infty$ for each value of K .

with $J = 0, 1, 2, \dots, K = J, J-1, \dots, -J$, and $M_J = J, J-1, \dots, -J$. Instead of considering these ranges, we can cover the same values by allowing K to range from $-\infty$ to ∞ , with J confined to $|K|, |K|+1, \dots, \infty$ for each value of K (Fig. 17.2). Because the energy is independent of M_J , and there are $2J+1$ values of M_J for each value of J , each value of J is $2J+1$ -fold degenerate. It follows that the partition function

$$q = \sum_{J=0}^{\infty} \sum_{K=-J}^J \sum_{M_J=-J}^J e^{-E_{JKM_J}/kT}$$

can be written equivalently as

$$\begin{aligned} q &= \sum_{K=-\infty}^{\infty} \sum_{J=|K|}^{\infty} (2J+1) e^{-E_{JKM_J}/kT} \\ &= \sum_{K=-\infty}^{\infty} \sum_{J=|K|}^{\infty} (2J+1) e^{-hc\{BJ(J+1)+(A-B)K^2\}/kT} \\ &= \sum_{K=-\infty}^{\infty} e^{-\{hc(A-B)/kT\}K^2} \sum_{J=|K|}^{\infty} (2J+1) e^{-hcBJ(J+1)/kT} \end{aligned}$$

Now we assume that the temperature is so high that numerous states are occupied and that the sums may be approximated by integrals. Then

$$q = \int_{-\infty}^{\infty} e^{-\{hc(A-B)/kT\}K^2} \int_{|K|}^{\infty} (2J+1) e^{-hcBJ(J+1)/kT} dJ dK$$

As before, the integral over J can be recognized as the integral of the derivative of a function, which is the function itself, so

$$\begin{aligned} \int_{|K|}^{\infty} (2J+1) e^{-hcBJ(J+1)/kT} dJ &= \int_{|K|}^{\infty} \left(-\frac{kT}{hcB} \right) \frac{d}{dJ} e^{-hcBJ(J+1)/kT} dJ \\ &= \left(-\frac{kT}{hcB} \right) e^{-hcBJ(J+1)/kT} \Big|_{|K|}^{\infty} = \left(\frac{kT}{hcB} \right) e^{-hcB|K|(|K|+1)/kT} \\ &\approx \left(\frac{kT}{hcB} \right) e^{-hcBK^2/kT} \end{aligned}$$

In the last line we have supposed that $|K| \gg 1$ for most contributions. Now we can write

$$\begin{aligned} q &= \frac{kT}{hcB} \int_{-\infty}^{\infty} e^{-\{hc(A-B)/kT\}K^2} e^{-hcBK^2/kT} dK \\ &= \frac{kT}{hcB} \int_{-\infty}^{\infty} e^{-\{hcA/kT\}K^2} dK = \left(\frac{kT}{hcB} \right) \left(\frac{kT}{hcA} \right)^{1/2} \int_{-\infty}^{\infty} e^{-x^2} dx \\ &= \left(\frac{kT}{hc} \right)^{3/2} \left(\frac{\pi}{AB^2} \right)^{1/2} \end{aligned}$$

For an asymmetric rotor, one of the B s is replaced by C , to give eqn 17.14b.

Synoptic table 17.1* Rotational and vibrational temperatures

Molecule	Mode	θ_V/K	θ_R/K
H ₂		6330	88
HCl		4300	9.4
I ₂		309	0.053
CO ₂	ν_1	1997	0.561
	ν_2	3380	
	ν_3	960	

* For more values, see Table 13.2 in the *Data section* and use $hc/k = 1.439$ K cm.

A useful way of expressing the temperature above which the rotational approximation is valid is to introduce the **characteristic rotational temperature**, $\theta_R = hcB/k$. Then 'high temperature' means $T \gg \theta_R$ and under these conditions the rotational partition function of a linear molecule is simply T/θ_R . Some typical values of θ_R are shown in Table 17.1. The value for H₂ is abnormally high and we must be careful with the approximation for this molecule.

The general conclusion at this stage is that molecules with large moments of inertia (and hence small rotational constants and low characteristic rotational temperatures) have large rotational partition functions. The large value of q^R reflects the closeness in energy (compared with kT) of the rotational levels in large, heavy molecules, and the large number of them that are accessible at normal temperatures.

We must take care, however, not to include too many rotational states in the sum. For a homonuclear diatomic molecule or a symmetrical linear molecule (such as CO_2 or $\text{HC}\equiv\text{CH}$), a rotation through 180° results in an indistinguishable state of the molecule. Hence, the number of thermally accessible states is only half the number that can be occupied by a heteronuclear diatomic molecule, where rotation through 180° does result in a distinguishable state. Therefore, for a symmetrical linear molecule,

$$q^R = \frac{kT}{2hcB} = \frac{T}{2\theta_R} \quad (17.15a)$$

The equations for symmetrical and nonsymmetrical molecules can be combined into a single expression by introducing the **symmetry number**, σ , which is the number of indistinguishable orientations of the molecule. Then

$$q^R = \frac{kT}{\sigma hcB} = \frac{T}{\sigma\theta_R} \quad (17.15b)$$

For a heteronuclear diatomic molecule $\sigma = 1$; for a homonuclear diatomic molecule or a symmetrical linear molecule, $\sigma = 2$.

Justification 17.2 The origin of the symmetry number

The quantum mechanical origin of the symmetry number is the Pauli principle, which forbids the occupation of certain states. We saw in Section 13.8, for example, that H_2 may occupy rotational states with even J only if its nuclear spins are paired (*para*-hydrogen), and odd J states only if its nuclear spins are parallel (*ortho*-hydrogen). There are three states of *ortho*- H_2 to each value of J (because there are three parallel spin states of the two nuclei).

To set up the rotational partition function we note that ‘ordinary’ molecular hydrogen is a mixture of one part *para*- H_2 (with only its even- J rotational states occupied) and three parts *ortho*- H_2 (with only its odd- J rotational states occupied). Therefore, the average partition function per molecule is

$$q^R = \frac{1}{4} \sum_{\text{even } J} (2J+1)e^{-\beta hcBJ(J+1)} + \frac{3}{4} \sum_{\text{odd } J} (2J+1)e^{-\beta hcBJ(J+1)}$$

The odd- J states are more heavily weighted than the even- J states (Fig. 17.3). From the illustration we see that we would obtain approximately the same answer for the partition function (the sum of all the populations) if each J term contributed half its normal value to the sum. That is, the last equation can be approximated as

$$q^R = \frac{1}{2} \sum_J (2J+1)e^{-\beta hcBJ(J+1)}$$

and this approximation is very good when many terms contribute (at high temperatures).

The same type of argument may be used for linear symmetrical molecules in which identical bosons are interchanged by rotation (such as CO_2). As pointed out in Section 13.8, if the nuclear spin of the bosons is 0, then only even- J states are admissible. Because only half the rotational states are occupied, the rotational partition function is only half the value of the sum obtained by allowing all values of J to contribute (Fig. 17.4).

Fig. 17.3 The values of the individual terms $(2J+1)e^{-\beta hcBJ(J+1)}$ contributing to the mean partition function of a 3:1 mixture of *ortho*- and *para*- H_2 . The partition function is the sum of all these terms. At high temperatures, the sum is approximately equal to the sum of the terms over all values of J , each with a weight of $\frac{1}{2}$. This is the sum of the contributions indicated by the curve.

Fig. 17.4 The relative populations of the rotational energy levels of CO_2 . Only states with even J values are occupied. The full line shows the smoothed, averaged population of levels.

Synoptic table 17.2* Symmetry numbers

Molecule	σ
H ₂ O	2
NH ₃	3
CH ₄	12
C ₆ H ₆	12

* For more values, see Table 13.2 in the Data section.

Fig. 17.5 The vibrational partition function of a molecule in the harmonic approximation. Note that the partition function is linearly proportional to the temperature when the temperature is high ($T \gg \theta_v$).

Exploration Plot the temperature dependence of the vibrational contribution to the molecular partition function for several values of the vibrational wavenumber. Estimate from your plots the temperature above which the harmonic oscillator is in the ‘high temperature’ limit.

The same care must be exercised for other types of symmetrical molecule, and for a nonlinear molecule we write

$$q^R = \frac{1}{\sigma} \left(\frac{kT}{hc} \right)^{3/2} \left(\frac{\pi}{ABC} \right)^{1/2} \quad (17.16)$$

Some typical values of the symmetry numbers required are given in Table 17.2. The value $\sigma(\text{H}_2\text{O}) = 2$ reflects the fact that a 180° rotation about the bisector of the H—O—H angle interchanges two indistinguishable atoms. In NH_3 , there are three indistinguishable orientations around the axis shown in (1). For CH_4 , any of three 120° rotations about any of its four C—H bonds leaves the molecule in an indistinguishable state, so the symmetry number is $3 \times 4 = 12$. For benzene, any of six orientations around the axis perpendicular to the plane of the molecule leaves it apparently unchanged, as does a rotation of 180° around any of six axes in the plane of the molecule (three of which pass along each C—H bond and the remaining three pass through each C—C bond in the plane of the molecule). For the way that group theory is used to identify the value of the symmetry number, see Problem 17.17.

(c) The vibrational contribution

The vibrational partition function of a molecule is calculated by substituting the measured vibrational energy levels into the exponentials appearing in the definition of q^V , and summing them numerically. In a polyatomic molecule each normal mode (Section 13.14) has its own partition function (provided the anharmonicities are so small that the modes are independent). The overall vibrational partition function is the product of the individual partition functions, and we can write $q^V = q^V(1)q^V(2) \dots$, where $q^V(K)$ is the partition function for the K th normal mode and is calculated by direct summation of the observed spectroscopic levels.

If the vibrational excitation is not too great, the harmonic approximation may be made, and the vibrational energy levels written as

$$E_v = (v + \frac{1}{2})hc\tilde{\nu} \quad v = 0, 1, 2, \dots \quad (17.17)$$

If, as usual, we measure energies from the zero-point level, then the permitted values are $\epsilon_v = vhc\tilde{\nu}$ and the partition function is

$$q^V = \sum_v e^{-\beta vhc\tilde{\nu}} = \sum_v (e^{-\beta h c \tilde{\nu}})^v \quad (17.18)$$

(because $e^{ax} = (e^x)^a$). We met this sum in Example 16.2 (which is no accident: the ladder-like array of levels in Fig. 16.3 is exactly the same as that of a harmonic oscillator). The series can be summed in the same way, and gives

$$q^V = \frac{1}{1 - e^{-\beta h c \tilde{\nu}}} \quad (17.19)$$

This function is plotted in Fig. 17.5. In a polyatomic molecule, each normal mode gives rise to a partition function of this form.

Example 17.3 Calculating a vibrational partition function

The wavenumbers of the three normal modes of H_2O are 3656.7 cm^{-1} , 1594.8 cm^{-1} , and 3755.8 cm^{-1} . Evaluate the vibrational partition function at 1500 K.

Method Use eqn 17.19 for each mode, and then form the product of the three contributions. At 1500 K, $kT/hc = 1042.6 \text{ cm}^{-1}$.

Answer We draw up the following table displaying the contributions of each mode:

Mode:	1	2	3
$\tilde{\nu}/\text{cm}^{-1}$	3656.7	1594.8	3755.8
$hc\tilde{\nu}/kT$	3.507	1.530	3.602
q^V	1.031	1.276	1.028

The overall vibrational partition function is therefore

$$q^V = 1.031 \times 1.276 \times 1.028 = 1.353$$

The three normal modes of H_2O are at such high wavenumbers that even at 1500 K most of the molecules are in their vibrational ground state. However, there may be so many normal modes in a large molecule that their excitation may be significant even though each mode is not appreciably excited. For example, a nonlinear molecule containing 10 atoms has $3N - 6 = 24$ normal modes (Section 13.14). If we assume a value of about 1.1 for the vibrational partition function of one normal mode, the overall vibrational partition function is about $q^V \approx (1.1)^{24} = 9.8$, which indicates significant vibrational excitation relative to a smaller molecule, such as H_2O .

Self-test 17.3 Repeat the calculation for CO_2 , where the vibrational wavenumbers are 1388 cm^{-1} , 667.4 cm^{-1} , and 2349 cm^{-1} , the second being the doubly degenerate bending mode. [6.79]

In many molecules the vibrational wavenumbers are so great that $\beta hc\tilde{\nu} > 1$. For example, the lowest vibrational wavenumber of CH_4 is 1306 cm^{-1} , so $\beta hc\tilde{\nu} = 6.3$ at room temperature. C—H stretches normally lie in the range 2850 to 2960 cm^{-1} , so for them $\beta hc\tilde{\nu} \approx 14$. In these cases, $e^{-\beta hc\tilde{\nu}}$ in the denominator of q^V is very close to zero (for example, $e^{-6.3} = 0.002$), and the vibrational partition function for a single mode is very close to 1 ($q^V = 1.002$ when $\beta hc\tilde{\nu} = 6.3$), implying that only the zero-point level is significantly occupied.

Now consider the case of bonds so weak that $\beta hc\tilde{\nu} \ll kT$. When this condition is satisfied, the partition function may be approximated by expanding the exponential ($e^x = 1 + x + \dots$):

$$q^V = \frac{1}{1 - (1 - \beta hc\tilde{\nu} + \dots)} \quad (17.20)$$

That is, for weak bonds at high temperatures,

$$q^V = \frac{1}{\beta hc\tilde{\nu}} = \frac{kT}{hc\tilde{\nu}} \quad (17.21)$$

The temperatures for which eqn 17.21 is valid can be expressed in terms of the **characteristic vibrational temperature**, $\theta_V = hc\tilde{\nu}/k$ (Table 17.1). The value for H_2 is abnormally high because the atoms are so light and the vibrational frequency is correspondingly high. In terms of the vibrational temperature, ‘high temperature’ means $T \gg \theta_V$ and, when this condition is satisfied, $q^V = T/\theta_V$ (the analogue of the rotational expression).

(d) The electronic contribution

Electronic energy separations from the ground state are usually very large, so for most cases $q^E = 1$. An important exception arises in the case of atoms and molecules having

Fig. 17.6 The doubly degenerate ground electronic level of NO (with the spin and orbital angular momentum around the axis in opposite directions) and the doubly degenerate first excited level (with the spin and orbital momenta parallel). The upper level is thermally accessible at room temperature.

Fig. 17.7 The variation with temperature of the electronic partition function of an NO molecule. Note that the curve resembles that for a two-level system (Fig. 16.5), but rises from 2 (the degeneracy of the lower level) and approaches 4 (the total number of states) at high temperatures.

Exploration Plot the temperature dependence of the electronic partition function for several values of the energy separation ϵ between two doubly degenerate levels. From your plots, estimate the temperature at which the population of the excited level begins to increase sharply.

electronically degenerate ground states, in which case $q^E = g^E$, where g^E is the degeneracy of the electronic ground state. Alkali metal atoms, for example, have doubly degenerate ground states (corresponding to the two orientations of their electron spin), so $q^E = 2$.

Some atoms and molecules have low-lying electronically excited states. (At high enough temperatures, all atoms and molecules have thermally accessible excited states.) An example is NO, which has a configuration of the form $\dots \pi^1$ (see *Impact I11.1*). The orbital angular momentum may take two orientations with respect to the molecular axis (corresponding to circulation clockwise or counter-clockwise around the axis), and the spin angular momentum may also take two orientations, giving four states in all (Fig. 17.6). The energy of the two states in which the orbital and spin momenta are parallel (giving the ${}^2\Pi_{3/2}$ term) is slightly greater than that of the two other states in which they are antiparallel (giving the ${}^2\Pi_{1/2}$ term). The separation, which arises from spin-orbit coupling (Section 10.8), is only 121 cm^{-1} . Hence, at normal temperatures, all four states are thermally accessible. If we denote the energies of the two levels as $E_{1/2} = 0$ and $E_{3/2} = \epsilon$, the partition function is

$$q^E = \sum_{\text{energy levels}} g_j e^{-\beta \epsilon_j} = 2 + 2e^{-\beta \epsilon} \quad (17.22)$$

Figure 17.7 shows the variation of this function with temperature. At $T = 0$, $q^E = 2$, because only the doubly degenerate ground state is accessible. At high temperatures, q^E approaches 4 because all four states are accessible. At 25°C , $q^E = 3.1$.

(e) The overall partition function

The partition functions for each mode of motion of a molecule are collected in Table 17.3 at the end of the chapter. The overall partition function is the product of each contribution. For a diatomic molecule with no low-lying electronically excited states and $T \gg \theta_R$,

$$q = g^E \left(\frac{V}{\Lambda^3} \right) \left(\frac{T}{\sigma \theta_R} \right) \left(\frac{1}{1 - e^{-T/\theta_v}} \right) \quad (17.23)$$

Example 17.4 Calculating a thermodynamic function from spectroscopic data

Calculate the value of $G_m^\ominus - G_m^\ominus(0)$ for $\text{H}_2\text{O}(\text{g})$ at 1500 K given that $A = 27.8778 \text{ cm}^{-1}$, $B = 14.5092 \text{ cm}^{-1}$, and $C = 9.2869 \text{ cm}^{-1}$ and the information in Example 17.3.

Method The starting point is eqn 17.9. For the standard value, we evaluate the translational partition function at $p^\ominus$ (that is, at 10^5 Pa exactly). The vibrational partition function was calculated in Example 17.3. Use the expressions in Table 17.3 for the other contributions.

Answer Because $m = 18.015 \text{ u}$, it follows that $q_m^{\text{T}\ominus}/N_A = 1.706 \times 10^8$. For the vibrational contribution we have already found that $q^V = 1.352$. From Table 17.2 we see that $\sigma = 2$, so the rotational contribution is $q^R = 486.7$. Therefore,

$$\begin{aligned} G_m^\ominus - G_m^\ominus(0) &= -(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (1500 \text{ K}) \\ &\quad \times \ln\{(1.706 \times 10^8) \times 486.7 \times 1.352\} \\ &= -317.3 \text{ kJ mol}^{-1} \end{aligned}$$

Self-test 17.4 Repeat the calculation for CO_2 . The vibrational data are given in Self-test 17.3; $B = 0.3902 \text{ cm}^{-1}$. [−366.6 kJ mol^{−1}]

Comment 17.1

The text's web site contains links to on-line databases of atomic and molecular spectra.

Overall partition functions obtained from eqn 17.23 are approximate because they assume that the rotational levels are very close together and that the vibrational levels are harmonic. These approximations are avoided by using the energy levels identified spectroscopically and evaluating the sums explicitly.

Using statistical thermodynamics

We can now calculate any thermodynamic quantity from a knowledge of the energy levels of molecules: we have merged thermodynamics and spectroscopy. In this section, we indicate how to do the calculations for four important properties.

17.3 Mean energies

It is often useful to know the mean energy, $\langle \epsilon \rangle$, of various modes of motion. When the molecular partition function can be factorized into contributions from each mode, the mean energy of each mode M (from eqn 16.29) is

$$\langle \epsilon^M \rangle = - \frac{1}{q^M} \left(\frac{\partial q^M}{\partial \beta} \right)_V \quad M = \text{T, R, V, or E} \quad (17.24)$$

Fig. 17.8 The mean rotational energy of a nonsymmetrical linear rotor as a function of temperature. At high temperatures ($T \gg \theta_R$), the energy is linearly proportional to the temperature, in accord with the equipartition theorem.

Exploration Plot the temperature dependence of the mean rotational energy for several values of the rotational constant (for reasonable values of the rotational constant, see the *Data section*). From your plots, estimate the temperature at which the mean rotational energy begins to increase sharply.

(a) The mean translational energy

To see a pattern emerging, we consider first a one-dimensional system of length X , for which $q^T = X/\Lambda$, with $\Lambda = h(\beta/2\pi m)^{1/2}$. Then, if we note that Λ is a constant times $\beta^{1/2}$,

$$\langle \epsilon^T \rangle = -\frac{\Lambda}{X} \left(\frac{\partial}{\partial \beta} \frac{X}{\Lambda} \right)_V = -\beta^{1/2} \frac{d}{d\beta} \left(\frac{1}{\beta^{1/2}} \right) = \frac{1}{2\beta} = \frac{1}{2} kT \quad (17.25a)$$

For a molecule free to move in three dimensions, the analogous calculation leads to

$$\langle \epsilon^T \rangle = \frac{3}{2} kT \quad (17.25b)$$

Both conclusions are in agreement with the classical equipartition theorem (see *Molecular interpretation 2.2*) that the mean energy of each quadratic contribution to the energy is $\frac{1}{2} kT$. Furthermore, the fact that the mean energy is independent of the size of the container is consistent with the thermodynamic result that the internal energy of a perfect gas is independent of its volume (*Molecular interpretation 2.2*).

(b) The mean rotational energy

The mean rotational energy of a linear molecule is obtained from the partition function given in eqn 17.13. When the temperature is low ($T < \theta_R$), the series must be summed term by term, which gives

$$q^R = 1 + 3e^{-2\beta hcB} + 5e^{-6\beta hcB} + \dots$$

Hence

$$\langle \epsilon^R \rangle = \frac{hcB(6e^{-2\beta hcB} + 30e^{-6\beta hcB} + \dots)}{1 + 3e^{-2\beta hcB} + 5e^{-6\beta hcB} + \dots} \quad (17.26a)$$

This function is plotted in Fig. 17.8. At high temperatures ($T \gg \theta_R$), q^R is given by eqn 17.15, and

$$\langle \epsilon^R \rangle = -\frac{1}{q^R} \frac{dq^R}{d\beta} = -\sigma hc\beta B \frac{d}{d\beta} \frac{1}{\sigma hc\beta B} = \frac{1}{\beta} = kT \quad (17.26b)$$

(q^R is independent of V , so the partial derivatives have been replaced by complete derivatives.) The high-temperature result is also in agreement with the equipartition theorem, for the classical expression for the energy of a linear rotor is $E_K = \frac{1}{2} I_{\perp} \omega_a^2 + \frac{1}{2} I_{\perp} \omega_b^2$. (There is no rotation around the line of atoms.) It follows from the equipartition theorem that the mean rotational energy is $2 \times \frac{1}{2} kT = kT$.

(c) The mean vibrational energy

The vibrational partition function in the harmonic approximation is given in eqn 17.19. Because q^V is independent of the volume, it follows that

$$\frac{dq^V}{d\beta} = \frac{d}{d\beta} \left(\frac{1}{1 - e^{-\beta hc\tilde{\nu}}} \right) = -\frac{hc\tilde{\nu}e^{-\beta hc\tilde{\nu}}}{(1 - e^{-\beta hc\tilde{\nu}})^2} \quad (17.27)$$

and hence from

$$\langle \epsilon^V \rangle = -\frac{1}{q^V} \frac{dq^V}{d\beta} = -(1 - e^{-\beta hc\tilde{\nu}}) \left\{ -\frac{hc\tilde{\nu}e^{-\beta hc\tilde{\nu}}}{(1 - e^{-\beta hc\tilde{\nu}})^2} \right\} = \frac{hc\tilde{\nu}e^{-\beta hc\tilde{\nu}}}{1 - e^{-\beta hc\tilde{\nu}}}$$

that

$$\langle \epsilon^V \rangle = \frac{hc\tilde{\nu}}{e^{\beta hc\tilde{\nu}} - 1} \quad (17.28)$$

The zero-point energy, $\frac{1}{2}hc\tilde{\nu}$, can be added to the right-hand side if the mean energy is to be measured from 0 rather than the lowest attainable level (the zero-point level). The variation of the mean energy with temperature is illustrated in Fig. 17.9. At high temperatures, when $T \gg \theta_v$, or $\beta hc\tilde{\nu} \ll 1$, the exponential functions can be expanded ($e^x = 1 + x + \dots$) and all but the leading terms discarded. This approximation leads to

$$\langle \epsilon^V \rangle = \frac{hc\tilde{\nu}}{(1 + \beta hc\tilde{\nu} + \dots) - 1} \approx \frac{1}{\beta} = kT \quad (17.29)$$

This result is in agreement with the value predicted by the classical equipartition theorem, because the energy of a one-dimensional oscillator is $E = \frac{1}{2}mv_x^2 + \frac{1}{2}kx^2$ and the mean energy of each quadratic term is $\frac{1}{2}kT$.

17.4 Heat capacities

The constant-volume heat capacity is defined as $C_V = (\partial U / \partial T)_V$. The derivative with respect to T is converted into a derivative with respect to β by using

$$\frac{d}{dT} = \frac{d\beta}{dT} \frac{d}{d\beta} = -\frac{1}{kT^2} \frac{d}{d\beta} = -k\beta^2 \frac{d}{d\beta} \quad (17.30)$$

It follows that

$$C_V = -k\beta^2 \left(\frac{\partial U}{\partial \beta} \right)_V \quad (17.31a)$$

Because the internal energy of a perfect gas is a sum of contributions, the heat capacity is also a sum of contributions from each mode. The contribution of mode M is

$$C_V^M = N \left(\frac{\partial \langle \epsilon^M \rangle}{\partial T} \right)_V = -Nk\beta^2 \left(\frac{\partial \langle \epsilon^M \rangle}{\partial \beta} \right)_V \quad (17.31b)$$

(a) The individual contributions

The temperature is always high enough (provided the gas is above its condensation temperature) for the mean translational energy to be $\frac{3}{2}kT$, the equipartition value. Therefore, the molar constant-volume heat capacity is

$$C_{V,m}^T = N_A \frac{d(\frac{3}{2}kT)}{dT} = \frac{3}{2}R \quad (17.32)$$

Translation is the only mode of motion for a monatomic gas, so for such a gas $C_{V,m} = \frac{3}{2}R = 12.47 \text{ J K}^{-1} \text{ mol}^{-1}$. This result is very reliable: helium, for example, has this value over a range of 2000 K. We saw in Section 2.5 that $C_{p,m} - C_{V,m} = R$, so for a monatomic perfect gas $C_{p,m} = \frac{5}{2}R$, and therefore

$$\gamma = \frac{C_p}{C_V} = \frac{5}{3} \quad (17.33)^\circ$$

When the temperature is high enough for the rotations of the molecules to be highly excited (when $T \gg \theta_R$), we can use the equipartition value kT for the mean rotational energy (for a linear rotor) to obtain $C_{V,m} = R$. For nonlinear molecules, the mean rotational energy rises to $\frac{3}{2}kT$, so the molar rotational heat capacity rises to $\frac{3}{2}R$ when $T \gg \theta_R$. Only the lowest rotational state is occupied when the temperature is very low, and then rotation does not contribute to the heat capacity. We can

Fig. 17.9 The mean vibrational energy of a molecule in the harmonic approximation as a function of temperature. At high temperatures ($T \gg \theta_v$), the energy is linearly proportional to the temperature, in accord with the equipartition theorem.

Exploration Plot the temperature dependence of the mean vibrational energy for several values of the vibrational wavenumber (for reasonable values of the vibrational wavenumber, see the *Data section*). From your plots, estimate the temperature at which the mean vibrational energy begins to increase sharply.

Fig. 17.10 The temperature dependence of the rotational contribution to the heat capacity of a linear molecule.

 **Exploration** The *Living graphs* section of the text's web site has applets for the calculation of the temperature dependence of the rotational contribution to the heat capacity. Explore the effect of the rotational constant on the plot of $C_{V,m}^R$ against T .

Fig. 17.11 The rotational heat capacity of a linear molecule can be regarded as the sum of contributions from a collection of two-level systems, in which the rise in temperature stimulates transitions between J levels, some of which are shown here. The calculation on which this illustration is based is sketched in Problem 17.19.

calculate the rotational heat capacity at intermediate temperatures by differentiating the equation for the mean rotational energy (eqn 17.26). The resulting (untidy) expression, which is plotted in Fig. 17.10, shows that the contribution rises from zero (when $T = 0$) to the equipartition value (when $T \gg \theta_R$). Because the translational contribution is always present, we can expect the molar heat capacity of a gas of diatomic molecules ($C_{V,m}^T + C_{V,m}^R$) to rise from $\frac{3}{2}R$ to $\frac{5}{2}R$ as the temperature is increased above θ_R . Problem 17.19 explores how the overall shape of the curve can be traced to the sum of thermal excitations between all the available rotational energy levels (Fig. 17.11).

Molecular vibrations contribute to the heat capacity, but only when the temperature is high enough for them to be significantly excited. The equipartition mean energy is kT for each mode, so the maximum contribution to the molar heat capacity is R . However, it is very unusual for the vibrations to be so highly excited that equipartition is valid, and it is more appropriate to use the full expression for the vibrational heat capacity, which is obtained by differentiating eqn 17.28:

$$C_{V,m}^V = Rf \quad f = \left(\frac{\theta_V}{T} \right)^2 \left(\frac{e^{-\theta_V/2T}}{1 - e^{-\theta_V/T}} \right)^2 \quad (17.34)$$

where $\theta_V = hc\tilde{\nu}/k$ is the characteristic vibrational temperature. The curve in Fig. 17.12 shows how the vibrational heat capacity depends on temperature. Note that even when the temperature is only slightly above θ_V the heat capacity is close to its equipartition value.

Comment 17.2

Equation 17.34 is essentially the same as the Einstein formula for the heat capacity of a solid (eqn 8.7) with θ_V the Einstein temperature, θ_E . The only difference is that vibrations can take place in three dimensions in a solid.

Fig. 17.12 The temperature dependence of the vibrational heat capacity of a molecule in the harmonic approximation calculated by using eqn 17.34. Note that the heat capacity is within 10 per cent of its classical value for temperatures greater than θ_v .

 **Exploration** The *Living graphs* section of the text's web site has applets for the calculation of the temperature dependence of the vibrational contribution to the heat capacity. Explore the effect of the vibrational wavenumber on the plot of $C_{V,m}^V$ against T .

Fig. 17.13 The general features of the temperature dependence of the heat capacity of diatomic molecules are as shown here. Each mode becomes active when its characteristic temperature is exceeded. The heat capacity becomes very large when the molecule dissociates because the energy is used to cause dissociation and not to raise the temperature. Then it falls back to the translation-only value of the atoms.

(b) The overall heat capacity

The total heat capacity of a molecular substance is the sum of each contribution (Fig. 17.13). When equipartition is valid (when the temperature is well above the characteristic temperature of the mode, $T \gg \theta_M$) we can estimate the heat capacity by counting the numbers of modes that are active. In gases, all three translational modes are always active and contribute $\frac{3}{2}R$ to the molar heat capacity. If we denote the number of active rotational modes by ν_R^* (so for most molecules at normal temperatures $\nu_R^* = 2$ for linear molecules, and 3 for nonlinear molecules), then the rotational contribution is $\frac{1}{2}\nu_R^*R$. If the temperature is high enough for ν_V^* vibrational modes to be active, the vibrational contribution to the molar heat capacity is ν_V^*R . In most cases $\nu_V^* \approx 0$. It follows that the total molar heat capacity is

$$C_{V,m} = \frac{1}{2}(3 + \nu_R^* + 2\nu_V^*)R \quad (17.35)$$

Example 17.5 Estimating the molar heat capacity of a gas

Estimate the molar constant-volume heat capacity of water vapour at 100°C. Vibrational wavenumbers are given in Example 17.3; the rotational constants of an H_2O molecule are 27.9, 14.5, and 9.3 cm^{-1} .

Method We need to assess whether the rotational and vibrational modes are active by computing their characteristic temperatures from the data (to do so, use $hc/k = 1.439 \text{ cm K}$).

Answer The characteristic temperatures (in round numbers) of the vibrations are 5300 K, 2300 K, and 5400 K; the vibrations are therefore not excited at 373 K. The three rotational modes have characteristic temperatures 40 K, 21 K, and 13 K, so they are fully excited, like the three translational modes. The translational contribution is $\frac{3}{2}R = 12.5 \text{ J K}^{-1} \text{ mol}^{-1}$. Fully excited rotations contribute a further $12.5 \text{ J K}^{-1} \text{ mol}^{-1}$. Therefore, a value close to $25 \text{ J K}^{-1} \text{ mol}^{-1}$ is predicted. The experimental value is $26.1 \text{ J K}^{-1} \text{ mol}^{-1}$. The discrepancy is probably due to deviations from perfect gas behaviour.

Self-test 17.5 Estimate the molar constant-volume heat capacity of gaseous I_2 at 25°C ($B = 0.037 \text{ cm}^{-1}$; see Table 13.2 for more data). $[29 \text{ J K}^{-1} \text{ mol}^{-1}]$

17.5 Equations of state

The relation between p and Q in eqn 17.3 is a very important route to the equations of state of real gases in terms of intermolecular forces, for the latter can be built into Q . We have already seen (Example 17.1) that the partition function for a gas of independent particles leads to the perfect gas equation of state, $pV = nRT$. Real gases differ from perfect gases in their equations of state and we saw in Section 1.3 that their equations of state may be written

$$\frac{pV_m}{RT} = 1 + \frac{B}{V_m} + \frac{C}{V_m^2} + \dots \quad (17.36)$$

where B is the second virial coefficient and C is the third virial coefficient.

The total kinetic energy of a gas is the sum of the kinetic energies of the individual molecules. Therefore, even in a real gas the canonical partition function factorizes into a part arising from the kinetic energy, which is the same as for the perfect gas, and a factor called the **configuration integral**, Z , which depends on the intermolecular potentials. We therefore write

$$Q = \frac{Z}{\Lambda^{3N}} \quad (17.37)$$

By comparing this equation with eqn 16.45 ($Q = q^N/N!$, with $q = V/\Lambda^3$), we see that for a perfect gas of atoms (with no contributions from rotational or vibrational modes)

$$Z = \frac{V^N}{N!} \quad (17.38)$$

For a real gas of atoms (for which the intermolecular interactions are isotropic), Z is related to the total potential energy E_p of interaction of all the particles by

$$Z = \frac{1}{N!} \int e^{-\beta E_p} d\tau_1 d\tau_2 \cdots d\tau_N \quad (17.39)$$

where $d\tau_i$ is the volume element for atom i . The physical origin of this term is that the probability of occurrence of each arrangement of molecules possible in the sample is given by a Boltzmann distribution in which the exponent is given by the potential energy corresponding to that arrangement.

Illustration 17.1 Calculating a configuration integral

When the molecules do not interact with one another, $E_p = 0$ and hence $e^{-\beta E_p} = 1$. Then

$$Z = \frac{1}{N!} \int d\tau_1 d\tau_2 \cdots d\tau_N = \frac{V^N}{N!}$$

because $\int d\tau = V$, where V is the volume of the container. This result coincides with eqn 17.39.

When we consider only interactions between pairs of particles the configuration integral simplifies to

$$Z = \frac{1}{2} \int e^{-\beta E_p} d\tau_1 d\tau_2 \quad (17.40)$$

The second virial coefficient then turns out to be

$$B = -\frac{N_A}{2V} \int f d\tau_1 d\tau_2 \quad (17.41)$$

The quantity f is the **Mayer f -function**: it goes to zero when the two particles are so far apart that $E_p = 0$. When the intermolecular interaction depends only on the separation r of the particles and not on their relative orientation or their absolute position in space, as in the interaction of closed-shell atoms in a uniform sample, the volume element simplifies to $4\pi r^2 dr$ (because the integrals over the angular variables in $d\tau = r^2 dr \sin \theta d\theta d\phi$ give a factor of 4π) and eqn 17.41 becomes

$$B = -2\pi N_A \int_0^\infty f r^2 dr \quad f = e^{-\beta E_p} - 1 \quad (17.42)$$

The integral can be evaluated (usually numerically) by substituting an expression for the intermolecular potential energy.

Intermolecular potential energies are discussed in more detail in Chapter 18, where several expressions are developed for them. At this stage, we can illustrate how eqn 17.42 is used by considering the **hard-sphere potential**, which is infinite when the separation of the two molecules, r , is less than or equal to a certain value σ , and is zero for greater separations. Then

$$e^{-\beta E_p} = 0 \quad f = -1 \quad \text{when } r \leq \sigma \quad (\text{and } E_p = \infty) \quad (17.43a)$$

$$e^{-\beta E_p} = 1 \quad f = 0 \quad \text{when } r > \sigma \quad (\text{and } E_p = 0) \quad (17.43b)$$

It follows from eqn 17.42 that the second virial coefficient is

$$B = 2\pi N_A \int_0^\sigma r^2 dr = \frac{2}{3} \pi N_A \sigma^3 \quad (17.44)$$

This calculation of B raises the question as to whether a potential can be found that, when the virial coefficients are evaluated, gives the van der Waals equation of state. Such a potential can be found for weak attractive interactions ($a \ll RT$): it consists of a hard-sphere repulsive core and a long-range, shallow attractive region (see Problem 17.15). A further point is that, once a second virial coefficient has been calculated for a given intermolecular potential, it is possible to calculate other thermodynamic properties that depend on the form of the potential. For example, it is possible to

calculate the isothermal Joule–Thomson coefficient, μ_T (Section 3.8), from the thermodynamic relation

$$\lim_{p \rightarrow 0} \mu_T = B - T \frac{dB}{dT} \quad (17.45)$$

and from the result calculate the Joule–Thomson coefficient itself by using eqn 3.48.

17.6 Molecular interactions in liquids

The starting point for the discussion of solids is the well ordered structure of a perfect crystal, which will be discussed in Chapter 20. The starting point for the discussion of gases is the completely disordered distribution of the molecules of a perfect gas, as we saw in Chapter 1. Liquids lie between these two extremes. We shall see that the structural and thermodynamic properties of liquids depend on the nature of intermolecular interactions and that an equation of state can be built in a similar way to that just demonstrated for real gases.

(a) The radial distribution function

The average relative locations of the particles of a liquid are expressed in terms of the **radial distribution function**, $g(r)$. This function is defined so that $g(r)r^2dr$ is the probability that a molecule will be found in the range dr at a distance r from another molecule. In a perfect crystal, $g(r)$ is a periodic array of sharp spikes, representing the certainty (in the absence of defects and thermal motion) that molecules (or ions) lie at definite locations. This regularity continues out to the edges of the crystal, so we say that crystals have **long-range order**. When the crystal melts, the long-range order is lost and, wherever we look at long distances from a given molecule, there is equal probability of finding a second molecule. Close to the first molecule, though, the nearest neighbours might still adopt approximately their original relative positions and, even if they are displaced by newcomers, the new particles might adopt their vacated positions. It is still possible to detect a sphere of nearest neighbours at a distance r_1 , and perhaps beyond them a sphere of next-nearest neighbours at r_2 . The existence of this **short-range order** means that the radial distribution function can be expected to oscillate at short distances, with a peak at r_1 , a smaller peak at r_2 , and perhaps some more structure beyond that.

The radial distribution function of the oxygen atoms in liquid water is shown in Fig. 17.14. Closer analysis shows that any given H_2O molecule is surrounded by other molecules at the corners of a tetrahedron. The form of $g(r)$ at 100°C shows that the intermolecular interactions (in this case, principally by hydrogen bonds) are strong enough to affect the local structure right up to the boiling point. Raman spectra indicate that in liquid water most molecules participate in either three or four hydrogen bonds. Infrared spectra show that about 90 per cent of hydrogen bonds are intact at the melting point of ice, falling to about 20 per cent at the boiling point.

The formal expression for the radial distribution function for molecules 1 and 2 in a fluid consisting of N particles is the somewhat fearsome equation

$$g(r_{12}) = \frac{\int \int \dots \int e^{-\beta V_N} d\tau_3 d\tau_4 \dots d\tau_N}{N^2 \int \int \dots \int e^{-\beta V_N} d\tau_1 d\tau_2 \dots d\tau_N} \quad (17.46)$$

where $\beta = 1/kT$ and V_N is the N -particle potential energy. Although fearsome, this expression is nothing more than the Boltzmann distribution for the relative locations of two molecules in a field provided by all the other molecules in the system.

Fig. 17.14 The radial distribution function of the oxygen atoms in liquid water at three temperatures. Note the expansion as the temperature is raised. (A.H. Narten, M.D. Danford, and H.A. Levy, *Discuss. Faraday. Soc.* **43**, 97 (1967).)

(b) The calculation of $g(r)$

Because the radial distribution function can be calculated by making assumptions about the intermolecular interactions, it can be used to test theories of liquid structure. However, even a fluid of hard spheres without attractive interactions (a collection of ball-bearings in a container) gives a function that oscillates near the origin (Fig. 17.15), and one of the factors influencing, and sometimes dominating, the structure of a liquid is the geometrical problem of stacking together reasonably hard spheres. Indeed, the radial distribution function of a liquid of hard spheres shows more pronounced oscillations at a given temperature than that of any other type of liquid. The attractive part of the potential modifies this basic structure, but sometimes only quite weakly. One of the reasons behind the difficulty of describing liquids theoretically is the similar importance of both the attractive and repulsive (hard core) components of the potential.

There are several ways of building the intermolecular potential into the calculation of $g(r)$. Numerical methods take a box of about 10^3 particles (the number increases as computers grow more powerful), and the rest of the liquid is simulated by surrounding the box with replications of the original box (Fig. 17.16). Then, whenever a particle leaves the box through one of its faces, its image arrives through the opposite face. When calculating the interactions of a molecule in a box, it interacts with all the molecules in the box and all the periodic replications of those molecules and itself in the other boxes.

In the **Monte Carlo method**, the particles in the box are moved through small but otherwise random distances, and the change in total potential energy of the N particles in the box, ΔV_N , is calculated using one of the intermolecular potentials discussed in Section 18.4. Whether or not this new configuration is accepted is then judged from the following rules:

- 1 If the potential energy is not greater than before the change, then the configuration is accepted.

If the potential energy is greater than before the change, then it is necessary to check if the new configuration is reasonable and can exist in equilibrium with configurations of lower potential energy at a given temperature. To make progress, we use the result that, at equilibrium, the ratio of populations of two states with energy separation ΔV_N is $e^{-\Delta V_N/kT}$. Because we are testing the viability of a configuration with a higher potential energy than the previous configuration in the calculation, $\Delta V_N > 0$ and the exponential factor varies between 0 and 1. In the Monte Carlo method, the second rule, therefore, is:

- 2 The exponential factor is compared with a random number between 0 and 1; if the factor is larger than the random number, then the configuration is accepted; if the factor is not larger, the configuration is rejected.

The configurations generated with Monte Carlo calculations can be used to construct $g(r)$ simply by counting the number of pairs of particles with a separation r and averaging the result over the whole collection of configurations.

In the **molecular dynamics** approach, the history of an initial arrangement is followed by calculating the trajectories of all the particles under the influence of the intermolecular potentials. To appreciate what is involved, we consider the motion of a particle in one dimension. We show in the following *Justification* that, after a time interval Δt , the position of a particle changes from x_{i-1} to a new value x_i given by

$$x_i = x_{i-1} + v_{i-1}\Delta t \quad (17.47)$$

where v_{i-1} is the velocity of the atom when it was at x_{i-1} , its location at the start of the interval. The velocity at x_i is related to v_{i-1} , the velocity at the start of the interval, by

Fig. 17.15 The radial distribution function for a simulation of a liquid using impenetrable hard spheres (ball bearings).

Fig. 17.16 In a two-dimensional simulation of a liquid that uses periodic boundary conditions, when one particle leaves the cell its mirror image enters through the opposite face.

$$v_i = v_{i-1} - m^{-1} \frac{dV_N(x)}{dx} \bigg|_{x_{i-1}} \Delta t \quad (17.48)$$

where the derivative of the potential energy $V_N(x)$ is evaluated at x_{i-1} . The time interval Δt is approximately 1 fs (10^{-15} s), which is shorter than the average time between collisions. The calculation of x_i and v_i is then repeated for tens of thousands of such steps. The time-consuming part of the calculation is the evaluation of the net force on the molecule arising from all the other molecules present in the system.

Justification 17.3 *Particle trajectories according to molecular dynamics*

Consider a particle of mass m moving along the x direction with an initial velocity v_1 given by

$$v_1 = \frac{\Delta x}{\Delta t}$$

If the initial and new positions of the atom are x_1 and x_2 , then $\Delta x = x_2 - x_1$ and

$$x_2 = x_1 + v_1 \Delta t$$

The particle moves under the influence of a force arising from interactions with other atoms in the molecule. From Newton's second law of motion, we write the force F_1 at x_1 as

$$F_1 = ma_1$$

where the acceleration a_1 at x_1 is given by $a_1 = \Delta v / \Delta t$. If the initial and new velocities are v_1 and v_2 , then $\Delta v = v_2 - v_1$ and

$$v_2 = v_1 + a_1 \Delta t = v_1 + \frac{F_1}{m} \Delta t$$

Because $F = -dV/dx$, the force acting on the atom is related to the potential energy of interaction with other nearby atoms, the potential energy $V_N(x)$, by

$$F_1 = - \frac{dV_N(x)}{dx} \bigg|_{x_1}$$

where the derivative is evaluated at x_1 . It follows that

$$v_2 = v_1 - m^{-1} \frac{dV_N(x)}{dx} \bigg|_{x_1} \Delta t$$

This expression generalizes to eqn 17.48 for the calculation of a velocity v_i from a previous velocity v_{i-1} .

Self-test 17.6 Consider a particle of mass m connected to a stationary wall with a spring of force constant k . Write an expression for the velocity of this particle once it is set into motion in the x direction from an equilibrium position x_0 .

$$[v_i = v_{i-1} + (k/m)(x_{i-1} - x_0)]$$

A molecular dynamics calculation gives a series of snapshots of the liquid, and $g(r)$ can be calculated as before. The temperature of the system is inferred by computing the mean kinetic energy of the particles and using the equipartition result that

$$\langle \frac{1}{2} m v_q^2 \rangle = \frac{1}{2} kT \quad (17.49)$$

for each coordinate q .

(c) The thermodynamic properties of liquids

Once $g(r)$ is known it can be used to calculate the thermodynamic properties of liquids. For example, the contribution of the pairwise additive intermolecular potential, V_2 , to the internal energy is given by the integral

$$U = \frac{2\pi N^2}{V} \int_0^\infty g(r) V_2 r^2 dr \quad (17.50)$$

That is, U is essentially the average two-particle potential energy weighted by $g(r)r^2 dr$, which is the probability that the pair of particles have a separation between r and $r + dr$. Likewise, the contribution that pairwise interactions make to the pressure is

$$\frac{pV}{nRT} = 1 - \frac{2\pi N}{kTV} \int_0^\infty g(r) v_2 r^2 dr \quad v_2 = r \frac{dV_2}{dr} \quad (17.51a)$$

The quantity v_2 is called the **virial** (hence the term ‘virial equation of state’). To understand the physical content of this expression, we rewrite it as

$$p = \frac{nRT}{V} - 2\pi \left(\frac{N}{V} \right)^2 \int_0^\infty g(r) v_2 r^2 dr \quad (17.51b)$$

The first term on the right is the **kinetic pressure**, the contribution to the pressure from the impact of the molecules in free flight. The second term is essentially the internal pressure, $\pi_T = (\partial U / \partial V)_T$, introduced in Section 2.11, representing the contribution to the pressure from the intermolecular forces. To see the connection, we should recognize $-dV_2/dr$ (in v_2) as the force required to move two molecules apart, and therefore $-r(dV_2/dr)$ as the work required to separate the molecules through a distance r . The second term is therefore the average of this work over the range of pairwise separations in the liquid as represented by the probability of finding two molecules at separations between r and $r + dr$, which is $g(r)r^2 dr$. In brief, the integral, when multiplied by the square of the number density, is the change in internal energy of the system as it expands, and therefore is equal to the internal pressure.

17.7 Residual entropies

Entropies may be calculated from spectroscopic data; they may also be measured experimentally (Section 3.3). In many cases there is good agreement, but in some the experimental entropy is less than the calculated value. One possibility is that the experimental determination failed to take a phase transition into account (and a contribution of the form $\Delta_{\text{trs}}H/T_{\text{trs}}$ incorrectly omitted from the sum). Another possibility is that some disorder is present in the solid even at $T = 0$. The entropy at $T = 0$ is then greater than zero and is called the **residual entropy**.

The origin and magnitude of the residual entropy can be explained by considering a crystal composed of AB molecules, where A and B are similar atoms (such as CO, with its very small electric dipole moment). There may be so little energy difference between $\dots AB AB AB AB \dots$, $\dots AB BA BA AB \dots$, and other arrangements that the molecules adopt the orientations AB and BA at random in the solid. We can readily calculate the entropy arising from residual disorder by using the Boltzmann formula $S = k \ln W$. To do so, we suppose that two orientations are equally probable, and that the sample consists of N molecules. Because the same energy can be achieved in 2^N different ways (because each molecule can take either of two orientations), the total number of ways of achieving the same energy is $W = 2^N$. It follows that

$$S = k \ln 2^N = Nk \ln 2 = nR \ln 2 \quad (17.52a)$$

Fig. 17.17 The possible locations of H atoms around a central O atom in an ice crystal are shown by the white spheres. Only one of the locations on each bond may be occupied by an atom, and two H atoms must be close to the O atom and two H atoms must be distant from it.

We can therefore expect a residual molar entropy of $R \ln 2 = 5.8 \text{ J K}^{-1} \text{ mol}^{-1}$ for solids composed of molecules that can adopt either of two orientations at $T = 0$. If s orientations are possible, the residual molar entropy will be

$$S_m = R \ln s \quad (17.52b)$$

An FCIO_3 molecule, for example, can adopt four orientations with about the same energy (with the F atom at any of the four corners of a tetrahedron), and the calculated residual molar entropy of $R \ln 4 = 11.5 \text{ J K}^{-1} \text{ mol}^{-1}$ is in good agreement with the experimental value ($10.1 \text{ J K}^{-1} \text{ mol}^{-1}$). For CO, the measured residual entropy is $5 \text{ J K}^{-1} \text{ mol}^{-1}$, which is close to $R \ln 2$, the value expected for a random structure of the form $\dots \text{CO CO OC CO OC OC} \dots$.

Illustration 17.2 Calculating a residual entropy

Consider a sample of ice with $N \text{ H}_2\text{O}$ molecules. Each O atom is surrounded tetrahedrally by four H atoms, two of which are attached by short σ bonds, the other two being attached by long hydrogen bonds (Fig. 17.17). It follows that each of the $2N$ H atoms can be in one of two positions (either close to or far from an O atom as shown in Fig. 17.18), resulting in 2^{2N} possible arrangements. However, not all these arrangements are acceptable. Indeed, of the $2^4 = 16$ ways of arranging four H atoms around one O atom, only 6 have two short and two long OH distances and hence are acceptable. Therefore, the number of permitted arrangements is

$$W = 2^{2N} \left(\frac{6}{16} \right)^N = \left(\frac{3}{2} \right)^N$$

It then follows that the residual molar entropy is

$$S_m(0) \approx k \ln \left(\frac{3}{2} \right)^{N_A} = N_A k \ln \left(\frac{3}{2} \right) = R \ln \left(\frac{3}{2} \right) = 3.4 \text{ J K}^{-1} \text{ mol}^{-1}$$

which is in good agreement with the experimental value of $3.4 \text{ J K}^{-1} \text{ mol}^{-1}$. The model, however, is not exact because it ignores the possibility that next-nearest neighbours and those beyond can influence the local arrangement of bonds.

17.8 Equilibrium constants

The Gibbs energy of a gas of independent molecules is given by eqn 17.9 in terms of the molar partition function, $q_m = q/n$. The equilibrium constant K of a reaction is related to the standard Gibbs energy of reaction by $\Delta_r G^\ominus = -RT \ln K$. To calculate the equilibrium constant, we need to combine these two equations. We shall consider gas phase reactions in which the equilibrium constant is expressed in terms of the partial pressures of the reactants and products.

Fig. 17.18 The six possible arrangements of H atoms in the locations identified in Fig. 17.17. Occupied locations are denoted by red spheres and unoccupied locations by white spheres.

(a) The relation between K and the partition function

To find an expression for the standard reaction Gibbs energy we need expressions for the standard molar Gibbs energies, G°/n , of each species. For these expressions, we need the value of the molar partition function when $p = p^\circ$ (where $p^\circ = 1$ bar): we denote this **standard molar partition function** q_{m}° . Because only the translational component depends on the pressure, we can find q_{m}° by evaluating the partition function with V replaced by V_{m}° , where $V_{\text{m}}^\circ = RT/p^\circ$. For a species J it follows that

$$G_{\text{m}}^\circ(J) = G_{\text{m}}^\circ(J, 0) - RT \ln \frac{q_{J,\text{m}}^\circ}{N_{\text{A}}} \quad (17.53)^\circ$$

where $q_{J,\text{m}}^\circ$ is the standard molar partition function of J . By combining expressions like this one (as shown in the *Justification* below), the equilibrium constant for the reaction

is given by the expression

$$K = \frac{(q_{\text{C},\text{m}}^\circ/N_{\text{A}})^c (q_{\text{D},\text{m}}^\circ/N_{\text{A}})^d}{(q_{\text{A},\text{m}}^\circ/N_{\text{A}})^a (q_{\text{B},\text{m}}^\circ/N_{\text{A}})^b} e^{-\Delta_{\text{r}}E_0/RT} \quad (17.54\text{a})$$

where $\Delta_{\text{r}}E_0$ is the difference in molar energies of the ground states of the products and reactants (this term is defined more precisely in the *Justification*), and is calculated from the bond dissociation energies of the species (Fig. 17.19). In terms of the stoichiometric numbers introduced in Section 7.2, we would write

$$K = \left\{ \prod_J \left(\frac{q_{J,\text{m}}^\circ}{N_{\text{A}}} \right)^{\nu_J} \right\} e^{-\Delta_{\text{r}}E_0/RT} \quad (17.54\text{b})$$

Fig. 17.19 The definition of $\Delta_{\text{r}}E_0$ for the calculation of equilibrium constants.

Justification 17.4 The equilibrium constant in terms of the partition function 1

The standard molar reaction Gibbs energy for the reaction is

$$\begin{aligned} \Delta_{\text{r}}G^\circ &= cG_{\text{m}}^\circ(\text{C}) + dG_{\text{m}}^\circ(\text{D}) - aG_{\text{m}}^\circ(\text{A}) - bG_{\text{m}}^\circ(\text{B}) \\ &= cG_{\text{m}}^\circ(\text{C}, 0) + dG_{\text{m}}^\circ(\text{D}, 0) - aG_{\text{m}}^\circ(\text{A}, 0) - bG_{\text{m}}^\circ(\text{B}, 0) \\ &\quad - RT \left\{ c \ln \frac{q_{\text{C},\text{m}}^\circ}{N_{\text{A}}} + d \ln \frac{q_{\text{D},\text{m}}^\circ}{N_{\text{A}}} - a \ln \frac{q_{\text{A},\text{m}}^\circ}{N_{\text{A}}} - b \ln \frac{q_{\text{B},\text{m}}^\circ}{N_{\text{A}}} \right\} \end{aligned}$$

Because $G(0) = U(0)$, the first term on the right is

$$\Delta_{\text{r}}E_0 = cU_{\text{m}}^\circ(\text{C}, 0) + dU_{\text{m}}^\circ(\text{D}, 0) - aU_{\text{m}}^\circ(\text{A}, 0) - bU_{\text{m}}^\circ(\text{B}, 0) \quad (17.55)$$

the reaction internal energy at $T = 0$ (a molar quantity).

Now we can write

$$\begin{aligned} \Delta_{\text{r}}G^\circ &= \Delta_{\text{r}}E_0 - RT \left\{ \ln \left(\frac{q_{\text{C},\text{m}}^\circ}{N_{\text{A}}} \right)^c + \ln \left(\frac{q_{\text{D},\text{m}}^\circ}{N_{\text{A}}} \right)^d - \ln \left(\frac{q_{\text{A},\text{m}}^\circ}{N_{\text{A}}} \right)^a - \ln \left(\frac{q_{\text{B},\text{m}}^\circ}{N_{\text{A}}} \right)^b \right\} \\ &= \Delta_{\text{r}}E_0 - RT \ln \frac{(q_{\text{C},\text{m}}^\circ/N_{\text{A}})^c (q_{\text{D},\text{m}}^\circ/N_{\text{A}})^d}{(q_{\text{A},\text{m}}^\circ/N_{\text{A}})^a (q_{\text{B},\text{m}}^\circ/N_{\text{A}})^b} \\ &= -RT \left\{ \frac{\Delta_{\text{r}}E_0}{RT} + \ln \frac{(q_{\text{C},\text{m}}^\circ/N_{\text{A}})^c (q_{\text{D},\text{m}}^\circ/N_{\text{A}})^d}{(q_{\text{A},\text{m}}^\circ/N_{\text{A}})^a (q_{\text{B},\text{m}}^\circ/N_{\text{A}})^b} \right\} \end{aligned}$$

At this stage we can pick out an expression for K by comparing this equation with $\Delta_{\text{r}}G^\circ = -RT \ln K$, which gives

$$\ln K = -\frac{\Delta_r E_0}{RT} + \ln \frac{(q_{C,m}^\ominus/N_A)^c (q_{D,m}^\ominus/N_A)^d}{(q_{A,m}^\ominus/N_A)^a (q_{B,m}^\ominus/N_A)^b}$$

This expression is easily rearranged into eqn 17.54a by forming the exponential of both sides.

(b) A dissociation equilibrium

We shall illustrate the application of eqn 17.54 to an equilibrium in which a diatomic molecule X_2 dissociates into its atoms:

According to eqn 17.54 (with $a = 1$, $b = 0$, $c = 2$, and $d = 0$):

$$K = \frac{(q_{X,m}^\ominus/N_A)^2}{q_{X_2,m}^\ominus/N_A} e^{-\Delta_r E_0/RT} = \frac{(q_{X,m}^\ominus)^2}{q_{X_2,m}^\ominus N_A} e^{-\Delta_r E_0/RT} \quad (17.56a)$$

with

$$\Delta_r E_0 = 2U_m^\ominus(X, 0) - U_m^\ominus(X_2, 0) = D_0(X-X) \quad (17.56b)$$

where $D_0(X-X)$ is the dissociation energy of the $X-X$ bond. The standard molar partition functions of the atoms X are

$$q_{X,m}^\ominus = g_X \left(\frac{V_m^\ominus}{\Lambda_X^3} \right) = \frac{RT g_X}{p^\ominus \Lambda_X^3}$$

where g_X is the degeneracy of the electronic ground state of X and we have used $V_m^\ominus = RT/p^\ominus$. The diatomic molecule X_2 also has rotational and vibrational degrees of freedom, so its standard molar partition function is

$$q_{X_2,m}^\ominus = g_{X_2} \left(\frac{V_m^\ominus}{\Lambda_{X_2}^3} \right) q_{X_2}^R q_{X_2}^V = \frac{RT g_{X_2} q_{X_2}^R q_{X_2}^V}{p^\ominus \Lambda_{X_2}^3}$$

where g_{X_2} is the degeneracy of the electronic ground state of X_2 . It follows from eqn 17.54 that the equilibrium constant is

$$K = \frac{kT g_X^2 \Lambda_{X_2}^3}{p^\ominus g_{X_2} q_{X_2}^R q_{X_2}^V \Lambda_X^6} e^{-D_0/RT} \quad (17.57)$$

where we have used $R/N_A = k$. All the quantities in this expression can be calculated from spectroscopic data. The Λ s are defined in Table 17.3 and depend on the masses of the species and the temperature; the expressions for the rotational and vibrational partition functions are also available in Table 17.3 and depend on the rotational constant and vibrational wavenumber of the molecule.

Example 17.6 Evaluating an equilibrium constant

Evaluate the equilibrium constant for the dissociation $Na_2(g) \rightleftharpoons 2 Na(g)$ at 1000 K from the following data: $B = 0.1547 \text{ cm}^{-1}$, $\tilde{\nu} = 159.2 \text{ cm}^{-1}$, $D_0 = 70.4 \text{ kJ mol}^{-1}$. The Na atoms have doublet ground terms.

Method The partition functions required are specified in eqn 17.54. They are evaluated by using the expressions in Table 17.3. For a homonuclear diatomic molecule, $\sigma = 2$. In the evaluation of $kT/p^\ominus$ use $p^\ominus = 10^5 \text{ Pa}$ and $1 \text{ Pa m}^3 = 1 \text{ J}$.

Answer The partition functions and other quantities required are as follows:

$$\Lambda(\text{Na}_2) = 8.14 \text{ pm} \quad \Lambda(\text{Na}) = 11.5 \text{ pm}$$

$$q^{\text{R}}(\text{Na}_2) = 2246 \quad q^{\text{V}}(\text{Na}_2) = 4.885$$

$$g(\text{Na}) = 2 \quad g(\text{Na}_2) = 1$$

Then, from eqn 17.54,

$$K = \frac{(1.38 \times 10^{-23} \text{ J K}^{-1}) \times (1000 \text{ K}) \times 4 \times (8.14 \times 10^{-12} \text{ m})^3}{(10^5 \text{ Pa}) \times 2246 \times 4.885 \times (1.15 \times 10^{-11} \text{ m})^6} \times e^{-8.47}$$

$$= 2.42$$

where we have used $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$ and $1 \text{ Pa} = 1 \text{ kg m}^{-1} \text{ s}^{-1}$.

Self-test 17.7 Evaluate K at 1500 K.

[52]

(c) Contributions to the equilibrium constant

We are now in a position to appreciate the physical basis of equilibrium constants. To see what is involved, consider a simple $\text{R} \rightleftharpoons \text{P}$ gas-phase equilibrium (R for reactants, P for products).

Figure 17.20 shows two sets of energy levels; one set of states belongs to R, and the other belongs to P. The populations of the states are given by the Boltzmann distribution, and are independent of whether any given state happens to belong to R or to P. We can therefore imagine a single Boltzmann distribution spreading, without distinction, over the two sets of states. If the spacings of R and P are similar (as in Fig. 17.20), and P lies above R, the diagram indicates that R will dominate in the equilibrium mixture. However, if P has a high density of states (a large number of states in a given energy range, as in Fig. 17.21), then, even though its zero-point energy lies above that of R, the species P might still dominate at equilibrium.

It is quite easy to show (see the *Justification* below) that the ratio of numbers of R and P molecules at equilibrium is given by

$$\frac{N_{\text{P}}}{N_{\text{R}}} = \frac{q_{\text{P}}}{q_{\text{R}}} e^{-\Delta_r E_0 / RT} \quad (17.58a)$$

and therefore that the equilibrium constant for the reaction is

$$K = \frac{q_{\text{P}}}{q_{\text{R}}} e^{-\Delta_r E_0 / RT} \quad (17.58b)$$

just as would be obtained from eqn 17.54.

Justification 17.5 The equilibrium constant in terms of the partition function 2

The population in a state i of the composite (R,P) system is

$$n_i = \frac{N e^{-\beta \varepsilon_i}}{q}$$

where N is the total number of molecules. The total number of R molecules is the sum of these populations taken over the states belonging to R; these states we label r with energies ε_r . The total number of P molecules is the sum over the states

Fig. 17.20 The array of R(eactants) and P(roduts) energy levels. At equilibrium all are accessible (to differing extents, depending on the temperature), and the equilibrium composition of the system reflects the overall Boltzmann distribution of populations. As ΔE_0 increases, R becomes dominant.

Comment 17.3

For an $\text{R} \rightleftharpoons \text{P}$ equilibrium, the V factors in the partition functions cancel, so the appearance of q in place of q° has no effect. In the case of a more general reaction, the conversion from q to q° comes about at the stage of converting the pressures that occur in K to numbers of molecules.

Fig. 17.21 It is important to take into account the densities of states of the molecules. Even though P might lie well above R in energy (that is, ΔE_0 is large and positive), P might have so many states that its total population dominates in the mixture. In classical thermodynamic terms, we have to take entropies into account as well as enthalpies when considering equilibria.

Fig. 17.22 The model used in the text for exploring the effects of energy separations and densities of states on equilibria. The products P can dominate provided ΔE_0 is not too large and P has an appreciable density of states.

belonging to P; these states we label p with energies ε'_p (the prime is explained in a moment):

$$N_R = \sum_r n_r = \frac{N}{q} \sum_r e^{-\beta \varepsilon_r} \quad N_P = \sum_p n_p = \frac{N}{q} \sum_p e^{-\beta \varepsilon'_p}$$

The sum over the states of R is its partition function, q_R , so

$$N_R = \frac{N q_R}{q}$$

The sum over the states of P is also a partition function, but the energies are measured from the ground state of the combined system, which is the ground state of R. However, because $\varepsilon'_p = \varepsilon_p + \Delta \varepsilon_0$, where $\Delta \varepsilon_0$ is the separation of zero-point energies (as in Fig. 17.21),

$$N_P = \frac{N}{q} \sum_p e^{-\beta(\varepsilon_p + \Delta \varepsilon_0)} = \frac{N}{q} \left(\sum_p e^{-\beta \varepsilon_p} \right) e^{-\beta \Delta \varepsilon_0} = \frac{N q_P}{q} e^{-\Delta_r E_0 / RT}$$

The switch from $\Delta \varepsilon_0/k$ to $\Delta_r E_0/R$ in the last step is the conversion of molecular energies to molar energies.

The equilibrium constant of the $R \rightleftharpoons P$ reaction is proportional to the ratio of the numbers of the two types of molecule. Therefore,

$$K = \frac{N_P}{N_R} = \frac{q_P}{q_R} e^{-\Delta_r E_0 / RT}$$

as in eqn 17.58b.

The content of eqn 17.58 can be seen most clearly by exaggerating the molecular features that contribute to it. We shall suppose that R has only a single accessible level, which implies that $q_R = 1$. We also suppose that P has a large number of evenly, closely spaced levels (Fig. 17.22). The partition function of P is then $q_P = kT/\varepsilon$. In this model system, the equilibrium constant is

$$K = \frac{kT}{\varepsilon} e^{-\Delta_r E_0 / RT} \quad (17.59)$$

When $\Delta_r E_0$ is very large, the exponential term dominates and $K \ll 1$, which implies that very little P is present at equilibrium. When $\Delta_r E_0$ is small but still positive, K can exceed 1 because the factor kT/ε may be large enough to overcome the small size of the exponential term. The size of K then reflects the predominance of P at equilibrium on account of its high density of states. At low temperatures $K \ll 1$ and the system consists entirely of R. At high temperatures the exponential function approaches 1 and the pre-exponential factor is large. Hence P becomes dominant. We see that, in this endothermic reaction (endothermic because P lies above R), a rise in temperature favours P, because its states become accessible. This behaviour is what we saw, from the outside, in Chapter 7.

The model also shows why the Gibbs energy, G , and not just the enthalpy, determines the position of equilibrium. It shows that the density of states (and hence the entropy) of each species as well as their relative energies controls the distribution of populations and hence the value of the equilibrium constant.

Checklist of key ideas

- ☐ 1. The molecular partition function can be written as $q = q^T q^R q^V q^E$, with the contributions summarized in Table 17.3.
- ☐ 2. Thermodynamic functions can be expressed in terms of the partition function as summarized in Table 17.4.
- ☐ 3. The mean energy of a mode is $\langle \epsilon^M \rangle = -(1/q^M)(\partial q^M / \partial \beta)_V$, with the contributions from each mode summarized in Table 17.5.
- ☐ 4. The contribution of a mode M to the constant-volume heat capacity is $C_V^M = -Nk\beta(\partial \langle \epsilon^M \rangle / \partial \beta)_V$, with the contributions from each mode summarized in Table 17.5.
- ☐ 5. The overall heat capacity is written as $C_{V,m} = \frac{1}{2}(3 + \nu_R^* + 2\nu_V^*)R$
- ☐ 6. The canonical partition function of a gas is $Q = Z/\Lambda^{3N}$, where Z is the configuration integral: $Z = V^N/N!$ for a perfect gas, and $Z = (1/N!) \int e^{-\beta E_p} d\tau_1 d\tau_2 \dots d\tau_N$ for a real gas.
- ☐ 7. In the virial equation of state, the second virial coefficient can be written as $B = -(N_A/2V) \int f d\tau_1 d\tau_2$, where the Mayer f -function is $f = e^{-\beta E_p} - 1$.
- ☐ 8. The radial distribution function, $g(r)$, where $g(r)r^2 dr$ is the probability that a molecule will be found in the range dr at a distance r from another molecule. The internal energy and pressure of a fluid may be expressed in terms of the radial distribution function (eqns 17.50 and 17.51, respectively).
- ☐ 9. The residual entropy is a non-zero entropy at $T = 0$ arising from molecular disorder.
- ☐ 10. The equilibrium constant can be written in terms of the partition function (eqn 17.54).

Table 17.5 Contributions to mean energies and heat capacities

Mode	Expression	
	Mean energy	Heat capacity*
General mode, M	$\langle \epsilon^M \rangle = - \left(\frac{\partial \ln q^M}{\partial \beta} \right)_V = - \frac{1}{q^M} \left(\frac{\partial q^M}{\partial \beta} \right)_V$	$C_V^M = -Nk\beta^2 \left(\frac{\partial \langle \epsilon^M \rangle}{\partial \beta} \right)_V$
Translation	$\langle \epsilon^T \rangle = \frac{3}{2}kT$	$C_V^T = \frac{3}{2}nR$
Rotation ($T \gg \theta_R$)	$\langle \epsilon^R \rangle = kT$, linear molecules	$C^R = nR$, linear molecules
	$\langle \epsilon^R \rangle = \frac{3}{2}kT$, nonlinear molecules	$C^R = \frac{3}{2}nR$, nonlinear molecules
Vibration	$\langle \epsilon^V \rangle = \frac{h\nu}{e^{-\theta_V/T} - 1} = \frac{h\nu}{e^{\theta_V/T} - 1}$	$C^V = nRf$, $f = \left(\frac{\theta_V}{T} \right)^2 \frac{e^{-\theta_V/T}}{(1 - e^{-\theta_V/T})^2}$
Vibration ($T \gg \theta_V$)	$\langle \epsilon^V \rangle = kT$	$C^V = nR$

* No distinction need be made between C_V and C_p for internal modes.

Discussion questions

17.1 Discuss the limitations of the expressions $q^R = kT/hcB$, $q^V = kT/hc\bar{\nu}$, and $q^E = g^E$.

17.2 Explain the origin of the symmetry number.

17.3 Explain the origin of residual entropy.

17.4 Use concepts of statistical thermodynamics to describe the molecular features that determine the magnitudes of the constant-volume molar heat capacity of a molecular substance.

17.5 Use concepts of statistical thermodynamics to describe the molecular features that lead to the equations of state of perfect and real gases.

17.6 Describe how liquids are investigated by using concepts of statistical thermodynamics.

17.7 Use concepts of statistical thermodynamics to describe the molecular features that determine the magnitudes of equilibrium constants and their variation with temperature.

Exercises

17.1a Use the equipartition theorem to estimate the constant-volume molar heat capacity of (a) I_2 , (b) CH_4 , (c) C_6H_6 in the gas phase at $25^\circ C$.

17.1b Use the equipartition theorem to estimate the constant-volume molar heat capacity of (a) O_3 , (b) C_2H_6 , (c) CO_2 in the gas phase at $25^\circ C$.

17.2a Estimate the values of $\gamma = C_p/C_V$ for gaseous ammonia and methane. Do this calculation with and without the vibrational contribution to the energy. Which is closer to the expected experimental value at $25^\circ C$?

17.2b Estimate the value of $\gamma = C_p/C_V$ for carbon dioxide. Do this calculation with and without the vibrational contribution to the energy. Which is closer to the expected experimental value at $25^\circ C$?

17.3a Estimate the rotational partition function of HCl at (a) $25^\circ C$ and (b) $250^\circ C$.

17.3b Estimate the rotational partition function of O_2 at (a) $25^\circ C$ and (b) $250^\circ C$.

17.4a Give the symmetry number for each of the following molecules:

(a) CO , (b) O_2 , (c) H_2S , and (d) SiH_4 , (e) $CHCl_3$.

17.4b Give the symmetry number for each of the following molecules:

(a) CO_2 , (b) O_3 , (c) SO_3 , (d) SF_6 , and (e) Al_2Cl_6 .

17.5a Calculate the rotational partition function of H_2O at 298 K from its rotational constants 27.878 cm^{-1} , 14.509 cm^{-1} , and 9.287 cm^{-1} . Above what temperature is the high-temperature approximation valid to within 10 per cent of the true value?

17.5b Calculate the rotational partition function of SO_2 at 298 K from its rotational constants 2.02736 cm^{-1} , 0.34417 cm^{-1} , and 0.293535 cm^{-1} . Above what temperature is the high-temperature approximation valid to within 10 per cent of the true value?

17.6a From the results of Exercise 17.5a, calculate the rotational contribution to the molar entropy of gaseous water at $25^\circ C$.

17.6b From the results of Exercise 17.5b, calculate the rotational contribution to the molar entropy of sulfur dioxide at $25^\circ C$.

17.7a Calculate the rotational partition function of CH_4 (a) by direct summation of the energy levels at 298 K and 500 K, and (b) by the high-temperature approximation. Take $B = 5.2412\text{ cm}^{-1}$.

17.7b Calculate the rotational partition function of CH_3CN (a) by direct summation of the energy levels at 298 K and 500 K, and (b) by the high-temperature approximation. Take $A = 5.28\text{ cm}^{-1}$ and $B = 0.307\text{ cm}^{-1}$.

17.8a The bond length of O_2 is 120.75 pm. Use the high-temperature approximation to calculate the rotational partition function of the molecule at 300 K.

17.8b The NOF molecule is an asymmetric rotor with rotational constants 3.1752 cm^{-1} , 0.3951 cm^{-1} , and 0.3505 cm^{-1} . Calculate the rotational partition function of the molecule at (a) $25^\circ C$, (b) $100^\circ C$.

17.9a Plot the molar heat capacity of a collection of harmonic oscillators as a function of T/θ_V , and predict the vibrational heat capacity of ethyne at (a) 298 K, (b) 500 K. The normal modes (and their degeneracies in parentheses) occur at wavenumbers $612(2)$, $729(2)$, 1974 , 3287 , and 3374 cm^{-1} .

17.9b Plot the molar entropy of a collection of harmonic oscillators as a function of T/θ_V , and predict the standard molar entropy of ethyne at (a) 298 K, (b) 500 K. For data, see the preceding exercise.

17.10a A CO_2 molecule is linear, and its vibrational wavenumbers are 1388.2 cm^{-1} , 667.4 cm^{-1} , and 2349.2 cm^{-1} , the last being doubly degenerate and the others non-degenerate. The rotational constant of the molecule is 0.3902 cm^{-1} . Calculate the rotational and vibrational contributions to the molar Gibbs energy at 298 K.

17.10b An O_3 molecule is angular, and its vibrational wavenumbers are 1110 cm^{-1} , 705 cm^{-1} , and 1042 cm^{-1} . The rotational constants of the molecule are 3.553 cm^{-1} , 0.4452 cm^{-1} , and 0.3948 cm^{-1} . Calculate the rotational and vibrational contributions to the molar Gibbs energy at 298 K.

17.11a The ground level of Cl is $^2P_{3/2}$ and a $^2P_{1/2}$ level lies 881 cm^{-1} above it. Calculate the electronic contribution to the heat capacity of Cl atoms at (a) 500 K and (b) 900 K.

17.11b The first electronically excited state of O_2 is $^1\Delta_g$ and lies 7918.1 cm^{-1} above the ground state, which is $^3\Sigma_g^-$. Calculate the electronic contribution to the molar Gibbs energy of O_2 at 400 K.

17.12a The ground state of the Co^{2+} ion in $CoSO_4 \cdot 7H_2O$ may be regarded as $^4T_{9/2}$. The entropy of the solid at temperatures below 1 K is derived almost entirely from the electron spin. Estimate the molar entropy of the solid at these temperatures.

17.12b Estimate the contribution of the spin to the molar entropy of a solid sample of a d -metal complex with $S = \frac{5}{2}$.

17.13a Calculate the residual molar entropy of a solid in which the molecules can adopt (a) three, (b) five, (c) six orientations of equal energy at $T = 0$.

17.13b Suppose that the hexagonal molecule $C_6H_nF_{6-n}$ has a residual entropy on account of the similarity of the H and F atoms. Calculate the residual for each value of n .

17.14a Calculate the equilibrium constant of the reaction $I_2(g) \rightleftharpoons 2I(g)$ at 1000 K from the following data for I_2 : $\bar{\nu} = 214.36\text{ cm}^{-1}$, $B = 0.0373\text{ cm}^{-1}$, $D_e = 1.5422\text{ eV}$. The ground state of the I atoms is $^2P_{3/2}$, implying fourfold degeneracy.

17.14b Calculate the value of K at 298 K for the gas-phase isotopic exchange reaction $2\text{}^{79}\text{Br}^{81}\text{Br} \rightleftharpoons \text{Br} + \text{}^{81}\text{Br}^{81}\text{Br}$. The Br_2 molecule has a non-degenerate ground state, with no other electronic states nearby. Base the calculation on the wavenumber of the vibration of $^{79}\text{Br}^{81}\text{Br}$, which is 323.33 cm^{-1} .

Problems*

Numerical problems

17.1 The NO molecule has a doubly degenerate electronic ground state and a doubly degenerate excited state at 121.1 cm^{-1} . Calculate the electronic contribution to the molar heat capacity of the molecule at (a) 50 K, (b) 298 K, and (c) 500 K.

17.2 Explore whether a magnetic field can influence the heat capacity of a paramagnetic molecule by calculating the electronic contribution to the heat capacity of an NO_2 molecule in a magnetic field. Estimate the total constant-volume heat capacity using equipartition, and calculate the percentage change in heat capacity brought about by a 5.0 T magnetic field at (a) 50 K, (b) 298 K.

17.3 The energy levels of a CH_3 group attached to a larger fragment are given by the expression for a particle on a ring, provided the group is rotating freely. What is the high-temperature contribution to the heat capacity and entropy of such a freely rotating group at 25°C ? The moment of inertia of CH_3 about its three-fold rotation axis (the axis that passes through the C atom and the centre of the equilateral triangle formed by the H atoms) is $5.341 \times 10^{-47}\text{ kg m}^2$.

17.4 Calculate the temperature dependence of the heat capacity of $p\text{-H}_2$ (in which only rotational states with even values of J are populated) at low temperatures on the basis that its rotational levels $J=0$ and $J=2$ constitute a system that resembles a two-level system except for the degeneracy of the upper level. Use $B = 60.864\text{ cm}^{-1}$ and sketch the heat capacity curve. The experimental heat capacity of $p\text{-H}_2$ does in fact show a peak at low temperatures.

17.5 The pure rotational microwave spectrum of HCl has absorption lines at the following wavenumbers (in cm^{-1}): 21.19, 42.37, 63.56, 84.75, 105.93, 127.12, 148.31, 169.49, 190.68, 211.87, 233.06, 254.24, 275.43, 296.62, 317.80, 338.99, 360.18, 381.36, 402.55, 423.74, 444.92, 466.11, 487.30, 508.48. Calculate the rotational partition function at 25°C by direct summation.

17.6 Calculate the standard molar entropy of $\text{N}_2(\text{g})$ at 298 K from its rotational constant $B = 1.9987\text{ cm}^{-1}$ and its vibrational wavenumber $\tilde{\nu} = 2358\text{ cm}^{-1}$. The thermochemical value is $192.1\text{ J K}^{-1}\text{ mol}^{-1}$. What does this suggest about the solid at $T = 0$?

17.7‡ J.G. Dojahn, E.C.M. Chen, and W.E. Wentworth (*J. Phys. Chem.* **100**, 9649 (1996)) characterized the potential energy curves of the ground and electronic states of homonuclear diatomic halogen anions. The ground state of F_2^- is $^2\Sigma_u^+$ with a fundamental vibrational wavenumber of 450.0 cm^{-1} and equilibrium internuclear distance of 190.0 pm. The first two excited states are at 1.609 and 1.702 eV above the ground state. Compute the standard molar entropy of F_2^- at 298 K.

17.8‡ In a spectroscopic study of buckminsterfullerene C_{60} , F. Negri, G. Orlandi, and F. Zerbetto (*J. Phys. Chem.* **100**, 10849 (1996)) reviewed the wavenumbers of all the vibrational modes of the molecule. The wavenumber for the single A_u mode is 976 cm^{-1} ; wavenumbers for the four threefold degenerate T_{1u} modes are 525, 578, 1180, and 1430 cm^{-1} ; wavenumbers for the five threefold degenerate T_{2u} modes are 354, 715, 1037, 1190, and 1540 cm^{-1} ; wavenumbers for the six fourfold degenerate G_u modes are 345, 757, 776, 963, 1315, and 1410 cm^{-1} ; and wavenumbers for the seven fivefold degenerate H_u modes are 403, 525, 667, 738, 1215, 1342, and 1566 cm^{-1} . How many modes have a vibrational temperature θ_v below 1000 K? Estimate the molar constant-volume heat capacity of C_{60} at 1000 K, counting as active all modes with θ_v below this temperature.

17.9‡ Treat carbon monoxide as a perfect gas and apply equilibrium statistical thermodynamics to the study of its properties, as specified below, in the temperature range 100–1000 K at 1 bar. $\tilde{\nu} = 2169.8\text{ cm}^{-1}$, $B = 1.931\text{ cm}^{-1}$, and $D_0 = 11.09\text{ eV}$; neglect anharmonicity and centrifugal distortion. (a) Examine the probability distribution of molecules over available rotational and vibrational states. (b) Explore numerically the differences, if any, between the rotational molecular partition function as calculated with the discrete energy distribution and that calculated with the classical, continuous energy distribution. (c) Calculate the individual contributions to $U_m(T) - U_m(100\text{ K})$, $C_{v,m}(T)$, and $S_m(T) - S_m(100\text{ K})$ made by the translational, rotational, and vibrational degrees of freedom.

17.10 Calculate and plot as a function of temperature, in the range 300 K to 1000 K, the equilibrium constant for the reaction $\text{CD}_4(\text{g}) + \text{HCl}(\text{g}) \rightleftharpoons \text{CHD}_3(\text{g}) + \text{DCl}(\text{g})$ using the following data (numbers in parentheses are degeneracies): $\tilde{\nu}(\text{CHD}_3)/\text{cm}^{-1} = 2993(1), 2142(1), 1003(3), 1291(2), 1036(2)$; $\tilde{\nu}(\text{CD}_4)/\text{cm}^{-1} = 2109(1), 1092(2), 2259(3), 996(3)$; $\tilde{\nu}(\text{HCl})/\text{cm}^{-1} = 2991$; $\tilde{\nu}(\text{DCl})/\text{cm}^{-1} = 2145$; $B(\text{HCl})/\text{cm}^{-1} = 10.59$; $B(\text{DCl})/\text{cm}^{-1} = 5.445$; $B(\text{CHD}_3)/\text{cm}^{-1} = 3.28$; $A(\text{CHD}_3)/\text{cm}^{-1} = 2.63$, $B(\text{CD}_4)/\text{cm}^{-1} = 2.63$.

17.11 The exchange of deuterium between acid and water is an important type of equilibrium, and we can examine it using spectroscopic data on the molecules. Calculate the equilibrium constant at (a) 298 K and (b) 800 K for the gas-phase exchange reaction $\text{H}_2\text{O} + \text{DCl} \rightleftharpoons \text{HDO} + \text{HCl}$ from the following data: $\tilde{\nu}(\text{H}_2\text{O})/\text{cm}^{-1} = 3656.7, 1594.8, 3755.8$; $\tilde{\nu}(\text{HDO})/\text{cm}^{-1} = 2726.7, 1402.2, 3707.5$; $A(\text{H}_2\text{O})/\text{cm}^{-1} = 27.88$; $B(\text{H}_2\text{O})/\text{cm}^{-1} = 14.51$; $C(\text{H}_2\text{O})/\text{cm}^{-1} = 9.29$; $A(\text{HDO})/\text{cm}^{-1} = 23.38$; $B(\text{HDO})/\text{cm}^{-1} = 9.102$; $C(\text{HDO})/\text{cm}^{-1} = 6.417$; $B(\text{HCl})/\text{cm}^{-1} = 10.59$; $B(\text{DCl})/\text{cm}^{-1} = 5.449$; $\tilde{\nu}(\text{HCl})/\text{cm}^{-1} = 2991$; $\tilde{\nu}(\text{DCl})/\text{cm}^{-1} = 2145$.

Theoretical problems

17.12 Derive the Sackur–Tetrode equation for a monatomic gas confined to a two-dimensional surface, and hence derive an expression for the standard molar entropy of condensation to form a mobile surface film.

17.13‡ For H_2 at very low temperatures, only translational motion contributes to the heat capacity. At temperatures above $\theta_R = hcB/k$, the rotational contribution to the heat capacity becomes significant. At still higher temperatures, above $\theta_v = hv/k$, the vibrations contribute. But at this latter temperature, dissociation of the molecule into the atoms must be considered. (a) Explain the origin of the expressions for θ_R and θ_v , and calculate their values for hydrogen. (b) Obtain an expression for the molar constant-pressure heat capacity of hydrogen at all temperatures taking into account the dissociation of hydrogen. (c) Make a plot of the molar constant-pressure heat capacity as a function of temperature in the high-temperature region where dissociation of the molecule is significant.

17.14 Derive expressions for the internal energy, heat capacity, entropy, Helmholtz energy, and Gibbs energy of a harmonic oscillator. Express the results in terms of the vibrational temperature, θ_v and plot graphs of each property against T/θ_v .

17.15 Suppose that an intermolecular potential has a hard-sphere core of radius r_1 and a shallow attractive well of uniform depth ε out to a distance r_2 . Show, by using eqn 17.42 and the condition $\varepsilon \ll kT$, that such a model is approximately consistent with a van der Waals equation of state when $b \ll V_m$, and relate the van der Waals parameters and the Joule–Thomson coefficient to the parameters in this model.

* Problems denoted with the symbol ‡ were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

17.16† (a) Show that the number of molecules in any given rotational state of a linear molecule is given by $N_j = C(2J+1)e^{-hcB(J+1/2)/kT}$, where C is independent of J . (b) Use this result to derive eqn 13.39 for the value of J of the most highly populated rotational level. (c) Estimate the temperature at which the spectrum of HCl shown in Fig. 13.44 was obtained. (d) What is the most highly populated level of a spherical rotor at a temperature T ?

17.17 A more formal way of arriving at the value of the symmetry number is to note that σ is the order (the number of elements) of the *rotational subgroup* of the molecule, the point group of the molecule with all but the identity and the rotations removed. The rotational subgroup of H_2O is $\{E, C_2\}$, so $\sigma = 2$. The rotational subgroup of NH_3 is $\{E, 2C_3\}$, so $\sigma = 3$. This recipe makes it easy to find the symmetry numbers for more complicated molecules. The rotational subgroup of CH_4 is obtained from the T character table as $\{E, 8C_3, 3C_2\}$, so $\sigma = 12$. For benzene, the rotational subgroup of D_{6h} is $\{E, 2C_6, 2C_3, C_2, 3C_2', 3C_2''\}$, so $\sigma = 12$. (a) Estimate the rotational partition function of ethene at 25°C given that $A = 4.828\text{ cm}^{-1}$, $B = 1.0012\text{ cm}^{-1}$, and $C = 0.8282\text{ cm}^{-1}$. (b) Evaluate the rotational partition function of pyridine, $\text{C}_5\text{H}_5\text{N}$, at room temperature ($A = 0.2014\text{ cm}^{-1}$, $B = 0.1936\text{ cm}^{-1}$, $C = 0.0987\text{ cm}^{-1}$).

17.18 Although expressions like $\langle \epsilon \rangle = -d \ln q / d\beta$ are useful for formal manipulations in statistical thermodynamics, and for expressing thermodynamic functions in neat formulas, they are sometimes more trouble than they are worth in practical applications. When presented with a table of energy levels, it is often much more convenient to evaluate the following sums directly:

$$q = \sum_j e^{-\beta \epsilon_j} \quad \bar{\epsilon} = \frac{\sum_j \epsilon_j e^{-\beta \epsilon_j}}{q} \quad \bar{\epsilon}^2 = \frac{\sum_j \epsilon_j^2 e^{-\beta \epsilon_j}}{q}$$

(a) Derive expressions for the internal energy, heat capacity, and entropy in terms of these three functions. (b) Apply the technique to the calculation of the electronic contribution to the constant-volume molar heat capacity of magnesium vapour at 5000 K using the following data:

Term	$1S$	$3P_0$	$3P_1$	$3P_2$	$1P_1$	$3S_1$
Degeneracy	1	1	3	5	3	3
$\bar{\nu}/\text{cm}^{-1}$	0	21 850	21 870	21 911	35 051	41 197

17.19 Show how the heat capacity of a linear rotor is related to the following sum:

$$\zeta(\beta) = \frac{1}{q^2} \sum_{J,J'} \{ \epsilon(J) - \epsilon(J') \}^2 g(J) g(J') e^{-\beta[\epsilon(J) + \epsilon(J')]}$$

by

$$C = \frac{1}{2} N k \beta^2 \zeta(\beta)$$

where the $\epsilon(J)$ are the rotational energy levels and $g(J)$ their degeneracies. Then go on to show graphically that the total contribution to the heat capacity of a linear rotor can be regarded as a sum of contributions due to transitions $0 \rightarrow 1$, $0 \rightarrow 2$, $1 \rightarrow 2$, $1 \rightarrow 3$, etc. In this way, construct Fig. 17.11 for the rotational heat capacities of a linear molecule.

17.20 Set up a calculation like that in Problem 17.19 to analyse the vibrational contribution to the heat capacity in terms of excitations between levels and illustrate your results graphically in terms of a diagram like that in Fig. 17.11.

17.21 Determine whether a magnetic field can influence the value of an equilibrium constant. Consider the equilibrium $\text{I}_2(\text{g}) \rightleftharpoons 2\text{I}(\text{g})$ at 1000 K, and calculate the ratio of equilibrium constants $K(\mathcal{B})/K$, where $K(\mathcal{B})$ is the equilibrium constant when a magnetic field $\mathcal{B}$ is present and removes the degeneracy of the four states of the $2P_{3/2}$ level. Data on the species are given in Exercise 17.14a. The electronic g value of the atoms is $\frac{4}{3}$. Calculate the field required to change the equilibrium constant by 1 per cent.

17.22 The heat capacity ratio of a gas determines the speed of sound in it through the formula $c_s = (\gamma RT/M)^{1/2}$, where $\gamma = C_p/C_v$ and M is the molar mass of the gas. Deduce an expression for the speed of sound in a perfect gas of (a) diatomic, (b) linear triatomic, (c) nonlinear triatomic molecules at high temperatures (with translation and rotation active). Estimate the speed of sound in air at 25°C .

Applications: to biology, materials science, environmental science, and astrophysics

17.23 An average human DNA molecule has 5×10^8 binucleotides (rungs on the DNA ladder) of four different kinds. If each rung were a random choice of one of these four possibilities, what would be the residual entropy associated with this typical DNA molecule?

17.24 It is possible to write an approximate expression for the partition function of a protein molecule by including contributions from only two states: the native and denatured forms of the polymer. Proceeding with this crude model gives us insight into the contribution of denaturation to the heat capacity of a protein. It follows from *Illustration* 16.4 that the total energy of a system of N protein molecules is

$$E = \frac{N\epsilon e^{-\epsilon/kT}}{1 + e^{-\epsilon/kT}}$$

where ϵ is the energy separation between the denatured and native forms.

(a) Show that the constant-volume molar heat capacity is

$$C_{V,m} = \frac{R(\epsilon_m/RT)^2 e^{-\epsilon_m/RT}}{(1 + e^{-\epsilon_m/RT})^2}$$

Hint. For two functions f and g , the quotient rule of differentiation states that $d(f/g)/dx = (1/g)df/dx - (f/g^2)dg/dx$. (b) Plot the variation of $C_{V,m}$ with temperature. (c) If the function $C_{V,m}(T)$ has a maximum or minimum, derive an expression for the temperature at which it occurs.

17.25† R. Viswanathan, R.W. Schmude, Jr., and K.A. Gingerich (*J. Phys. Chem.* **100**, 10784 (1996)) studied thermodynamic properties of several boron–silicon gas-phase species experimentally and theoretically. These species can occur in the high-temperature chemical vapour deposition (CVD) of silicon-based semiconductors. Among the computations they reported was computation of the Gibbs energy of $\text{BSi}(\text{g})$ at several temperatures based on a $4\Sigma^-$ ground state with equilibrium internuclear distance of 190.5 pm and fundamental vibrational wavenumber of 772 cm^{-1} and a $2P_0$ first excited level 8000 cm^{-1} above the ground level. Compute the standard molar Gibbs energy $G_m^\circ(2000\text{ K}) - G_m^\circ(0)$.

17.26† The molecule Cl_2O_2 , which is believed to participate in the seasonal depletion of ozone over Antarctica, has been studied by several means. M. Birk, R.R. Friedl, E.A. Cohen, H.M. Pickett, and S.P. Sander (*J. Chem. Phys.* **91**, 6588 (1989)) report its rotational constants (actually cB) as 13 109.4, 2409.8, and 2139.7 MHz. They also report that its rotational spectrum indicates a molecule with a symmetry number of 2. J. Jacobs, M. Kronberg, H.S.P. Möller, and H. Willner (*J. Amer. Chem. Soc.* **116**, 1106 (1994)) report its vibrational wavenumbers as 753, 542, 310, 127, 646, and 419 cm^{-1} . Compute $G_m^\circ(200\text{ K}) - G_m^\circ(0)$ of Cl_2O_2 .

17.27† J. Hutter, H.P. Lüthi, and F. Diederich (*J. Amer. Chem. Soc.* **116**, 750 (1994)) examined the geometric and vibrational structure of several carbon molecules of formula C_n . Given that the ground state of C_3 , a molecule found in interstellar space and in flames, is an angular singlet with moments of inertia 39.340, 39.032, and 0.3082 u Å^2 (where $1\text{ Å} = 10^{-10}\text{ m}$) and with vibrational wavenumbers of 63.4, 1224.5, and 2040 cm^{-1} , compute $G_m^\circ(10.00\text{ K}) - G_m^\circ(0)$ and $G_m^\circ(1000\text{ K}) - G_m^\circ(0)$ for C_3 .

Problems

In this chapter we examine molecular interactions in gases and liquids and interpret them in terms of electric properties of molecules, such as electric dipole moments and polarizabilities. All these properties reflect the degree to which the nuclei of atoms exert control over the electrons in a molecule, either by causing electrons to accumulate in particular regions, or by permitting them to respond more or less strongly to the effects of external electric fields.

Molecular interactions are responsible for the unique properties of substances as simple as water and as complex as polymers. We begin our examination of molecular interactions by describing the electric properties of molecules, which may be interpreted in terms of concepts in electronic structure introduced in Chapter 11. We shall see that small imbalances of charge distributions in molecules allow them to interact with one another and with externally applied fields. One result of this interaction is the cohesion of molecules to form the bulk phases of matter. These interactions are also important for understanding the shapes adopted by biological and synthetic macromolecules, as we shall see in Chapter 19. The interaction between ions is treated in Chapter 5 (for solutions) and Chapter 20 (for solids).

Electric properties of molecules

Many of the electric properties of molecules can be traced to the competing influences of nuclei with different charges or the competition between the control exercised by a nucleus and the influence of an externally applied field. The former competition may result in an electric dipole moment. The latter may result in properties such as refractive index and optical activity.

18.1 Electric dipole moments

An **electric dipole** consists of two electric charges $+q$ and $-q$ separated by a distance R . This arrangement of charges is represented by a vector $\boldsymbol{\mu}$ (1). The magnitude of $\boldsymbol{\mu}$ is $\mu = qR$ and, although the SI unit of dipole moment is coulomb metre (C m), it is still commonly reported in the non-SI unit debye, D, named after Peter Debye, a pioneer in the study of dipole moments of molecules, where

$$1 \text{ D} = 3.335\,64 \times 10^{-30} \text{ C m} \quad (18.1)$$

The dipole moment of a pair of charges $+e$ and $-e$ separated by 100 pm is $1.6 \times 10^{-29} \text{ C m}$, corresponding to 4.8 D. Dipole moments of small molecules are typically about 1 D. The conversion factor in eqn 18.1 stems from the original definition of the debye in terms of c.g.s. units: 1 D is the dipole moment of two equal and opposite charges of magnitude 1 e.s.u. separated by 1 Å.

(a) Polar molecules

A **polar molecule** is a molecule with a permanent electric dipole moment. The permanent dipole moment stems from the partial charges on the atoms in the molecule that arise from differences in electronegativity or other features of bonding (Section 11.6). Nonpolar molecules acquire an induced dipole moment in an electric field on account of the distortion the field causes in their electronic distributions and nuclear positions; however, this induced moment is only temporary, and disappears as soon as the perturbing field is removed. Polar molecules also have their existing dipole moments temporarily modified by an applied field.

The Stark effect (Section 13.5) is used to measure the electric dipole moments of molecules for which a rotational spectrum can be observed. In many cases microwave spectroscopy cannot be used because the sample is not volatile, decomposes on vaporization, or consists of molecules that are so complex that their rotational spectra cannot be interpreted. In such cases the dipole moment may be obtained by measurements on a liquid or solid bulk sample using a method explained later. Computational software is now widely available, and typically computes electric dipole moments by assessing the electron density at each point in the molecule and its coordinates relative to the centroid of the molecule; however, it is still important to be able to formulate simple models of the origin of these moments and to understand how they arise. The following paragraphs focus on this aspect.

All heteronuclear diatomic molecules are polar, and typical values of μ include 1.08 D for HCl and 0.42 D for HI (Table 18.1). Molecular symmetry is of the greatest importance in deciding whether a polyatomic molecule is polar or not. Indeed, molecular symmetry is more important than the question of whether or not the atoms in the molecule belong to the same element. Homonuclear polyatomic molecules may be polar if they have low symmetry and the atoms are in inequivalent positions. For instance, the angular molecule ozone, O_3 (2), is homonuclear; however, it is polar because the central O atom is different from the outer two (it is bonded to two atoms, they are bonded only to one); moreover, the dipole moments associated with each bond make an angle to each other and do not cancel. Heteronuclear polyatomic molecules may be nonpolar if they have high symmetry, because individual bond dipoles may then cancel. The heteronuclear linear triatomic molecule CO_2 , for example, is nonpolar because, although there are partial charges on all three atoms, the dipole moment associated with the OC bond points in the opposite direction to the dipole moment associated with the CO bond, and the two cancel (3).

To a first approximation, it is possible to resolve the dipole moment of a polyatomic molecule into contributions from various groups of atoms in the molecule and the directions in which these individual contributions lie (Fig. 18.1). Thus,

Synoptic table 18.1* Dipole moments (μ) and polarizability volumes (α')

	μ/D	$\alpha'/(10^{-30} \text{ m}^3)$
CCl_4	0	10.5
H_2	0	0.819
H_2O	1.85	1.48
HCl	1.08	2.63
HI	0.42	5.45

* More values are given in the Data section.

1 Electric dipole

Comment 18.1

In elementary chemistry, an electric dipole moment is represented by the arrow $\rightarrow$ added to the Lewis structure for the molecule, with the + marking the positive end. Note that the direction of the arrow is opposite to that of μ .

Fig. 18.1 The resultant dipole moments (pale yellow) of the dichlorobenzene isomers (b to d) can be obtained approximately by vectorial addition of two chlorobenzene dipole moments (1.57 D), purple.

4 Addition of dipole moments

Comment 18.2

Operations involving vectors are described in *Appendix 2*, where eqn 18.2 is also derived.

Comment 18.3

In three dimensions, a vector μ has components μ_x , μ_y , and μ_z along the x -, y -, and z -axes, respectively, as shown in the illustration. The direction of each of the components is denoted with a plus sign or minus sign. For example, if $\mu_x = -1.0$ D, the x -component of the vector μ has a magnitude of 1.0 D and points in the $-x$ direction.

5 Amide group

Table 18.2 Partial charges in polypeptides

Atom	Partial charge/ e
C(=O)	+0.45
C(-CO)	+0.06
H(-C)	+0.02
H(-N)	+0.18
H(-O)	+0.42
N	-0.36
O	-0.38

1,4-dichlorobenzene is nonpolar by symmetry on account of the cancellation of two equal but opposing C—Cl moments (exactly as in carbon dioxide). 1,2-Dichlorobenzene, however, has a dipole moment which is approximately the resultant of two chlorobenzene dipole moments arranged at 60° to each other. This technique of ‘vector addition’ can be applied with fair success to other series of related molecules, and the resultant μ_{res} of two dipole moments μ_1 and μ_2 that make an angle θ to each other (4) is approximately

$$\mu_{\text{res}} \approx (\mu_1^2 + \mu_2^2 + 2\mu_1\mu_2 \cos \theta)^{1/2} \quad (18.2a)$$

When the two dipole moments have the same magnitude (as in the dichlorobenzenes), this equation simplifies to

$$\mu_{\text{res}} \approx 2\mu_1 \cos \frac{1}{2}\theta \quad (18.2b)$$

Self-test 18.1 Estimate the ratio of the electric dipole moments of *ortho* (1,2-) and *meta* (1,3-) disubstituted benzenes. [$\mu(\text{ortho})/\mu(\text{meta}) = 1.7$]

A better approach to the calculation of dipole moments is to take into account the locations and magnitudes of the partial charges on all the atoms. These partial charges are included in the output of many molecular structure software packages. To calculate the x -component, for instance, we need to know the partial charge on each atom and the atom’s x -coordinate relative to a point in the molecule and form the sum

$$\mu_x = \sum_j q_j x_j \quad (18.3a)$$

Here q_j is the partial charge of atom J , x_j is the x -coordinate of atom J , and the sum is over all the atoms in the molecule. Analogous expressions are used for the y - and z -components. For an electrically neutral molecule, the origin of the coordinates is arbitrary, so it is best chosen to simplify the measurements. In common with all vectors, the magnitude of μ is related to the three components μ_x , μ_y , and μ_z by

$$\mu = (\mu_x^2 + \mu_y^2 + \mu_z^2)^{1/2} \quad (18.3b)$$

Example 18.1 Calculating a molecular dipole moment

Estimate the electric dipole moment of the amide group shown in (5) by using the partial charges (as multiples of e) in Table 18.2 and the locations of the atoms shown.

Method We use eqn 18.3a to calculate each of the components of the dipole moment and then eqn 18.3b to assemble the three components into the magnitude of the dipole moment. Note that the partial charges are multiples of the fundamental charge, $e = 1.609 \times 10^{-19}$ C.

Answer The expression for μ_x is

$$\begin{aligned} \mu_x &= (-0.36e) \times (132 \text{ pm}) + (0.45e) \times (0 \text{ pm}) + (0.18e) \times (182 \text{ pm}) \\ &\quad + (-0.38e) \times (-62.0 \text{ pm}) \\ &= 8.8e \text{ pm} \\ &= 8.8 \times (1.609 \times 10^{-19} \text{ C}) \times (10^{-12} \text{ m}) = 1.4 \times 10^{-30} \text{ C m} \end{aligned}$$

corresponding to $\mu_x = 0.42$ D. The expression for μ_y is:

$$\begin{aligned}\mu_y &= (-0.36e) \times (0 \text{ pm}) + (0.45e) \times (0 \text{ pm}) + (0.18e) \times (-86.6 \text{ pm}) \\ &\quad + (-0.38e) \times (107 \text{ pm}) \\ &= -56e \text{ pm} = -9.1 \times 10^{-30} \text{ C m}\end{aligned}$$

It follows that $\mu_y = -2.7$ D. Therefore, because $\mu_z = 0$,

$$\mu = \{(0.42 \text{ D})^2 + (-2.7 \text{ D})^2\}^{1/2} = 2.7 \text{ D}$$

We can find the orientation of the dipole moment by arranging an arrow of length 2.7 units of length to have x , y , and z components of 0.42, -2.7 , and 0 units; the orientation is superimposed on (6).

Self-test 18.2 Calculate the electric dipole moment of formaldehyde, using the information in (7). [-3.2 D]

6

7

(b) Polarization

The **polarization**, P , of a sample is the electric dipole moment density, the mean electric dipole moment of the molecules, $\langle \mu \rangle$, multiplied by the number density, $\mathcal{N}$:

$$P = \langle \mu \rangle \mathcal{N} \quad (18.4)$$

In the following pages we refer to the sample as a **dielectric**, by which is meant a polarizable, nonconducting medium.

The polarization of an isotropic fluid sample is zero in the absence of an applied field because the molecules adopt random orientations, so $\langle \mu \rangle = 0$. In the presence of a field, the dipoles become partially aligned because some orientations have lower energies than others. As a result, the electric dipole moment density is nonzero. We show in the *Justification* below that, at a temperature T

$$\langle \mu_z \rangle = \frac{\mu^2 \mathcal{E}}{3kT} \quad (18.5)$$

where z is the direction of the applied field $\mathcal{E}$. Moreover, as we shall see, there is an additional contribution from the dipole moment induced by the field.

Justification 18.1 The thermally averaged dipole moment

The probability dp that a dipole has an orientation in the range θ to $\theta + d\theta$ is given by the Boltzmann distribution (Section 16.1b), which in this case is

$$dp = \frac{e^{-E(\theta)/kT} \sin \theta d\theta}{\int_0^\pi e^{-E(\theta)/kT} \sin \theta d\theta}$$

where $E(\theta)$ is the energy of the dipole in the field: $E(\theta) = -\mu \mathcal{E} \cos \theta$, with $0 \leq \theta \leq \pi$. The average value of the component of the dipole moment parallel to the applied electric field is therefore

$$\langle \mu_z \rangle = \int \mu \cos \theta dp = \mu \int \cos \theta dp = \frac{\mu \int_0^\pi e^{x \cos \theta} \cos \theta \sin \theta d\theta}{\int_0^\pi e^{x \cos \theta} \sin \theta d\theta}$$

with $x = \mu E/kT$. The integral takes on a simpler appearance when we write $y = \cos \theta$ and note that $dy = -\sin \theta d\theta$.

$$\langle \mu_z \rangle = \frac{\mu \int_{-1}^1 y e^{xy} dy}{\int_{-1}^1 e^{xy} dy}$$

At this point we use

$$\int_{-1}^1 e^{xy} dy = \frac{e^x - e^{-x}}{x} \quad \int_{-1}^1 y e^{xy} dy = \frac{e^x + e^{-x}}{x} - \frac{e^x - e^{-x}}{x^2}$$

It is now straightforward algebra to combine these two results and to obtain

$$\langle \mu_z \rangle = \mu L(x) \quad L(x) = \frac{e^x + e^{-x}}{e^x - e^{-x}} - \frac{1}{x} \quad x = \frac{\mu E}{kT} \quad (18.6)$$

$L(x)$ is called the **Langevin function**.

Under most circumstances, x is very small (for example, if $\mu = 1$ D and $T = 300$ K, then x exceeds 0.01 only if the field strength exceeds 100 kV cm^{-1} , and most measurements are done at much lower strengths). When $x \ll 1$, the exponentials in the Langevin function can be expanded, and the largest term that survives is

$$L(x) = \frac{1}{3}x + \dots \quad (18.7)$$

Therefore, the average molecular dipole moment is given by eqn 18.6.

Comment 18.4

When x is small, it is possible to simplify expressions by using the expansion $e^x = 1 + x + \frac{1}{2}x^2 + \frac{1}{6}x^3 + \dots$; it is important when developing approximations that all terms of the same order are retained because low-order terms might cancel.

18.2 Polarizabilities

An applied electric field can distort a molecule as well as align its permanent electric dipole moment. The **induced dipole moment**, μ^* , is generally proportional to the field strength, $\mathcal{E}$, and we write

$$\mu^* = \alpha \mathcal{E} \quad (18.8)$$

(See Section 20.10 for exceptions to eqn 18.8.) The constant of proportionality α is the **polarizability** of the molecule. The greater the polarizability, the larger is the induced dipole moment for a given applied field. In a formal treatment, we should use vector quantities and allow for the possibility that the induced dipole moment might not lie parallel to the applied field, but for simplicity we discuss polarizabilities in terms of (scalar) magnitudes.

(a) Polarizability volumes

Polarizability has the units (coulomb metre)² per joule ($\text{C}^2 \text{ m}^2 \text{ J}^{-1}$). That collection of units is awkward, so α is often expressed as a **polarizability volume**, α' , by using the relation

$$\alpha' = \frac{\alpha}{4\pi\epsilon_0} \quad [18.9]$$

where ϵ_0 is the vacuum permittivity. Because the units of $4\pi\epsilon_0$ are coulomb-squared per joule per metre ($\text{C}^2 \text{ J}^{-1} \text{ m}^{-1}$), it follows that α' has the dimensions of volume (hence its name). Polarizability volumes are similar in magnitude to actual molecular volumes (of the order of 10^{-30} m^3 , 10^{-3} nm^3 , $1 \text{ \AA}^3$).

Comment 18.5

When using older compilations of data, it is useful to note that polarizability volumes have the same numerical values as the 'polarizabilities' reported using c.g.s. electrical units, so the tabulated values previously called 'polarizabilities' can be used directly.

Some experimental polarizability volumes of molecules are given in Table 18.1. As shown in the *Justification* below, polarizability volumes correlate with the HOMO–LUMO separations in atoms and molecules. The electron distribution can be distorted readily if the LUMO lies close to the HOMO in energy, so the polarizability is then large. If the LUMO lies high above the HOMO, an applied field cannot perturb the electron distribution significantly, and the polarizability is low. Molecules with small HOMO–LUMO gaps are typically large, with numerous electrons.

Justification 18.2 *Polarizabilities and molecular structures*

When an electric field is increased by $d\mathcal{E}$, the energy of a molecule changes by $-\mu d\mathcal{E}$, and if the molecule is polarizable, we interpret μ as μ^* (eqn 18.8). Therefore, the change in energy when the field is increased from 0 to $\mathcal{E}$ is

$$\Delta E = -\int_0^{\mathcal{E}} \mu^* d\mathcal{E} = -\int_0^{\mathcal{E}} \alpha \mathcal{E} d\mathcal{E} = -\frac{1}{2} \alpha \mathcal{E}^2$$

The contribution to the hamiltonian when a dipole moment is exposed to an electric field $\mathcal{E}$ in the z -direction is

$$H^{(1)} = -\mu_z \mathcal{E}$$

Comparison of these two expressions suggests that we should use second-order perturbation theory to calculate the energy of the system in the presence of the field, because then we shall obtain an expression proportional to $\mathcal{E}^2$. According to eqn 9.65b, the second-order contribution to the energy is

$$E^{(2)} = \sum_n' \frac{\left| \int \psi_n^* H^{(1)} \psi_0 d\tau \right|^2}{E_0^{(0)} - E_n^{(0)}} = \mathcal{E}^2 \sum_n' \frac{\left| \int \psi_n^* \mu_z \psi_0 d\tau \right|^2}{E_0^{(0)} - E_n^{(0)}} = \mathcal{E}^2 \sum_n' \frac{|\mu_{z,0n}|^2}{E_0^{(0)} - E_n^{(0)}}$$

where $\mu_{z,0n}$ is the *transition* electric dipole moment in the z -direction (eqn 9.70). By comparing the two expressions for the energy, we conclude that the polarizability of the molecule in the z -direction is

$$\alpha = 2 \sum_n' \frac{|\mu_{z,0n}|^2}{E_n^{(0)} - E_0^{(0)}} \quad (18.10)$$

The content of eqn 18.10 can be appreciated by approximating the excitation energies by a mean value ΔE (an indication of the HOMO–LUMO separation), and supposing that the most important transition dipole moment is approximately equal to the charge of an electron multiplied by the radius, R , of the molecule. Then

$$\alpha \approx \frac{2e^2 R^2}{\Delta E}$$

This expression shows that α increases with the size of the molecule and with the ease with which it can be excited (the smaller the value of ΔE).

If the excitation energy is approximated by the energy needed to remove an electron to infinity from a distance R from a single positive charge, we can write $\Delta E \approx e^2/4\pi\epsilon_0 R$. When this expression is substituted into the equation above, both sides are divided by $4\pi\epsilon_0$, and the factor of 2 ignored in this approximation, we obtain $\alpha' \approx R^3$, which is of the same order of magnitude as the molecular volume.

For most molecules, the polarizability is anisotropic, by which is meant that its value depends on the orientation of the molecule relative to the field. The polarizability volume of benzene when the field is applied perpendicular to the ring is 0.0067 nm^3

and it is 0.0123 nm^3 when the field is applied in the plane of the ring. The anisotropy of the polarizability determines whether a molecule is rotationally Raman active (Section 13.7).

(b) Polarization at high frequencies

When the applied field changes direction slowly, the permanent dipole moment has time to reorientate—the whole molecule rotates into a new direction—and follow the field. However, when the frequency of the field is high, a molecule cannot change direction fast enough to follow the change in direction of the applied field and the dipole moment then makes no contribution to the polarization of the sample. Because a molecule takes about 1 ps to turn through about 1 radian in a fluid, the loss of this contribution to the polarization occurs when measurements are made at frequencies greater than about 10^{11} Hz (in the microwave region). We say that the **orientation polarization**, the polarization arising from the permanent dipole moments, is lost at such high frequencies.

The next contribution to the polarization to be lost as the frequency is raised is the **distortion polarization**, the polarization that arises from the distortion of the positions of the nuclei by the applied field. The molecule is bent and stretched by the applied field, and the molecular dipole moment changes accordingly. The time taken for a molecule to bend is approximately the inverse of the molecular vibrational frequency, so the distortion polarization disappears when the frequency of the radiation is increased through the infrared. The disappearance of polarization occurs in stages: as shown in the *Justification* below, each successive stage occurs as the incident frequency rises above the frequency of a particular mode of vibration.

At even higher frequencies, in the visible region, only the electrons are mobile enough to respond to the rapidly changing direction of the applied field. The polarization that remains is now due entirely to the distortion of the electron distribution, and the surviving contribution to the molecular polarizability is called the **electronic polarizability**.

Justification 18.3 The frequency-dependence of polarizabilities

The quantum mechanical expression for the polarizability of a molecule in the presence of an electric field that is oscillating at a frequency ω in the z -direction is obtained by using time-dependent perturbation theory (*Further information 9.2*) and is

$$\alpha(\omega) = \frac{2}{\hbar} \sum_n \frac{\omega_{n0} |\mu_{z,0n}|^2}{\omega_{n0}^2 - \omega^2} \quad (18.11)$$

The quantities in this expression (which is valid provided that ω is not close to ω_{n0}) are the same as those in the previous *Justification*, with $\hbar\omega_{n0} = E_n^{(0)} - E_0^{(0)}$. As $\omega \rightarrow 0$, the equation reduces to eqn 18.10 for the static polarizability. As ω becomes very high (and much higher than any excitation frequency of the molecule so that the ω_{n0}^2 in the denominator can be ignored), the polarizability becomes

$$\alpha(\omega) = -\frac{2}{\hbar\omega^2} \sum_n \omega_{n0} |\mu_{0n}|^2 \rightarrow 0 \quad \text{as} \quad \omega \rightarrow \infty$$

That is, when the incident frequency is much higher than any excitation frequency, the polarizability becomes zero. The argument applies to each type of excitation, vibrational as well as electronic, and accounts for the successive decreases in polarizability as the frequency is increased.

18.3 Relative permittivities

When two charges q_1 and q_2 are separated by a distance r in a vacuum, the potential energy of their interaction is (see *Appendix 3*):

$$V = \frac{q_1 q_2}{4\pi\epsilon_0 r} \quad (18.12a)$$

When the same two charges are immersed in a medium (such as air or a liquid), their potential energy is reduced to

$$V = \frac{q_1 q_2}{4\pi\epsilon r} \quad (18.12b)$$

where ϵ is the **permittivity** of the medium. The permittivity is normally expressed in terms of the dimensionless **relative permittivity**, ϵ_r , (formerly and still widely called the dielectric constant) of the medium:

$$\epsilon_r = \frac{\epsilon}{\epsilon_0} \quad [18.13]$$

The relative permittivity can have a very significant effect on the strength of the interactions between ions in solution. For instance, water has a relative permittivity of 78 at 25°C, so the interionic Coulombic interaction energy is reduced by nearly two orders of magnitude from its vacuum value. Some of the consequences of this reduction for electrolyte solutions were explored in Chapter 5.

The relative permittivity of a substance is large if its molecules are polar or highly polarizable. The quantitative relation between the relative permittivity and the electric properties of the molecules is obtained by considering the polarization of a medium, and is expressed by the **Debye equation** (for the derivation of this and the following equations, see *Further reading*):

$$\frac{\epsilon_r - 1}{\epsilon_r + 2} = \frac{\rho P_m}{M} \quad (18.14)$$

where ρ is the mass density of the sample, M is the molar mass of the molecules, and P_m is the **molar polarization**, which is defined as

$$P_m = \frac{N_A}{3\epsilon_0} \left(\alpha + \frac{\mu^2}{3kT} \right) \quad [18.15]$$

The term $\mu^2/3kT$ stems from the thermal averaging of the electric dipole moment in the presence of the applied field (eqn 18.5). The corresponding expression without the contribution from the permanent dipole moment is called the **Clausius–Mossotti equation**:

$$\frac{\epsilon_r - 1}{\epsilon_r + 2} = \frac{\rho N_A \alpha}{3M\epsilon_0} \quad (18.16)$$

The Clausius–Mossotti equation is used when there is no contribution from permanent electric dipole moments to the polarization, either because the molecules are non-polar or because the frequency of the applied field is so high that the molecules cannot orientate quickly enough to follow the change in direction of the field.

8 Camphor

Example 18.2 Determining dipole moment and polarizability

The relative permittivity of a substance is measured by comparing the capacitance of a capacitor with and without the sample present (C and C_0 , respectively) and using $\epsilon_r = C/C_0$. The relative permittivity of camphor (**8**) was measured at a series of temperatures with the results given below. Determine the dipole moment and the polarizability volume of the molecule.

$\theta/^{\circ}\text{C}$	$\rho/(\text{g cm}^{-3})$	ϵ_r
0	0.99	12.5
20	0.99	11.4
40	0.99	10.8
60	0.99	10.0
80	0.99	9.50
100	0.99	8.90
120	0.97	8.10
140	0.96	7.60
160	0.95	7.11
200	0.91	6.21

Method Equation 18.14 implies that the polarizability and permanent electric dipole moment of the molecules in a sample can be determined by measuring ϵ_r at a series of temperatures, calculating P_m , and plotting it against $1/T$. The slope of the graph is $N_A \mu^2 / 9 \epsilon_0 k$ and its intercept at $1/T = 0$ is $N_A \alpha / 3 \epsilon_0$. We need to calculate $(\epsilon_r - 1)/(\epsilon_r + 2)$ at each temperature, and then multiply by M/ρ to form P_m .

Answer For camphor, $M = 152.23 \text{ g mol}^{-1}$. We can therefore use the data to draw up the following table:

$\theta/^{\circ}\text{C}$	$(10^3 \text{ K})/T$	ϵ_r	$(\epsilon_r - 1)/(\epsilon_r + 2)$	$P_m/(\text{cm}^3 \text{ mol}^{-1})$
0	3.66	12.5	0.793	122
20	3.41	11.4	0.776	119
40	3.19	10.8	0.766	118
60	3.00	10.0	0.750	115
80	2.83	9.50	0.739	114
100	2.68	8.90	0.725	111
120	2.54	8.10	0.703	110
140	2.42	7.60	0.688	109
160	2.31	7.11	0.670	107
200	2.11	6.21	0.634	106

The points are plotted in Fig. 18.2. The intercept lies at 82.7, so $\alpha' = 3.3 \times 10^{-23} \text{ cm}^3$. The slope is 10.9, so $\mu = 4.46 \times 10^{-30} \text{ C m}$, corresponding to 1.34 D. Because the Debye equation describes molecules that are free to rotate, the data show that camphor, which does not melt until 175°C , is rotating even in the solid. It is an approximately spherical molecule.

Self-test 18.3 The relative permittivity of chlorobenzene is 5.71 at 20°C and 5.62 at 25°C . Assuming a constant density (1.11 g cm^{-3}), estimate its polarizability volume and dipole moment. [$1.4 \times 10^{-23} \text{ cm}^3$, 1.2 D]

Fig. 18.2 The plot of $P_m/(\text{cm}^3 \text{ mol}^{-1})$ against $(10^3 \text{ K})/T$ used in Example 18.2 for the determination of the polarizability and dipole moment of camphor.

The Maxwell equations that describe the properties of electromagnetic radiation (see *Further reading*) relate the refractive index at a (visible or ultraviolet) specified wavelength to the relative permittivity at that frequency:

$$n_r = \epsilon_r^{1/2} \quad (18.17)$$

Therefore, the molar polarization, P_m , and the molecular polarizability, α , can be measured at frequencies typical of visible light (about 10^{15} to 10^{16} Hz) by measuring the refractive index of the sample and using the Clausius–Mossotti equation.

Comment 18.6

The refractive index, n_r , of the medium is the ratio of the speed of light in a vacuum, c , to its speed c' in the medium: $n_r = c/c'$. A beam of light changes direction ('bends') when it passes from a region of one refractive index to a region with a different refractive index. See *Appendix 3* for details.

Interactions between molecules

A **van der Waals interaction** is the attractive interaction between closed-shell molecules that depends on the distance between the molecules as $1/r^6$. In addition, there are interactions between ions and the partial charges of polar molecules and repulsive interactions that prevent the complete collapse of matter to nuclear densities. The repulsive interactions arise from Coulombic repulsions and, indirectly, from the Pauli principle and the exclusion of electrons from regions of space where the orbitals of neighbouring species overlap.

18.4 Interactions between dipoles

Most of the discussion in this section is based on the Coulombic potential energy of interaction between two charges (eqn 18.12a). We can easily adapt this expression to find the potential energy of a point charge and a dipole and to extend it to the interaction between two dipoles.

(a) The potential energy of interaction

We show in the *Justification* below that the potential energy of interaction between a point dipole $\mu_1 = q_1 l$ and the point charge q_2 in the arrangement shown in (9) is

$$V = -\frac{\mu_1 q_2}{4\pi\epsilon_0 r^2} \quad (18.18)$$

With μ in coulomb metres, q_2 in coulombs, and r in metres, V is obtained in joules. A **point dipole** is a dipole in which the separation between the charges is much smaller than the distance at which the dipole is being observed, $l \ll r$. The potential energy rises towards zero (the value at infinite separation of the charge and the dipole) more rapidly (as $1/r^2$) than that between two point charges (which varies as $1/r$) because, from the viewpoint of the point charge, the partial charges of the dipole seem to merge and cancel as the distance r increases (Fig. 18.3).

Fig. 18.3 There are two contributions to the diminishing field of an electric dipole with distance (here seen from the side). The potentials of the charges decrease (shown here by a fading intensity) and the two charges appear to merge, so their combined effect approaches zero more rapidly than by the distance effect alone.

Justification 18.4 The interaction between a point charge and a point dipole

The sum of the potential energies of repulsion between like charges and attraction between opposite charges in the orientation shown in (9) is

$$V = \frac{1}{4\pi\epsilon_0} \left(-\frac{q_1 q_2}{r - \frac{1}{2}l} + \frac{q_1 q_2}{r + \frac{1}{2}l} \right) = \frac{q_1 q_2}{4\pi\epsilon_0 r} \left(-\frac{1}{1 - x} + \frac{1}{1 + x} \right)$$

where $x = l/2r$. Because $l \ll r$ for a point dipole, this expression can be simplified by expanding the terms in x and retaining only the leading term:

$$V = \frac{q_1 q_2}{4\pi\epsilon_0 r} \{ -(1 + x + \dots) + (1 - x + \dots) \} \approx -\frac{2x q_1 q_2}{4\pi\epsilon_0 r} = -\frac{q_1 q_2 l}{4\pi\epsilon_0 r^2}$$

With $\mu_1 = q_1 l$, this expression becomes eqn 18.18. This expression should be multiplied by $\cos \theta$ when the point charge lies at an angle θ to the axis of the dipole.

Comment 18.7

The following expansions are often useful:

$$\frac{1}{1+x} = 1 - x + x^2 - \dots$$

$$\frac{1}{1-x} = 1 + x + x^2 + \dots$$

Fig. 18.4 Typical charge arrays corresponding to electric multipoles. The field arising from an arbitrary finite charge distribution can be expressed as the superposition of the fields arising from a superposition of multipoles.

Example 18.3 Calculating the interaction energy of two dipoles

Calculate the potential energy of interaction of two dipoles in the arrangement shown in (10) when their separation is r .

Method We proceed in exactly the same way as in *Justification 18.4*, but now the total interaction energy is the sum of four pairwise terms, two attractions between opposite charges, which contribute negative terms to the potential energy, and two repulsions between like charges, which contribute positive terms.

Answer The sum of the four contributions is

$$V = \frac{1}{4\pi\epsilon_0} \left(-\frac{q_1q_2}{r+l} + \frac{q_1q_2}{r} + \frac{q_1q_2}{r} - \frac{q_1q_2}{r-l} \right) = -\frac{q_1q_2}{4\pi\epsilon_0 r} \left(\frac{1}{1+x} - 2 + \frac{1}{1-x} \right)$$

with $x = l/r$. As before, provided $l \ll r$ we can expand the two terms in x and retain only the first surviving term, which is equal to $2x^2$. This step results in the expression

$$V = -\frac{2xq_1q_2}{4\pi\epsilon_0 r}$$

Therefore, because $\mu_1 = q_1l$ and $\mu_2 = q_2l$, the potential energy of interaction in the alignment shown in the illustration is

$$V = -\frac{\mu_1\mu_2}{2\pi\epsilon_0 r^3}$$

This interaction energy approaches zero more rapidly (as $1/r^3$) than for the previous case: now both interacting entities appear neutral to each other at large separations. See *Further information 18.1* for the general expression.

Self-test 18.4 Derive an expression for the potential energy when the dipoles are in the arrangement shown in (11).
[$V = \mu_1\mu_2/4\pi\epsilon_0 r^3$]

Table 18.3 summarizes the various expressions for the interaction of charges and dipoles. It is quite easy to extend the formulas given there to obtain expressions for the energy of interaction of higher **multipoles**, or arrays of point charges (Fig. 18.4). Specifically, an ***n*-pole** is an array of point charges with an *n*-pole moment but no lower moment. Thus, a **monopole** ($n = 1$) is a point charge, and the monopole moment is what we normally call the overall charge. A dipole ($n = 2$), as we have seen, is an array

Table 18.3 Multipole interaction potential energies

Interaction type	Distance dependence of potential energy	Typical energy/ (kJ mol ⁻¹)	Comment
Ion-ion	$1/r$	250	Only between ions*
Ion-dipole	$1/r^2$	15	
Dipole-dipole	$1/r^3$	2	Between stationary polar molecules
	$1/r^6$	0.6	Between rotating polar molecules
London (dispersion)	$1/r^6$	2	Between all types of molecules

The energy of a hydrogen bond A—H...B is typically 20 kJ mol⁻¹ and occurs on contact for A, B = O, N, or F.

* Electrolyte solutions are treated in Chapter 5, ionic solids in Chapter 20.

of charges that has no monopole moment (no net charge). A **quadrupole** ($n = 3$) consists of an array of point charges that has neither net charge nor dipole moment (as for CO_2 molecules, **3**). An **octupole** ($n = 4$) consists of an array of point charges that sum to zero and which has neither a dipole moment nor a quadrupole moment (as for CH_4 molecules, **12**). The feature to remember is that the interaction energy falls off more rapidly the higher the order of the multipole. For the interaction of an n -pole with an m -pole, the potential energy varies with distance as

$$V \propto \frac{1}{r^{n+m-1}} \quad (18.19)$$

The reason for the even steeper decrease with distance is the same as before: the array of charges appears to blend together into neutrality more rapidly with distance the higher the number of individual charges that contribute to the multipole. Note that a given molecule may have a charge distribution that corresponds to a superposition of several different multipoles.

(b) The electric field

The same kind of argument as that used to derive expressions for the potential energy can be used to establish the distance dependence of the strength of the electric field generated by a dipole. We shall need this expression when we calculate the dipole moment induced in one molecule by another.

The starting point for the calculation is the strength of the electric field generated by a point electric charge:

$$\mathcal{E} = \frac{q}{4\pi\epsilon_0 r^2} \quad (18.20)$$

The field generated by a dipole is the sum of the fields generated by each partial charge. For the point-dipole arrangement shown in Fig. 18.5, the same procedure that was used to derive the potential energy gives

$$\mathcal{E} = \frac{\mu}{2\pi\epsilon_0 r^3} \quad (18.21)$$

The electric field of a multipole (in this case a dipole) decreases more rapidly with distance (as $1/r^3$ for a dipole) than a monopole (a point charge).

(c) Dipole-dipole interactions

The potential energy of interaction between two polar molecules is a complicated function of their relative orientation. When the two dipoles are parallel (as in **13**), the potential energy is simply (see *Further information* 18.1)

$$V = \frac{\mu_1 \mu_2 f(\theta)}{4\pi\epsilon_0 r^3} \quad f(\theta) = 1 - 3 \cos^2 \theta \quad (18.22)$$

This expression applies to polar molecules in a fixed, parallel, orientation in a solid.

In a fluid of freely rotating molecules, the interaction between dipoles averages to zero because $f(\theta)$ changes sign as the orientation changes, and its average value is zero. Physically, the like partial charges of two freely rotating molecules are close together as much as the two opposite charges, and the repulsion of the former is cancelled by the attraction of the latter.

The interaction energy of two *freely* rotating dipoles is zero. However, because their mutual potential energy depends on their relative orientation, the molecules do not in fact rotate completely freely, even in a gas. In fact, the lower energy orientations are

Comment 18.8

The electric field is actually a vector, and we cannot simply add and subtract magnitudes without taking into account the directions of the fields. In the cases we consider, this will not be a complication because the two charges of the dipoles will be collinear and give rise to fields in the same direction. Be careful, though, with more general arrangements of charges.

Fig. 18.5 The electric field of a dipole is the sum of the opposing fields from the positive and negative charges, each of which is proportional to $1/r^2$. The difference, the net field, is proportional to $1/r^3$.

Comment 18.9

The average (or mean value) of a function $f(x)$ over the range from $x = a$ to $x = b$ is

$$\langle f \rangle = \frac{1}{b-a} \int_a^b f(x) dx$$

The volume element in polar coordinates is proportional to $\sin \theta d\theta$, and θ ranges from 0 to π . Therefore the average value of $(1 - 3 \cos^2 \theta)$ is

$$(1/\pi) \int_0^\pi (1 - 3 \cos^2 \theta) \sin \theta d\theta = 0.$$

marginally favoured, so there is a nonzero average interaction between polar molecules. We show in the following *Justification* that the average potential energy of two rotating molecules that are separated by a distance r is

$$\langle V \rangle = -\frac{C}{r^6} \quad C = \frac{2\mu_1^2\mu_2^2}{3(4\pi\epsilon_0)^2kT} \quad (18.23)$$

This expression describes the **Keesom interaction**, and is the first of the contributions to the van der Waals interaction.

Justification 18.5 *The Keesom interaction*

The detailed calculation of the Keesom interaction energy is quite complicated, but the form of the final answer can be constructed quite simply. First, we note that the average interaction energy of two polar molecules rotating at a fixed separation r is given by

$$\langle V \rangle = \frac{\mu_1\mu_2\langle f \rangle}{4\pi\epsilon_0 r^3}$$

where $\langle f \rangle$ now includes a weighting factor in the averaging that is equal to the probability that a particular orientation will be adopted. This probability is given by the Boltzmann distribution $p \propto e^{-E/kT}$, with E interpreted as the potential energy of interaction of the two dipoles in that orientation. That is,

$$p \propto e^{-V/kT} \quad V = \frac{\mu_1\mu_2 f}{4\pi\epsilon_0 r^3}$$

When the potential energy of interaction of the two dipoles is very small compared with the energy of thermal motion, we can use $V \ll kT$, expand the exponential function in p , and retain only the first two terms:

$$p \propto 1 - V/kT + \dots$$

The weighted average of f is therefore

$$\langle f \rangle = \langle f \rangle_0 - \frac{\mu_1\mu_2}{4\pi\epsilon_0 kTr^3} \langle f^2 \rangle_0 + \dots$$

where $\langle \dots \rangle_0$ denotes an unweighted spherical average. The spherical average of f is zero, so the first term vanishes. However, the average value of f^2 is nonzero because f^2 is positive at all orientations, so we can write

$$\langle V \rangle = -\frac{\mu_1^2\mu_2^2\langle f^2 \rangle_0}{(4\pi\epsilon_0)^2kTr^6}$$

The average value $\langle f^2 \rangle_0$ turns out to be $\frac{2}{3}$ when the calculation is carried through in detail. The final result is that quoted in eqn 18.23.

The important features of eqn 18.23 are its negative sign (the average interaction is attractive), the dependence of the average interaction energy on the inverse sixth power of the separation (which identifies it as a van der Waals interaction), and its inverse dependence on the temperature. The last feature reflects the way that the greater thermal motion overcomes the mutual orientating effects of the dipoles at higher temperatures. The inverse sixth power arises from the inverse third power of the interaction potential energy that is weighted by the energy in the Boltzmann term, which is also proportional to the inverse third power of the separation.

At 25°C the average interaction energy for pairs of molecules with $\mu = 1$ D is about -0.07 kJ mol⁻¹ when the separation is 0.5 nm. This energy should be compared with

the average molar kinetic energy of $\frac{3}{2}RT = 3.7 \text{ kJ mol}^{-1}$ at the same temperature. The interaction energy is also much smaller than the energies involved in the making and breaking of chemical bonds.

(d) Dipole-induced-dipole interactions

A polar molecule with dipole moment μ_1 can induce a dipole μ_2^* in a neighbouring polarizable molecule (Fig. 18.6). The induced dipole interacts with the permanent dipole of the first molecule, and the two are attracted together. The average interaction energy when the separation of the molecules is r is (for a derivation, see *Further reading*)

$$V = -\frac{C}{r^6} \quad C = \frac{\mu_1^2 \alpha'_2}{4\pi\epsilon_0} \quad (18.24)$$

where α'_2 is the polarizability volume of molecule 2 and μ_1 is the permanent dipole moment of molecule 1. Note that the C in this expression is different from the C in eqn 18.23 and other expressions below: we are using the same symbol in C/r^6 to emphasize the similarity of form of each expression.

The dipole-induced-dipole interaction energy is independent of the temperature because thermal motion has no effect on the averaging process. Moreover, like the dipole-dipole interaction, the potential energy depends on $1/r^6$: this distance dependence stems from the $1/r^3$ dependence of the field (and hence the magnitude of the induced dipole) and the $1/r^3$ dependence of the potential energy of interaction between the permanent and induced dipoles. For a molecule with $\mu = 1 \text{ D}$ (such as HCl) near a molecule of polarizability volume $\alpha' = 10 \times 10^{-30} \text{ m}^3$ (such as benzene, Table 18.1), the average interaction energy is about -0.8 kJ mol^{-1} when the separation is 0.3 nm .

(e) Induced-dipole-induced-dipole interactions

Nonpolar molecules (including closed-shell atoms, such as Ar) attract one another even though neither has a permanent dipole moment. The abundant evidence for the existence of interactions between them is the formation of condensed phases of nonpolar substances, such as the condensation of hydrogen or argon to a liquid at low temperatures and the fact that benzene is a liquid at normal temperatures.

The interaction between nonpolar molecules arises from the transient dipoles that all molecules possess as a result of fluctuations in the instantaneous positions of electrons. To appreciate the origin of the interaction, suppose that the electrons in one molecule flicker into an arrangement that gives the molecule an instantaneous dipole moment μ_1^* . This dipole generates an electric field that polarizes the other molecule, and induces in that molecule an instantaneous dipole moment μ_2^* . The two dipoles attract each other and the potential energy of the pair is lowered. Although the first molecule will go on to change the size and direction of its instantaneous dipole, the electron distribution of the second molecule will follow; that is, the two dipoles are correlated in direction (Fig. 18.7). Because of this correlation, the attraction between the two instantaneous dipoles does not average to zero, and gives rise to an induced-dipole-induced-dipole interaction. This interaction is called either the **dispersion interaction** or the **London interaction** (for Fritz London, who first described it).

Polar molecules also interact by a dispersion interaction: such molecules also possess instantaneous dipoles, the only difference being that the time average of each fluctuating dipole does not vanish, but corresponds to the permanent dipole. Such molecules therefore interact both through their permanent dipoles and through the correlated, instantaneous fluctuations in these dipoles.

The strength of the dispersion interaction depends on the polarizability of the first molecule because the instantaneous dipole moment μ_1^* depends on the looseness of

Fig. 18.6 (a) A polar molecule (purple arrow) can induce a dipole (white arrow) in a nonpolar molecule, and (b) the latter's orientation follows the former's, so the interaction does not average to zero.

Fig. 18.7 (a) In the dispersion interaction, an instantaneous dipole on one molecule induces a dipole on another molecule, and the two dipoles then interact to lower the energy. (b) The two instantaneous dipoles are correlated and, although they occur in different orientations at different instants, the interaction does not average to zero.

the control that the nuclear charge exercises over the outer electrons. The strength of the interaction also depends on the polarizability of the second molecule, for that polarizability determines how readily a dipole can be induced by another molecule. The actual calculation of the dispersion interaction is quite involved, but a reasonable approximation to the interaction energy is given by the **London formula**:

$$V = -\frac{C}{r^6} \quad C = \frac{3}{2} \alpha'_1 \alpha'_2 \frac{I_1 I_2}{I_1 + I_2} \quad (18.25)$$

where I_1 and I_2 are the ionization energies of the two molecules (Table 10.4). This interaction energy is also proportional to the inverse sixth power of the separation of the molecules, which identifies it as a third contribution to the van der Waals interaction. The dispersion interaction generally dominates all the interactions between molecules other than hydrogen bonds.

Illustration 18.1 Calculating the strength of the dispersion interaction

For two CH_4 molecules, we can substitute $\alpha' = 2.6 \times 10^{-30} \text{ m}^3$ and $I \approx 700 \text{ kJ mol}^{-1}$ to obtain $V = -2 \text{ kJ mol}^{-1}$ for $r = 0.3 \text{ nm}$. A very rough check on this figure is the enthalpy of vaporization of methane, which is 8.2 kJ mol^{-1} . However, this comparison is insecure, partly because the enthalpy of vaporization is a many-body quantity and partly because the long-distance assumption breaks down.

Fig. 18.8 The molecular orbital interpretation of the formation of an $\text{A} \cdots \text{H} \cdots \text{B}$ hydrogen bond. From the three A, H, and B orbitals, three molecular orbitals can be formed (their relative contributions are represented by the sizes of the spheres). Only the two lower energy orbitals are occupied, and there may therefore be a net lowering of energy compared with the separate AH and B species.

(f) Hydrogen bonding

The interactions described so far are universal in the sense that they are possessed by all molecules independent of their specific identity. However, there is a type of interaction possessed by molecules that have a particular constitution. A **hydrogen bond** is an attractive interaction between two species that arises from a link of the form $\text{A}-\text{H} \cdots \text{B}$, where A and B are highly electronegative elements and B possesses a lone pair of electrons. Hydrogen bonding is conventionally regarded as being limited to N, O, and F but, if B is an anionic species (such as Cl^-), it may also participate in hydrogen bonding. There is no strict cutoff for an ability to participate in hydrogen bonding, but N, O, and F participate most effectively.

The formation of a hydrogen bond can be regarded either as the approach between a partial positive charge of H and a partial negative charge of B or as a particular example of delocalized molecular orbital formation in which A, H, and B each supply one atomic orbital from which three molecular orbitals are constructed (Fig. 18.8). Thus, if the $\text{A}-\text{H}$ bond is regarded as formed from the overlap of an orbital on A, ψ_{A} , and a hydrogen 1s orbital, ψ_{H} , and the lone pair on B occupies an orbital on B, ψ_{B} , then, when the two molecules are close together, we can build three molecular orbitals from the three basis orbitals:

$$\Psi = c_1 \psi_{\text{A}} + c_2 \psi_{\text{H}} + c_3 \psi_{\text{B}}$$

One of the molecular orbitals is bonding, one almost nonbonding, and the third antibonding. These three orbitals need to accommodate four electrons (two from the original $\text{A}-\text{H}$ bond and two from the lone pair of B), so two enter the bonding orbital and two enter the nonbonding orbital. Because the antibonding orbital remains empty, the net effect—depending on the precise location of the almost nonbonding orbital—may be a lowering of energy.

In practice, the strength of the bond is found to be about 20 kJ mol^{-1} . Because the bonding depends on orbital overlap, it is virtually a contact-like interaction that is

turned on when AH touches B and is zero as soon as the contact is broken. If hydrogen bonding is present, it dominates the other intermolecular interactions. The properties of liquid and solid water, for example, are dominated by the hydrogen bonding between H_2O molecules. The structure of DNA and hence the transmission of genetic information is crucially dependent on the strength of hydrogen bonds between base pairs. The structural evidence for hydrogen bonding comes from noting that the internuclear distance between formally non-bonded atoms is less than their van der Waals contact distance, which suggests that a dominating attractive interaction is present. For example, the O—O distance in $\text{O—H}\cdots\text{O}$ is expected to be 280 pm on the basis of van der Waals radii, but is found to be 270 pm in typical compounds. Moreover, the $\text{H}\cdots\text{O}$ distance is expected to be 260 pm but is found to be only 170 pm.

Hydrogen bonds may be either symmetric or unsymmetric. In a symmetric hydrogen bond, the H atom lies midway between the two other atoms. This arrangement is rare, but occurs in $\text{F—H}\cdots\text{F}^-$, where both bond lengths are 120 pm. More common is the unsymmetrical arrangement, where the A—H bond is shorter than the $\text{H}\cdots\text{B}$ bond. Simple electrostatic arguments, treating $\text{A—H}\cdots\text{B}$ as an array of point charges (partial negative charges on A and B, partial positive on H) suggest that the lowest energy is achieved when the bond is linear, because then the two partial negative charges are furthest apart. The experimental evidence from structural studies support a linear or near-linear arrangement.

(g) The hydrophobic interaction

Nonpolar molecules do dissolve slightly in polar solvents, but strong interactions between solute and solvent are not possible and as a result it is found that each individual solute molecule is surrounded by a solvent cage (Fig. 18.9). To understand the consequences of this effect, consider the thermodynamics of transfer of a nonpolar hydrocarbon solute from a nonpolar solvent to water, a polar solvent. Experiments indicate that the process is endergonic ($\Delta_{\text{transfer}}G > 0$), as expected on the basis of the increase in polarity of the solvent, but exothermic ($\Delta_{\text{transfer}}H < 0$). Therefore, it is a large decrease in the entropy of the system ($\Delta_{\text{transfer}}S < 0$) that accounts for the positive Gibbs energy of transfer. For example, the process

has $\Delta_{\text{transfer}}G = +12 \text{ kJ mol}^{-1}$, $\Delta_{\text{transfer}}H = -10 \text{ kJ mol}^{-1}$, and $\Delta_{\text{transfer}}S = -75 \text{ J K}^{-1} \text{ mol}^{-1}$ at 298 K. Substances characterized by a positive Gibbs energy of transfer from a nonpolar to a polar solvent are called **hydrophobic**.

It is possible to quantify the hydrophobicity of a small molecular group R by defining the **hydrophobicity constant**, π , as

$$\pi = \log \frac{S}{S_0} \quad [18.26]$$

where S is the ratio of the molar solubility of the compound R—A in octanol, a non-polar solvent, to that in water, and S_0 is the ratio of the molar solubility of the compound H—A in octanol to that in water. Therefore, positive values of π indicate hydrophobicity and negative values of π indicate hydrophilicity, the thermodynamic preference for water as a solvent. It is observed experimentally that the π values of most groups do not depend on the nature of A. However, measurements do suggest group additivity of π values. For example, π for $\text{R} = \text{CH}_3$, CH_2CH_3 , $(\text{CH}_2)_2\text{CH}_3$, $(\text{CH}_2)_3\text{CH}_3$, and $(\text{CH}_2)_4\text{CH}_3$ is, respectively, 0.5, 1.0, 1.5, 2.0, and 2.5 and we conclude that acyclic saturated hydrocarbons become more hydrophobic as the carbon chain length increases. This trend can be rationalized by $\Delta_{\text{transfer}}H$ becoming more positive and $\Delta_{\text{transfer}}S$ more negative as the number of carbon atoms in the chain increases.

Fig. 18.9 When a hydrocarbon molecule is surrounded by water, the H_2O molecules form a clathrate cage. As a result of this acquisition of structure, the entropy of the water decreases, so the dispersal of the hydrocarbon into the water is entropy-opposed; its coalescence is entropy-favoured.

At the molecular level, formation of a solvent cage around a hydrophobic molecule involves the formation of new hydrogen bonds among solvent molecules. This is an exothermic process and accounts for the negative values of $\Delta_{\text{transfer}}H$. On the other hand, the increase in order associated with formation of a very large number of small solvent cages decreases the entropy of the system and accounts for the negative values of $\Delta_{\text{transfer}}S$. However, when many solute molecules cluster together, fewer (albeit larger) cages are required and more solvent molecules are free to move. The net effect of formation of large clusters of hydrophobic molecules is then a decrease in the organization of the solvent and therefore a net *increase* in entropy of the system. This increase in entropy of the solvent is large enough to render spontaneous the association of hydrophobic molecules in a polar solvent.

The increase in entropy that results from fewer structural demands on the solvent placed by the clustering of nonpolar molecules is the origin of the **hydrophobic interaction**, which tends to stabilize groupings of hydrophobic groups in micelles and biopolymers (Chapter 19). The hydrophobic interaction is an example of an ordering process that is stabilized by a tendency toward greater disorder of the solvent.

(h) The total attractive interaction

We shall consider molecules that are unable to participate in hydrogen bond formation. The total attractive interaction energy between rotating molecules is then the sum of the three van der Waals contributions discussed above. (Only the dispersion interaction contributes if both molecules are nonpolar.) In a fluid phase, all three contributions to the potential energy vary as the inverse sixth power of the separation of the molecules, so we may write

$$V = -\frac{C_6}{r^6} \quad (18.27)$$

where C_6 is a coefficient that depends on the identity of the molecules.

Although attractive interactions between molecules are often expressed as in eqn 18.27, we must remember that this equation has only limited validity. First, we have taken into account only dipolar interactions of various kinds, for they have the longest range and are dominant if the average separation of the molecules is large. However, in a complete treatment we should also consider quadrupolar and higher-order multipole interactions, particularly if the molecules do not have permanent electric dipole moments. Secondly, the expressions have been derived by assuming that the molecules can rotate reasonably freely. That is not the case in most solids, and in rigid media the dipole–dipole interaction is proportional to $1/r^3$ because the Boltzmann averaging procedure is irrelevant when the molecules are trapped into a fixed orientation.

A different kind of limitation is that eqn 18.27 relates to the interactions of pairs of molecules. There is no reason to suppose that the energy of interaction of three (or more) molecules is the sum of the pairwise interaction energies alone. The total dispersion energy of three closed-shell atoms, for instance, is given approximately by the **Axilrod–Teller formula**:

$$V = -\frac{C_6}{r_{AB}^6} - \frac{C_6}{r_{BC}^6} - \frac{C_6}{r_{CA}^6} + \frac{C'}{(r_{AB}r_{BC}r_{CA})^3} \quad (18.28a)$$

where

$$C' = a(3 \cos \theta_A \cos \theta_B \cos \theta_C + 1) \quad (18.28b)$$

The parameter a is approximately equal to $\frac{3}{4}\alpha'C_6$; the angles θ are the internal angles of the triangle formed by the three atoms (**14**). The term in C' (which represents the non-additivity of the pairwise interactions) is negative for a linear arrangement of

atoms (so that arrangement is stabilized) and positive for an equilateral triangular cluster. It is found that the three-body term contributes about 10 per cent of the total interaction energy in liquid argon.

18.5 Repulsive and total interactions

When molecules are squeezed together, the nuclear and electronic repulsions and the rising electronic kinetic energy begin to dominate the attractive forces. The repulsions increase steeply with decreasing separation in a way that can be deduced only by very extensive, complicated molecular structure calculations of the kind described in Chapter 11 (Fig. 18.10).

In many cases, however, progress can be made by using a greatly simplified representation of the potential energy, where the details are ignored and the general features expressed by a few adjustable parameters. One such approximation is the **hard-sphere potential**, in which it is assumed that the potential energy rises abruptly to infinity as soon as the particles come within a separation d :

$$V = \infty \quad \text{for } r \leq d \quad V = 0 \quad \text{for } r > d \quad (18.29)$$

This very simple potential is surprisingly useful for assessing a number of properties. Another widely used approximation is the **Mie potential**:

$$V = \frac{C_n}{r^n} - \frac{C_m}{r^m} \quad (18.30)$$

with $n > m$. The first term represents repulsions and the second term attractions. The **Lennard-Jones potential** is a special case of the Mie potential with $n = 12$ and $m = 6$ (Fig. 18.11); it is often written in the form

$$V = 4\epsilon \left\{ \left(\frac{r_0}{r} \right)^{12} - \left(\frac{r_0}{r} \right)^6 \right\} \quad (18.31)$$

The two parameters are ϵ , the depth of the well (not to be confused with the symbol of the permittivity of a medium used in Section 18.3), and r_0 , the separation at which $V = 0$ (Table 18.4). The well minimum occurs at $r_e = 2^{1/6}r_0$. Although the Lennard-Jones potential has been used in many calculations, there is plenty of evidence to show that $1/r^{12}$ is a very poor representation of the repulsive potential, and that an exponential form, e^{-r/r_0} , is greatly superior. An exponential function is more faithful to the exponential decay of atomic wavefunctions at large distances, and hence to the overlap that is responsible for repulsion. The potential with an exponential repulsive term and a $1/r^6$ attractive term is known as an **exp-6 potential**. These potentials can be used to calculate the virial coefficients of gases, as explained in Section 17.5, and through them various properties of real gases, such as the Joule–Thompson coefficient. The potentials are also used to model the structures of condensed fluids.

With the advent of **atomic force microscopy** (AFM), in which the force between a molecular sized probe and a surface is monitored (see *Impact I9.1*), it has become possible to measure directly the forces acting between molecules. The force, F , is the negative slope of potential, so for a Lennard-Jones potential between individual molecules we write

$$F = -\frac{dV}{dr} = \frac{24\epsilon}{r_0} \left\{ 2 \left(\frac{r_0}{r} \right)^{13} - \left(\frac{r_0}{r} \right)^7 \right\} \quad (18.32)$$

The net attractive force is greatest (from $dF/dr = 0$) at $r = (\frac{26}{7})^{1/6}r_0$, or $1.244r_0$, and at that distance is equal to $-144(\frac{7}{26})^{7/6}\epsilon/13r_0$, or $-2.397\epsilon/r_0$. For typical parameters, the magnitude of this force is about 10 pN.

Fig. 18.10 The general form of an intermolecular potential energy curve. At long range the interaction is attractive, but at close range the repulsions dominate.

IMPACT ON MEDICINE

118.1 Molecular recognition and drug design

A drug is a small molecule or protein that binds to a specific receptor site of a target molecule, such as a larger protein or nucleic acid, and inhibits the progress of disease. To devise efficient therapies, we need to know how to characterize and optimize molecular interactions between drug and target.

Molecular interactions are responsible for the assembly of many biological structures. Hydrogen bonding and hydrophobic interactions are primarily responsible for the three-dimensional structures of biopolymers, such as proteins, nucleic acids, and cell membranes. The binding of a ligand, or *guest*, to a biopolymer, or *host*, is also governed by molecular interactions. Examples of biological *host–guest complexes* include enzyme–substrate complexes, antigen–antibody complexes, and drug–receptor complexes. In all these cases, a site on the guest contains functional groups that can interact with complementary functional groups of the host. For example, a hydrogen bond donor group of the guest must be positioned near a hydrogen bond acceptor group of the host for tight binding to occur. It is generally true that many specific intermolecular contacts must be made in a biological host–guest complex and, as a result, a guest binds only hosts that are chemically similar. The strict rules governing molecular recognition of a guest by a host control every biological process, from metabolism to immunological response, and provide important clues for the design of effective drugs for the treatment of disease.

Interactions between nonpolar groups can be important in the binding of a guest to a host. For example, many enzyme active sites have hydrophobic pockets that bind nonpolar groups of a substrate. In addition to dispersion, repulsive, and hydrophobic interactions, π stacking interactions are also possible, in which the planar π systems of aromatic macrocycles lie one on top of the other, in a nearly parallel orientation. Such interactions are responsible for the stacking of hydrogen-bonded base pairs in DNA (Fig. 18.12). Some drugs with planar π systems, shown as a green rectangle in Fig. 18.12, are effective because they intercalate between base pairs through π stacking interactions, causing the helix to unwind slightly and altering the function of DNA.

Coulombic interactions can be important in the interior of a biopolymer host, where the relative permittivity can be much lower than that of the aqueous exterior. For example, at physiological pH, amino acid side chains containing carboxylic acid or amine groups are negatively and positively charged, respectively, and can attract each other. Dipole–dipole interactions are also possible because many of the building blocks of biopolymers are polar, including the peptide link, —CONH— (see *Example 18.1*). However, hydrogen bonding interactions are by far the most prevalent in a biological host–guest complexes. Many effective drugs bind tightly and inhibit the action of enzymes that are associated with the progress of a disease. In many cases, a successful inhibitor will be able to form the same hydrogen bonds with the binding site that the normal substrate of the enzyme can form, except that the drug is chemically inert toward the enzyme.

There are two main strategies for the discovery of a drug. In *structure-based design*, new drugs are developed on the basis of the known structure of the receptor site of a known target. However, in many cases a number of so-called *lead compounds* are known to have some biological activity but little information is available about the target. To design a molecule with improved pharmacological efficacy, **quantitative structure–activity relationships** (QSAR) are often established by correlating data on activity of lead compounds with molecular properties, also called *molecular descriptors*, which can be determined either experimentally or computationally.

In broad terms, the first stage of the QSAR method consists of compiling molecular descriptors for a very large number of lead compounds. Descriptors such as molar

Fig. 18.12 Some drugs with planar π systems, shown as a green rectangle, intercalate between base pairs of DNA.

mass, molecular dimensions and volume, and relative solubility in water and nonpolar solvents are available from routine experimental procedures. Quantum mechanical descriptors determined by semi-empirical and *ab initio* calculations include bond orders and HOMO and LUMO energies.

In the second stage of the process, biological activity is expressed as a function of the molecular descriptors. An example of a QSAR equation is:

$$\text{Activity} = c_0 + c_1 d_1 + c_2 d_1^2 + c_3 d_2 + c_4 d_2^2 + \dots \quad (18.33)$$

where d_i is the value of the descriptor and c_i is a coefficient calculated by fitting the data by regression analysis. The quadratic terms account for the fact that biological activity can have a maximum or minimum value at a specific descriptor value. For example, a molecule might not cross a biological membrane and become available for binding to targets in the interior of the cell if it is too hydrophilic (water-loving), in which case it will not partition into the hydrophobic layer of the cell membrane (see Section 19.14 for details of membrane structure), or too hydrophobic (water-repelling), for then it may bind too tightly to the membrane. It follows that the activity will peak at some intermediate value of a parameter that measures the relative solubility of the drug in water and organic solvents.

In the final stage of the QSAR process, the activity of a drug candidate can be estimated from its molecular descriptors and the QSAR equation either by interpolation or extrapolation of the data. The predictions are more reliable when a large number of lead compounds and molecular descriptors are used to generate the QSAR equation.

The traditional QSAR technique has been refined into 3D QSAR, in which sophisticated computational methods are used to gain further insight into the three-dimensional features of drug candidates that lead to tight binding to the receptor site of a target. The process begins by using a computer to superimpose three-dimensional structural models of lead compounds and looking for common features, such as similarities in shape, location of functional groups, and electrostatic potential plots, which can be obtained from molecular orbital calculations. The key assumption of the method is that common structural features are indicative of molecular properties that enhance binding of the drug to the receptor. The collection of superimposed molecules is then placed inside a three-dimensional grid of points. An atomic probe, typically an sp^3 -hybridized carbon atom, visits each grid point and two energies of interaction are calculated: E_{steric} , the steric energy reflecting interactions between the probe and electrons in uncharged regions of the drug, and E_{elec} , the electrostatic energy arising from interactions between the probe and a region of the molecule carrying a partial charge. The measured equilibrium constant for binding of the drug to the target, K_{bind} , is then assumed to be related to the interaction energies at each point r by the 3D QSAR equation

$$\log K_{\text{bind}} = c_0 + \sum_r \{c_s(r)E_{\text{steric}}(r) + c_e(r)E_{\text{elec}}(r)\} \quad (18.34)$$

where the $c(r)$ are coefficients calculated by regression analysis, with the coefficients c_s and c_e reflecting the relative importance of steric and electrostatic interactions, respectively, at the grid point r . Visualization of the regression analysis is facilitated by colouring each grid point according to the magnitude of the coefficients. Figure 18.13 shows results of a 3D QSAR analysis of the binding of steroids, molecules with the carbon skeleton shown, to human corticosteroid-binding globulin (CBG). Indeed, we see that the technique lives up to the promise of opening a window into the chemical nature of the binding site even when its structure is not known.

The QSAR and 3D QSAR methods, though powerful, have limited power: the predictions are only as good as the data used in the correlations are both reliable and

Fig. 18.13 A 3D QSAR analysis of the binding of steroids, molecules with the carbon skeleton shown, to human corticosteroid-binding globulin (CBG). The ellipses indicate areas in the protein's binding site with positive or negative electrostatic potentials and with little or much steric crowding. It follows from the calculations that addition of large substituents near the left-hand side of the molecule (as it is drawn on the page) leads to poor affinity of the drug to the binding site. Also, substituents that lead to the accumulation of negative electrostatic potential at either end of the drug are likely to show enhanced affinity for the binding site. (Adapted from P. Krogsgaard-Larsen, T. Liljefors, U. Madsen (ed.), *Textbook of drug design and discovery*, Taylor & Francis, London (2002).)

(The target molecule is taken to be so heavy that it remains virtually stationary.)

abundant. However, the techniques have been used successfully to identify compounds that deserve further synthetic elaboration, such as addition or removal of functional groups, and testing.

Gases and liquids

The form of matter with the least order is a gas. In a perfect gas there are no intermolecular interactions and the distribution of molecules is completely random. In a real gas there are weak attractions and repulsions that have minimal effect on the relative locations of the molecules but that cause deviations from the perfect gas law for the dependence of pressure on the volume, temperature, and amount (Section 1.3).

The attractions between molecules are responsible for the condensation of gases into liquids at low temperatures. At low enough temperatures the molecules of a gas have insufficient kinetic energy to escape from each other's attraction and they stick together. Second, although molecules attract each other when they are a few diameters apart, as soon as they come into contact they repel each other. This repulsion is responsible for the fact that liquids and solids have a definite bulk and do not collapse to an infinitesimal point. The molecules are held together by molecular interactions, but their kinetic energies are comparable to their potential energies. As a result, we saw in Section 17.6 that, although the molecules of a liquid are not free to escape completely from the bulk, the whole structure is very mobile and we can speak only of the *average* relative locations of molecules. In the following sections we build on those concepts and add thermodynamic arguments to describe the surface of a liquid and the condensation of a gas into a liquid.

18.6 Molecular interactions in gases

Molecular interactions in the gas phase can be studied in **molecular beams**, which consist of a collimated, narrow stream of molecules travelling through an evacuated vessel. The beam is directed towards other molecules, and the scattering that occurs on impact is related to the intermolecular interactions.

The primary experimental information from a molecular beam experiment is the fraction of the molecules in the incident beam that are scattered into a particular direction. The fraction is normally expressed in terms of dI , the rate at which molecules are scattered into a cone that represents the area covered by the 'eye' of the detector (Fig. 18.14). This rate is reported as the **differential scattering cross-section**, σ , the constant of proportionality between the value of dI and the intensity, I , of the incident beam, the number density of target molecules, $\mathcal{N}$, and the infinitesimal path length dx through the sample:

$$dI = \sigma I \mathcal{N} dx \quad (18.35)$$

The value of σ (which has the dimensions of area) depends on the **impact parameter**, b , the initial perpendicular separation of the paths of the colliding molecules (Fig. 18.15), and the details of the intermolecular potential. The role of the impact parameter is most easily seen by considering the impact of two hard spheres (Fig. 18.16). If $b = 0$, the lighter projectile is on a trajectory that leads to a head-on collision, so the only scattering intensity is detected when the detector is at $\theta = \pi$. When the impact parameter is so great that the spheres do not make contact ($b > R_A + R_B$), there is no scattering and the scattering cross-section is zero at all angles except $\theta = 0$. Glancing blows, with $0 < b \leq R_A + R_B$, lead to scattering intensity in cones around the forward direction.

The scattering pattern of real molecules, which are not hard spheres, depends on the details of the intermolecular potential, including the anisotropy that is present when the molecules are non-spherical. The scattering also depends on the relative speed of approach of the two particles: a very fast particle might pass through the interaction region without much deflection, whereas a slower one on the same path might be temporarily captured and undergo considerable deflection (Fig. 18.17). The variation of the scattering cross-section with the relative speed of approach should therefore give information about the strength and range of the intermolecular potential.

A further point is that the outcome of collisions is determined by quantum, not classical, mechanics. The wave nature of the particles can be taken into account, at least to some extent, by drawing all classical trajectories that take the projectile particle from source to detector, and then considering the effects of interference between them.

Two quantum mechanical effects are of great importance. A particle with a certain impact parameter might approach the attractive region of the potential in such a way that the particle is deflected towards the repulsive core (Fig. 18.18), which then repels it out through the attractive region to continue its flight in the forward direction. Some molecules, however, also travel in the forward direction because they have impact parameters so large that they are undeflected. The wavefunctions of the particles that take the two types of path interfere, and the intensity in the forward direction is modified. The effect is called **quantum oscillation**. The same phenomenon accounts for the optical ‘glory effect’, in which a bright halo can sometimes be seen surrounding an illuminated object. (The coloured rings around the shadow of an aircraft cast on clouds by the Sun, and often seen in flight, is an example of an optical glory.)

The second quantum effect we need consider is the observation of a strongly enhanced scattering in a non-forward direction. This effect is called **rainbow scattering** because the same mechanism accounts for the appearance of an optical rainbow. The origin of the phenomenon is illustrated in Fig. 18.19. As the impact parameter decreases, there comes a stage at which the scattering angle passes through a maximum and the interference between the paths results in a strongly scattered beam. The **rainbow angle**, θ_r , is the angle for which $d\theta/db = 0$ and the scattering is strong.

Another phenomenon that can occur in certain beams is the capturing of one species by another. The vibrational temperature in supersonic beams is so low that **van der Waals molecules** may be formed, which are complexes of the form AB in which A and B are held together by van der Waals forces or hydrogen bonds. Large numbers of such molecules have been studied spectroscopically, including ArHCl, (HCl)₂, ArCO₂, and (H₂O)₂. More recently, van der Waals clusters of water molecules have been pursued as far as (H₂O)₆. The study of their spectroscopic properties gives detailed information about the intermolecular potentials involved.

18.7 The liquid–vapour interface

So far, we have concentrated on the properties of gases. In Section 17.6, we described the structure of liquids. Now we turn our attention to the physical boundary between phases, such as the surface where solid is in contact with liquid or liquid is in contact with its vapour, has interesting properties. In this section we concentrate on the liquid–vapour interface, which is interesting because it is so mobile. Chapter 25 deals with solid surfaces and their important role in catalysis.

(a) Surface tension

Liquids tend to adopt shapes that minimize their surface area, for then the maximum number of molecules are in the bulk and hence surrounded by and interacting with neighbours. Droplets of liquids therefore tend to be spherical, because a sphere is the

Fig. 18.17 The extent of scattering may depend on the relative speed of approach as well as the impact parameter. The darker central zone represents the repulsive core; the fuzzy outer zone represents the long-range attractive potential.

Fig. 18.18 Two paths leading to the same destination will interfere quantum mechanically; in this case they give rise to quantum oscillations in the forward direction.

Fig. 18.19 The interference of paths leading to rainbow scattering. The rainbow angle, θ_r , is the maximum scattering angle reached as b is decreased. Interference between the numerous paths at that angle modifies the scattering intensity markedly.

† Note that $1 \text{ N m}^{-1} = 1 \text{ J m}^{-2}$.

shape with the smallest surface-to-volume ratio. However, there may be other forces present that compete against the tendency to form this ideal shape, and in particular gravity may flatten spheres into puddles or oceans.

Surface effects may be expressed in the language of Helmholtz and Gibbs energies (Chapter 3). The link between these quantities and the surface area is the work needed to change the area by a given amount, and the fact that dA and dG are equal (under different conditions) to the work done in changing the energy of a system. The work needed to change the surface area, σ , of a sample by an infinitesimal amount $d\sigma$ is proportional to $d\sigma$, and we write

$$dw = \gamma d\sigma \quad [18.36]$$

The constant of proportionality, γ , is called the **surface tension**; its dimensions are energy/area and its units are typically joules per metre squared (J m^{-2}). However, as in Table 18.5, values of γ are usually reported in newtons per metre (N m^{-1} , because $1 \text{ J} = 1 \text{ N m}$). The work of surface formation at constant volume and temperature can be identified with the change in the Helmholtz energy, and we can write

$$dA = \gamma d\sigma \quad (18.37)$$

Because the Helmholtz energy decreases ($dA < 0$) if the surface area decreases ($d\sigma < 0$), surfaces have a natural tendency to contract. This is a more formal way of expressing what we have already described.

Fig. 18.20 The model used for calculating the work of forming a liquid film when a wire of length l is raised and pulls the surface with it through a height h .

Example 18.4 Using the surface tension

Calculate the work needed to raise a wire of length l and to stretch the surface of a liquid through a height h in the arrangement shown in Fig. 18.20. Disregard gravitational potential energy.

Method According to eqn 18.36, the work required to create a surface area given that the surface tension does not vary as the surface is formed is $w = \gamma\sigma$. Therefore, all we need do is to calculate the surface area of the two-sided rectangle formed as the frame is withdrawn from the liquid.

Answer When the wire of length l is raised through a height h it increases the area of the liquid by twice the area of the rectangle (because there is a surface on each side). The total increase is therefore $2lh$ and the work done is $2\gamma lh$. The work can be expressed as a force $\times$ distance by writing it as $2\gamma l \times h$, and identifying γl as the opposing force on the wire of length l . This is why γ is called a tension and why its units are often chosen to be newtons per metre (N m^{-1} , so γl is a force in newtons).

Self-test 18.5 Calculate the work of creating a spherical cavity of radius r in a liquid of surface tension γ . $[4\pi r^2\gamma]$

(b) Curved surfaces

The minimization of the surface area of a liquid may result in the formation of a curved surface. A **bubble** is a region in which vapour (and possibly air too) is trapped by a thin film; a **cavity** is a vapour-filled hole in a liquid. What are widely called ‘bubbles’ in liquids are therefore strictly cavities. True bubbles have two surfaces (one on each side of the film); cavities have only one. The treatments of both are similar, but a factor of 2 is required for bubbles to take into account the doubled surface area. A **droplet** is a small volume of liquid at equilibrium surrounded by its vapour (and possibly also air).

The pressure on the concave side of an interface, p_{in} , is always greater than the pressure on the convex side, p_{out} . This relation is expressed by the **Laplace equation**, which is derived in the following *Justification*:

$$p_{\text{in}} = p_{\text{out}} + \frac{2\gamma}{r} \quad (18.38)$$

Justification 18.6 *The Laplace equation*

The cavities in a liquid are at equilibrium when the tendency for their surface area to decrease is balanced by the rise of internal pressure which would then result. When the pressure inside a cavity is p_{in} and its radius is r , the outward force is

$$\text{pressure} \times \text{area} = 4\pi r^2 p_{\text{in}}$$

The force inwards arises from the external pressure and the surface tension. The former has magnitude $4\pi r^2 p_{\text{out}}$. The latter is calculated as follows. The change in surface area when the radius of a sphere changes from r to $r + dr$ is

$$d\sigma = 4\pi(r + dr)^2 - 4\pi r^2 = 8\pi r dr$$

(The second-order infinitesimal, $(dr)^2$, is ignored.) The work done when the surface is stretched by this amount is therefore

$$dw = 8\pi \gamma r dr$$

As force $\times$ distance is work, the force opposing stretching through a distance dr when the radius is r is

$$F = 8\pi \gamma r$$

The total inward force is therefore $4\pi r^2 p_{\text{out}} + 8\pi \gamma r$. At equilibrium, the outward and inward forces are balanced, so we can write

$$4\pi r^2 p_{\text{in}} = 4\pi r^2 p_{\text{out}} + 8\pi \gamma r$$

which rearranges into eqn 18.38.

The Laplace equation shows that the difference in pressure decreases to zero as the radius of curvature becomes infinite (when the surface is flat, Fig. 18.21). Small cavities have small radii of curvature, so the pressure difference across their surface is quite large. For instance, a ‘bubble’ (actually, a cavity) of radius 0.10 mm in champagne implies a pressure difference of 1.5 kPa, which is enough to sustain a column of water of height 15 cm.

(c) Capillary action

The tendency of liquids to rise up capillary tubes (tubes of narrow bore), which is called **capillary action**, is a consequence of surface tension. Consider what happens when a glass capillary tube is first immersed in water or any liquid that has a tendency to adhere to the walls. The energy is lowest when a thin film covers as much of the glass as possible. As this film creeps up the inside wall it has the effect of curving the surface of the liquid inside the tube. This curvature implies that the pressure just beneath the curving meniscus is less than the atmospheric pressure by approximately $2\gamma/r$, where r is the radius of the tube and we assume a hemispherical surface. The pressure immediately under the flat surface outside the tube is p , the atmospheric pressure; but inside the tube under the curved surface it is only $p - 2\gamma/r$. The excess external pressure presses the liquid up the tube until hydrostatic equilibrium (equal pressures at equal depths) has been reached (Fig. 18.22).

Fig. 18.21 The dependence of the pressure inside a curved surface on the radius of the surface, for two different values of the surface tension.

Fig. 18.22 When a capillary tube is first stood in a liquid, the latter climbs up the walls, so curving the surface. The pressure just under the meniscus is less than that arising from the atmosphere by $2\gamma/r$. The pressure is equal at equal heights throughout the liquid provided the hydrostatic pressure (which is equal to ρgh) cancels the pressure difference arising from the curvature.

Fig. 18.23 The variation of the surface tension of water with temperature.

Fig. 18.24 The balance of forces that results in a contact angle, θ_c .

To calculate the height to which the liquid rises, we note that the pressure exerted by a column of liquid of mass density ρ and height h is

$$p = \rho gh \quad (18.39)$$

This hydrostatic pressure matches the pressure difference $2\gamma/r$ at equilibrium. Therefore, the height of the column at equilibrium is obtained by equating $2\gamma/r$ and ρgh , which gives

$$h = \frac{2\gamma}{\rho gr} \quad (18.40)$$

This simple expression provides a reasonably accurate way of measuring the surface tension of liquids. Surface tension decreases with increasing temperature (Fig. 18.23).

Illustration 18.2 Calculating the surface tension of a liquid from its capillary rise

If water at 25°C rises through 7.36 cm in a capillary of radius 0.20 mm, its surface tension at that temperature is

$$\begin{aligned} \gamma &= \frac{1}{2} \rho g h r \\ &= \frac{1}{2} \times (997.1 \text{ kg m}^{-3}) \times (9.81 \text{ m s}^{-2}) \times (7.36 \times 10^{-2} \text{ m}) \times (2.0 \times 10^{-4} \text{ m}) \\ &= 72 \text{ mN m}^{-1} \end{aligned}$$

where we have used $1 \text{ kg m s}^{-2} = 1 \text{ N}$.

When the adhesive forces between the liquid and the material of the capillary wall are weaker than the cohesive forces within the liquid (as for mercury in glass), the liquid in the tube retracts from the walls. This retraction curves the surface with the concave, high pressure side downwards. To equalize the pressure at the same depth throughout the liquid the surface must fall to compensate for the heightened pressure arising from its curvature. This compensation results in a capillary depression.

In many cases there is a nonzero angle between the edge of the meniscus and the wall. If this contact angle is θ_c , then eqn 18.40 should be modified by multiplying the right-hand side by $\cos \theta_c$. The origin of the contact angle can be traced to the balance of forces at the line of contact between the liquid and the solid (Fig. 18.24). If the solid–gas, solid–liquid, and liquid–gas surface tensions (essentially the energy needed to create unit area of each of the interfaces) are denoted γ_{sg} , γ_{sl} , and γ_{lg} , respectively, then the vertical forces are in balance if

$$\gamma_{sg} = \gamma_{sl} + \gamma_{lg} \cos \theta_c \quad (18.41)$$

This expression solves to

$$\cos \theta_c = \frac{\gamma_{sg} - \gamma_{sl}}{\gamma_{lg}} \quad (18.42)$$

If we note that the superficial work of adhesion of the liquid to the solid (the work of adhesion divided by the area of contact) is

$$w_{ad} = \gamma_{sg} + \gamma_{lg} - \gamma_{sl} \quad (18.43)$$

eqn 18.42 can be written

$$\cos \theta_c = \frac{w_{ad}}{\gamma_{lg}} - 1 \quad (18.44)$$

We now see that the liquid ‘wets’ (spreads over) the surface, corresponding to $0 < \theta_c < 90^\circ$, when $1 < w_{ad}/\gamma_{lg} < 2$ (Fig. 18.25). The liquid does not wet the surface,

corresponding to $90^\circ < \theta_c < 180^\circ$, when $0 < w_{ad}/\gamma_{lg} < 1$. For mercury in contact with glass, $\theta_c = 140^\circ$, which corresponds to $w_{ad}/\gamma_{lg} = 0.23$, indicating a relatively low work of adhesion of the mercury to glass on account of the strong cohesive forces within mercury.

18.8 Condensation

We now bring together concepts from this chapter and Chapter 4 to explain the condensation of a gas to a liquid. We saw in Section 4.5 that the vapour pressure of a liquid depends on the pressure applied to the liquid. Because curving a surface gives rise to a pressure differential of $2\gamma/r$, we can expect the vapour pressure above a curved surface to be different from that above a flat surface. By substituting this value of the pressure difference into eqn 4.3 ($p = p^* e^{V_m \Delta P/RT}$, where p^* is the vapour pressure when the pressure difference is zero) we obtain the **Kelvin equation** for the vapour pressure of a liquid when it is dispersed as droplets of radius r :

$$p = p^* e^{2\gamma V_m / rRT} \quad (18.45)$$

The analogous expression for the vapour pressure inside a cavity can be written at once. The pressure of the liquid outside the cavity is less than the pressure inside, so the only change is in the sign of the exponent in the last expression.

For droplets of water of radius $1\text{ }\mu\text{m}$ and 1 nm the ratios p/p^* at 25°C are about 1.001 and 3, respectively. The second figure, although quite large, is unreliable because at that radius the droplet is less than about 10 molecules in diameter and the basis of the calculation is suspect. The first figure shows that the effect is usually small; nevertheless it may have important consequences.

Consider, for example, the formation of a cloud. Warm, moist air rises into the cooler regions higher in the atmosphere. At some altitude the temperature is so low that the vapour becomes thermodynamically unstable with respect to the liquid and we expect it to condense into a cloud of liquid droplets. The initial step can be imagined as a swarm of water molecules congregating into a microscopic droplet. Because the initial droplet is so small it has an enhanced vapour pressure. Therefore, instead of growing it evaporates. This effect stabilizes the vapour because an initial tendency to condense is overcome by a heightened tendency to evaporate. The vapour phase is then said to be **supersaturated**. It is thermodynamically unstable with respect to the liquid but not unstable with respect to the small droplets that need to form before the bulk liquid phase can appear, so the formation of the latter by a simple, direct mechanism is hindered.

Clouds do form, so there must be a mechanism. Two processes are responsible. The first is that a sufficiently large number of molecules might congregate into a droplet so big that the enhanced evaporative effect is unimportant. The chance of one of these **spontaneous nucleation centres** forming is low, and in rain formation it is not a dominant mechanism. The more important process depends on the presence of minute dust particles or other kinds of foreign matter. These **nucleate** the condensation (that is, provide centres at which it can occur) by providing surfaces to which the water molecules can attach.

Liquids may be **superheated** above their boiling temperatures and **supercooled** below their freezing temperatures. In each case the thermodynamically stable phase is not achieved on account of the kinetic stabilization that occurs in the absence of nucleation centres. For example, superheating occurs because the vapour pressure inside a cavity is artificially low, so any cavity that does form tends to collapse. This instability is encountered when an unstirred beaker of water is heated, for its temperature may be raised above its boiling point. Violent bumping often ensues as spontaneous nucleation leads to bubbles big enough to survive. To ensure smooth boiling at the true boiling temperature, nucleation centres, such as small pieces of sharp-edged glass or bubbles (cavities) of air, should be introduced.

Fig. 18.25 The variation of contact angle (shown by the semaphore-like object) as the ratio w_{ad}/γ_{lg} changes.

Checklist of key ideas

- ☐ 1. A polar molecule is a molecule with a permanent electric dipole moment; the magnitude of a dipole moment is the product of the partial charge and the separation.
- ☐ 2. The polarization is the electric dipole moment density, $P = \langle \mu \rangle / \mathcal{V}$. Orientation polarization is the polarization arising from the permanent dipole moments. Distortion polarization is the polarization arising from the distortion of the positions of the nuclei by the applied field.
- ☐ 3. The polarizability is a measure of the ability of an electric field to induce a dipole moment in a molecule ($\mu = \alpha E$). Electronic polarizability is the polarizability due to the distortion of the electron distribution.
- ☐ 4. The permittivity is the quantity ϵ in the Coulomb potential energy, $V = q_1 q_2 / 4\pi\epsilon r$.
- ☐ 5. The relative permittivity is given by $\epsilon_r = \epsilon / \epsilon_0$ and may be calculated from electric properties by using the Debye equation (eqn 18.14) or the Clausius–Mossotti equation (eqn 18.16).
- ☐ 6. A van der Waals interaction between closed-shell molecules is inversely proportional to the sixth power of their separation.
- ☐ 7. The potential energy of the dipole–dipole interaction between two fixed (non-rotating) molecules is proportional to $\mu_1 \mu_2 / r^3$ and that between molecules that are free to rotate is proportional to $\mu_1^2 \mu_2^2 / kTr^6$.
- ☐ 8. The dipole–induced-dipole interaction between two molecules is proportional to $\mu_1^2 \alpha_2 / r^6$, where α is the polarizability.
- ☐ 9. The potential energy of the dispersion (or London) interaction is proportional to $\alpha_1 \alpha_2 / r^6$.
- ☐ 10. A hydrogen bond is an interaction of the form $A-H \cdots B$, where A and B are N, O, or F.
- ☐ 11. A hydrophobic interaction is an interaction that favours formation of clusters of hydrophobic groups in aqueous environments and that stems from changes in entropy of water molecules.
- ☐ 12. The Lennard-Jones (12,6) potential, $V = 4\epsilon\{(r_0/r)^{12} - (r_0/r)^6\}$, is a model of the total intermolecular potential energy.
- ☐ 13. A molecular beam is a collimated, narrow stream of molecules travelling through an evacuated vessel. Molecular beam techniques are used to investigate molecular interactions in gases.
- ☐ 14. The work of forming a liquid surface is $dw = \gamma d\sigma$, where γ is the surface tension.
- ☐ 15. The Laplace equation for the vapour pressure at a curved surface is $p_{\text{in}} = p_{\text{out}} + 2\gamma/r$.
- ☐ 16. The Kelvin equation for the vapour pressure of droplets is $p = p^* e^{2\gamma V_m / rRT}$.
- ☐ 17. Capillary action is the tendency of liquids to rise up capillary tubes.
- ☐ 18. Nucleation provides surfaces to which molecules can attach and thereby induce condensation.

Further information

Further information 18.1 The dipole–dipole interaction

An important problem in physical chemistry is the calculation of the potential energy of interaction between two point dipoles with moments μ_1 and μ_2 , separated by a vector $\mathbf{r}$. From classical

electromagnetic theory, the potential energy of μ_2 in the electric field $\mathcal{E}_1$ generated by μ_1 is given by the dot (scalar) product

$$V = -\mathcal{E}_1 \cdot \mu_2 \quad (18.46)$$

To calculate $\mathcal{E}_1$, we consider a distribution of point charges q_i located at x_i, y_i , and z_i from the origin. The Coulomb potential ϕ due to this distribution at a point with coordinates x, y , and z is:

$$\phi = \sum_i q_i \frac{1}{4\pi\epsilon_0 \{(x-x_i)^2 + (y-y_i)^2 + (z-z_i)^2\}^{1/2}} \quad (18.47)$$

Comment 18.10

The potential energy of a charge q_1 in the presence of another charge q_2 may be written as $V = q_1\phi$, where $\phi = q_2/4\pi\epsilon_0 r$ is the Coulomb potential. If there are several charges $q_2, q_3, \dots$ present in the system, then the total potential experienced by the charge q_1 is the sum of the potential generated by each charge: $\phi = \phi_2 + \phi_3 + \dots$. The electric field strength is the negative gradient of the electric potential: $\mathcal{E} = -\nabla\phi$. See Appendix 3 for more details.

where r is the location of the point of interest and the $\mathbf{r}_i$ are the locations of the charges q_i . If we suppose that all the charges are close to the origin (in the sense that $r_i \ll r$), we can use a Taylor expansion to write

$$\begin{aligned} \phi(\mathbf{r}) &= \sum_i \frac{q_i}{4\pi\epsilon_0} \left\{ \frac{1}{r} + \left(\frac{\partial \{(x-x_i)^2 + (y-y_i)^2 + (z-z_i)^2\}^{1/2}}{\partial x_i} \right)_{x_i=0} x_i + \dots \right\} \\ &= \sum_i \frac{q_i}{4\pi\epsilon_0} \left\{ \frac{1}{r} + \frac{x x_i}{r^3} + \dots \right\} \end{aligned} \quad (18.48)$$

where the ellipses include the terms arising from derivatives with respect to y_i and z_i and higher derivatives. If the charge distribution is electrically neutral, the first term disappears because $\sum_i q_i = 0$. Next we note that $\sum_i q_i x_i = \mu_x$, and likewise for the y - and z -components. That is,

$$\phi = \frac{1}{4\pi\epsilon_0 r^3} (\mu_x x + \mu_y y + \mu_z z) = \frac{1}{4\pi\epsilon_0 r^3} \boldsymbol{\mu}_1 \cdot \mathbf{r} \quad (18.49)$$

The electric field strength is (see Comment 18.10)

$$\mathcal{E}_1 = \frac{1}{4\pi\epsilon_0} \nabla \frac{\boldsymbol{\mu}_1 \cdot \mathbf{r}}{r^3} = -\frac{\boldsymbol{\mu}_1}{4\pi\epsilon_0 r^3} - \frac{\boldsymbol{\mu}_1 \cdot \mathbf{r}}{4\pi\epsilon_0} \nabla \frac{1}{r^3} \quad (18.50)$$

It follows from eqns 18.46 and 18.50 that

$$V = \frac{\boldsymbol{\mu}_1 \cdot \boldsymbol{\mu}_2}{4\pi\epsilon_0 r^3} - 3 \frac{(\boldsymbol{\mu}_1 \cdot \mathbf{r})(\boldsymbol{\mu}_2 \cdot \mathbf{r})}{4\pi\epsilon_0 r^5} \quad (18.51)$$

For the arrangement shown in (13), in which $\boldsymbol{\mu}_1 \cdot \mathbf{r} = \mu_1 r \cos \theta$ and $\boldsymbol{\mu}_2 \cdot \mathbf{r} = \mu_2 r \cos \theta$, eqn 18.51 becomes:

$$V = \frac{\mu_1 \mu_2 f(\theta)}{4\pi\epsilon_0 r^3} \quad f(\theta) = 1 - 3 \cos^2 \theta \quad (18.52)$$

which is eqn 18.22.

Further information 18.2 The basic principles of molecular beams

The basic arrangement for a molecular beam experiment is shown in Fig. 18.26. If the pressure of vapour in the source is increased so that the mean free path of the molecules in the emerging beam is much shorter than the diameter of the pinhole, many collisions take place even outside the source. The net effect of these collisions, which give rise to **hydrodynamic flow**, is to transfer momentum into the

Fig. 18.26 The basic arrangement of a molecular beam apparatus. The atoms or molecules emerge from a heated source, and pass through the velocity selector, a rotating slotted cylinder such as that discussed in Section 1.3a. The scattering occurs from the target gas (which might take the form of another beam), and the flux of particles entering the detector set at some angle is recorded.

Fig. 18.27 The shift in the mean speed and the width of the distribution brought about by use of a supersonic nozzle.

direction of the beam. The molecules in the beam then travel with very similar speeds, so further downstream few collisions take place between them. This condition is called **molecular flow**. Because the spread in speeds is so small, the molecules are effectively in a state of very low translational temperature (Fig. 18.27). The translational temperature may reach as low as 1 K. Such jets are called **supersonic** because the average speed of the molecules in the jet is much greater than the speed of sound for the molecules that are not part of the jet.

A supersonic jet can be converted into a more parallel **supersonic beam** if it is 'skimmed' in the region of hydrodynamic flow and the excess gas pumped away. A skimmer consists of a conical nozzle shaped to avoid any supersonic shock waves spreading back into the gas and so increasing the translational temperature (Fig. 18.28). A jet or beam may also be formed by using helium or neon as the principal

Fig. 18.28 A supersonic nozzle skims off some of the molecules of the beam and leads to a beam with well defined velocity.

gas, and injecting molecules of interest into it in the hydrodynamic region of flow.

The low translational temperature of the molecules is reflected in the low rotational and vibrational temperatures of the molecules. In

this context, a rotational or vibrational temperature means the temperature that should be used in the Boltzmann distribution to reproduce the observed populations of the states. However, as rotational modes equilibrate more slowly, and vibrational modes equilibrate even more slowly, the rotational and vibrational populations of the species correspond to somewhat higher temperatures, of the order of 10 K for rotation and 100 K for vibrations.

The target gas may be either a bulk sample or another molecular beam. The latter **crossed beam technique** gives a lot of information because the states of both the target and projectile molecules may be controlled. The intensity of the incident beam is measured by the **incident beam flux**, I , which is the number of particles passing through a given area in a given interval divided by the area and the duration of the interval.

The detectors may consist of a chamber fitted with a sensitive pressure gauge, a bolometer (a detector that responds to the incident energy by making use of the temperature-dependence of resistance), or an ionization detector, in which the incoming molecule is first ionized and then detected electronically. The state of the scattered molecules may also be determined spectroscopically, and is of interest when the collisions change their vibrational or rotational states.

Discussion questions

18.1 Explain how the permanent dipole moment and the polarizability of a molecule arise.

18.2 Explain why the polarizability of a molecule decreases at high frequencies.

18.3 Describe the experimental procedures available for determining the electric dipole moment of a molecule.

18.4 Account for the theoretical conclusion that many attractive interactions between molecules vary with their separation as $1/r^6$.

18.5 Describe the formation of a hydrogen bond in terms of molecular orbitals.

18.6 Account for the hydrophobic interaction and discuss its manifestations.

18.7 Describe how molecular beams are used to investigate intermolecular potentials.

Exercises

18.1a Which of the following molecules may be polar: ClF_3 , O_3 , H_2O_2 ?

18.1b Which of the following molecules may be polar: SO_3 , XeF_4 , SF_4 ?

18.2a The electric dipole moment of toluene (methylbenzene) is 0.4 D. Estimate the dipole moments of the three xylenes (dimethylbenzene). Which answer can you be sure about?

18.2b Calculate the resultant of two dipole moments of magnitude 1.5 D and 0.80 D that make an angle of 109.5° to each other.

18.3a Calculate the magnitude and direction of the dipole moment of the following arrangement of charges in the xy -plane: $3e$ at $(0, 0)$, $-e$ at $(0.32 \text{ nm}, 0)$, and $-2e$ at an angle of 20° from the x -axis and a distance of 0.23 nm from the origin.

18.3b Calculate the magnitude and direction of the dipole moment of the following arrangement of charges in the xy -plane: $4e$ at $(0, 0)$, $-2e$ at $(162 \text{ pm}, 0)$, and $-2e$ at an angle of 30° from the x -axis and a distance of 143 pm from the origin.

18.4a The molar polarization of fluorobenzene vapour varies linearly with T^{-1} , and is $70.62 \text{ cm}^3 \text{ mol}^{-1}$ at 351.0 K and $62.47 \text{ cm}^3 \text{ mol}^{-1}$ at 423.2 K . Calculate the polarizability and dipole moment of the molecule.

18.4b The molar polarization of the vapour of a compound was found to vary linearly with T^{-1} , and is $75.74 \text{ cm}^3 \text{ mol}^{-1}$ at 320.0 K and $71.43 \text{ cm}^3 \text{ mol}^{-1}$ at 421.7 K . Calculate the polarizability and dipole moment of the molecule.

18.5a At 0°C , the molar polarization of liquid chlorine trifluoride is $27.18 \text{ cm}^3 \text{ mol}^{-1}$ and its density is 1.89 g cm^{-3} . Calculate the relative permittivity of the liquid.

18.5b At 0°C , the molar polarization of a liquid is $32.16 \text{ cm}^3 \text{ mol}^{-1}$ and its density is 1.92 g cm^{-3} . Calculate the relative permittivity of the liquid. Take $M = 55.0 \text{ g mol}^{-1}$.

18.6a The polarizability volume of H_2O is $1.48 \times 10^{-24} \text{ cm}^3$; calculate the dipole moment of the molecule (in addition to the permanent dipole moment) induced by an applied electric field of strength 1.0 kV cm^{-1} .

18.6b The polarizability volume of NH_3 is $2.22 \times 10^{-30} \text{ m}^3$; calculate the dipole moment of the molecule (in addition to the permanent dipole moment) induced by an applied electric field of strength 15.0 kV m^{-1} .

18.7a The refractive index of CH_2I_2 is 1.732 for 656 nm light. Its density at 20°C is 3.32 g cm^{-3} . Calculate the polarizability of the molecule at this wavelength.

18.7b The refractive index of a compound is 1.622 for 643 nm light. Its density at 20°C is 2.99 g cm⁻³. Calculate the polarizability of the molecule at this wavelength. Take $M = 65.5$ g mol⁻¹.

18.8a The polarizability volume of H₂O at optical frequencies is 1.5×10^{-24} cm³; estimate the refractive index of water. The experimental value is 1.33; what may be the origin of the discrepancy?

18.8b The polarizability volume of a liquid of molar mass 72.3 g mol⁻¹ and density 865 kg mol⁻¹ at optical frequencies is 2.2×10^{-30} m³; estimate the refractive index of the liquid.

18.9a The dipole moment of chlorobenzene is 1.57 D and its polarizability volume is 1.23×10^{-23} cm³. Estimate its relative permittivity at 25°C, when its density is 1.173 g cm⁻³.

18.9b The dipole moment of bromobenzene is 5.17×10^{-30} C m and its polarizability volume is approximately 1.5×10^{-29} m³. Estimate its relative permittivity at 25°C, when its density is 1491 kg m⁻³.

18.10a Calculate the vapour pressure of a spherical droplet of water of radius 10 nm at 20°C. The vapour pressure of bulk water at that temperature is 2.3 kPa and its density is 0.9982 g cm⁻³.

18.10b Calculate the vapour pressure of a spherical droplet of water of radius 20.0 nm at 35.0°C. The vapour pressure of bulk water at that temperature is 5.623 kPa and its density is 994.0 kg m⁻³.

18.11a The contact angle for water on clean glass is close to zero. Calculate the surface tension of water at 20°C given that at that temperature water climbs to a height of 4.96 cm in a clean glass capillary tube of internal radius 0.300 mm. The density of water at 20°C is 998.2 kg m⁻³.

18.11b The contact angle for water on clean glass is close to zero. Calculate the surface tension of water at 30°C given that at that temperature water climbs to a height of 9.11 cm in a clean glass capillary tube of internal radius 0.320 mm. The density of water at 30°C is 0.9956 g cm⁻³.

18.12a Calculate the pressure differential of water across the surface of a spherical droplet of radius 200 nm at 20°C.

18.12b Calculate the pressure differential of ethanol across the surface of a spherical droplet of radius 220 nm at 20°C. The surface tension of ethanol at that temperature is 22.39 mN m⁻¹.

Problems*

Numerical problems

18.1 Suppose an H₂O molecule ($\mu = 1.85$ D) approaches an anion. What is the favourable orientation of the molecule? Calculate the electric field (in volts per metre) experienced by the anion when the water dipole is (a) 1.0 nm, (b) 0.3 nm, (c) 30 nm from the ion.

18.2 An H₂O molecule is aligned by an external electric field of strength 1.0 kV m⁻¹ and an Ar atom ($\alpha' = 1.66 \times 10^{-24}$ cm³) is brought up slowly from one side. At what separation is it energetically favourable for the H₂O molecule to flip over and point towards the approaching Ar atom?

18.3 The relative permittivity of chloroform was measured over a range of temperatures with the following results:

$\theta/^{\circ}\text{C}$	-80	-70	-60	-40	-20	0	20
ϵ_r	3.1	3.1	7.0	6.5	6.0	5.5	5.0
$\rho/(\text{g cm}^{-3})$	1.65	1.64	1.64	1.61	1.57	1.53	1.50

The freezing point of chloroform is -64°C. Account for these results and calculate the dipole moment and polarizability volume of the molecule.

18.4 The relative permittivities of methanol (m.p. -95°C) corrected for density variation are given below. What molecular information can be deduced from these values? Take $\rho = 0.791$ g cm⁻³ at 20°C.

$\theta/^{\circ}\text{C}$	-185	-170	-150	-140	-110	-80	-50	-20	0	20
ϵ_r	3.2	3.6	4.0	5.1	67	57	4	43	38	34

18.5 In his classic book *Polar molecules*, Debye reports some early measurements of the polarizability of ammonia. From the selection below, determine the dipole moment and the polarizability volume of the molecule.

T/K	292.2	309.0	333.0	387.0	413.0	446.0
$P_m/(\text{cm}^3 \text{ mol}^{-1})$	57.57	55.01	51.22	44.99	42.51	39.59

The refractive index of ammonia at 273 K and 100 kPa is 1.000 379 (for yellow sodium light). Calculate the molar polarizability of the gas at this temperature

and at 292.2 K. Combine the value calculated with the static molar polarizability at 292.2 K and deduce from this information alone the molecular dipole moment.

18.6 Values of the molar polarization of gaseous water at 100 kPa as determined from capacitance measurements are given below as a function of temperature.

T/K	384.3	420.1	444.7	484.1	522.0
$P_m/(\text{cm}^3 \text{ mol}^{-1})$	57.4	53.5	50.1	46.8	43.1

Calculate the dipole moment of H₂O and its polarizability volume.

18.7‡ F. Luo, G.C. MeBane, O. Kim, C.F. Giese, and W.R. Gentry (*J. Chem. Phys.* **98**, 3564 (1993)) reported experimental observation of the He₂ complex, a species that had escaped detection for a long time. The fact that the observation required temperatures in the neighbourhood of 1 mK is consistent with computational studies which suggest that hcD_0 for He₂ is about 1.51×10^{-23} J, hcD_0 about 2×10^{-26} J, and R about 297 pm. (a) Determine the Lennard-Jones parameters r_0 , and ϵ and plot the Lennard-Jones potential for He-He interactions. (b) Plot the Morse potential given that $a = 5.79 \times 10^{10}$ m⁻¹.

18.8‡ D.D. Nelson, G.T. Fraser, and W. Klemperer (*Science* **238**, 1670 (1987)) examined several weakly bound gas-phase complexes of ammonia in search of examples in which the H atoms in NH₃ formed hydrogen bonds, but found none. For example, they found that the complex of NH₃ and CO₂ has the carbon atom nearest the nitrogen (299 pm away): the CO₂ molecule is at right angles to the C-N 'bond', and the H atoms of NH₃ are pointing away from the CO₂. The permanent dipole moment of this complex is reported as 1.77 D. If the N and C atoms are the centres of the negative and positive charge distributions, respectively, what is the magnitude of those partial charges (as multiples of e)?

18.9‡ From data in Table 18.1 calculate the molar polarization, relative permittivity, and refractive index of methanol at 20°C. Its density at that temperature is 0.7914 g cm⁻³.

* Problems denoted with the symbol‡ were supplied by Charles Trapp and Carmen Giunta.

Theoretical problems

18.10 Calculate the potential energy of the interaction between two linear quadrupoles when they are (a) collinear, (b) parallel and separated by a distance r .

18.11 Show that, in a gas (for which the refractive index is close to 1), the refractive index depends on the pressure as $n_r = 1 + \text{const} \times p$, and find the constant of proportionality. Go on to show how to deduce the polarizability volume of a molecule from measurements of the refractive index of a gaseous sample.

18.12 Acetic acid vapour contains a proportion of planar, hydrogen-bonded dimers. The relative permittivity of pure liquid acetic acid is 7.14 at 290 K and increases with increasing temperature. Suggest an interpretation of the latter observation. What effect should isothermal dilution have on the relative permittivity of solutions of acetic acid in benzene?

18.13 Show that the mean interaction energy of N atoms of diameter d interacting with a potential energy of the form C_6/R^6 is given by $U = -2N^2C_6/3Vd^3$, where V is the volume in which the molecules are confined and all effects of clustering are ignored. Hence, find a connection between the van der Waals parameter a and C_6 , from $n^2a/V^2 = (\partial U/\partial V)_T$.

18.14 Suppose the repulsive term in a Lennard-Jones (12,6)-potential is replaced by an exponential function of the form $e^{-r/d}$. Sketch the form of the potential energy and locate the distance at which it is a minimum.

18.15 The *cohesive energy density*, $\mathcal{V}$, is defined as U/V , where U is the mean potential energy of attraction within the sample and V its volume. Show that $\mathcal{V} = \frac{1}{2}\mathcal{N}\int V(R)d\tau$, where $\mathcal{N}$ is the number density of the molecules and $V(R)$ is their attractive potential energy and where the integration ranges from d to infinity and over all angles. Go on to show that the cohesive energy density of a uniform distribution of molecules that interact by a van der Waals attraction of the form $-C_6/R^6$ is equal to $(2\pi/3)(N_A^2/d^3M^2)\rho^2C_6$, where ρ is the mass density of the solid sample and M is the molar mass of the molecules.

18.16 Consider the collision between a hard-sphere molecule of radius R_1 and mass m , and an infinitely massive impenetrable sphere of radius R_2 . Plot the scattering angle θ as a function of the impact parameter b . Carry out the calculation using simple geometrical considerations.

18.17 The dependence of the scattering characteristics of atoms on the energy of the collision can be modelled as follows. We suppose that the two colliding atoms behave as impenetrable spheres, as in Problem 18.16, but that the effective radius of the heavy atoms depends on the speed v of the light atom. Suppose its effective radius depends on v as R_2e^{-v/v^*} , where v^* is a constant. Take $R_1 = \frac{1}{2}R_2$ for simplicity and an impact parameter $b = \frac{1}{2}R_2$, and plot the scattering angle as a function of (a) speed, (b) kinetic energy of approach.

Applications: to biochemistry

18.18 Phenylalanine (Phe, **15**) is a naturally occurring amino acid. What is the energy of interaction between its phenyl group and the electric dipole moment of a neighbouring peptide group? Take the distance between the groups as 4.0 nm and treat the phenyl group as a benzene molecule. The dipole moment of the peptide group is $\mu = 2.7$ D and the polarizability volume of benzene is $\alpha' = 1.04 \times 10^{-29} \text{ m}^3$.

15

18.19 Now consider the London interaction between the phenyl groups of two Phe residues (see Problem 18.18). (a) Estimate the potential energy of interaction between two such rings (treated as benzene molecules) separated by 4.0 nm. For the ionization energy, use $I = 5.0$ eV. (b) Given that force is the negative slope of the potential, calculate the distance dependence of the force acting between two nonbonded groups of atoms, such as the phenyl groups of Phe, in a polypeptide chain that can have a London dispersion interaction with each other. What is the separation at which the force between the phenyl groups (treated as benzene molecules) of two Phe residues is zero? *Hint.* Calculate the slope by considering the potential energy at r and $r + \delta r$, with $\delta r \ll r$, and evaluating $\{V(r + \delta r) - V(r)\}/\delta r$. At the end of the calculation, let δr become vanishingly small.

18.20 Molecular orbital calculations may be used to predict structures of intermolecular complexes. Hydrogen bonds between purine and pyrimidine bases are responsible for the double helix structure of DNA (see Chapter 19). Consider methyl-adenine (**16**, with $R = \text{CH}_3$) and methyl-thymine (**17**, with $R = \text{CH}_3$) as models of two bases that can form hydrogen bonds in DNA. (a) Using molecular modelling software and the computational method of your choice, calculate the atomic charges of all atoms in methyl-adenine and methyl-thymine. (b) Based on your tabulation of atomic charges, identify the atoms in methyl-adenine and methyl-thymine that are likely to participate in hydrogen bonds. (c) Draw all possible adenine–thymine pairs that can be linked by hydrogen bonds, keeping in mind that linear arrangements of the $A \cdots B$ fragments are preferred in DNA. For this step, you may want to use your molecular modelling software to align the molecules properly. (d) Consult Chapter 19 and determine which of the pairs that you drew in part (c) occur naturally in DNA molecules. (e) Repeat parts (a)–(d) for cytosine and guanine, which also form base pairs in DNA (see Chapter 19 for the structures of these bases).

16

17

18.21 Molecular orbital calculations may be used to predict the dipole moments of molecules. (a) Using molecular modelling software and the computational method of your choice, calculate the dipole moment of the peptide link, modelled as a *trans-N*-methylacetamide (**18**). Plot the energy of interaction between these dipoles against the angle θ for $r = 3.0$ nm (see eqn 18.22). (b) Compare the maximum value of the dipole–dipole interaction energy from part (a) to 20 kJ mol^{-1} , a typical value for the energy of a hydrogen-bonding interaction in biological systems.

18

18.22 This problem gives a simple example of a quantitative structure–activity relation (QSAR). The binding of nonpolar groups of amino acid to hydrophobic sites in the interior of proteins is governed largely by hydrophobic interactions. (a) Consider a family of hydrocarbons $R-H$. The

hydrophobicity constants, π , for $R = \text{CH}_3$, CH_2CH_3 , $(\text{CH}_2)_2\text{CH}_3$, $(\text{CH}_2)_3\text{CH}_3$, and $(\text{CH}_2)_4\text{CH}_3$ are, respectively, 0.5, 1.0, 1.5, 2.0, and 2.5. Use these data to predict the π value for $(\text{CH}_2)_6\text{CH}_3$. (b) The equilibrium constants K_1 for the dissociation of inhibitors (**19**) from the enzyme chymotrypsin were measured for different substituents R:

R	CH_3CO	CN	NO_2	CH_3	Cl
π	-0.20	-0.025	0.33	0.5	0.9
$\log K_1$	-1.73	-1.90	-2.43	-2.55	-3.40

Plot $\log K_1$ against π . Does the plot suggest a linear relationship? If so, what are the slope and intercept to the $\log K_1$ axis of the line that best fits the data? (c) Predict the value of K_1 for the case $R = \text{H}$.

18.23 Derivatives of the compound TIBO (**20**) inhibit the enzyme reverse transcriptase, which catalyses the conversion of retroviral RNA to DNA. A QSAR analysis of the activity A of a number of TIBO derivatives suggests the following equation:

$$\log A = b_0 + b_1 S + b_2 W$$

where S is a parameter related to the drug's solubility in water and W is a parameter related to the width of the first atom in a substituent X shown in **20**.

(a) Use the following data to determine the values of b_0 , b_1 , and b_2 . *Hint.* The QSAR equation relates one dependent variable, $\log A$, to two independent variables, S and W . To fit the data, you must use the mathematical procedure of *multiple regression*, which can be performed with mathematical software or an electronic spreadsheet.

X	H	Cl	SCH_3	OCH_3	CN	CHO	Br	CH_3	CCH
$\log A$	7.36	8.37	8.3	7.47	7.25	6.73	8.52	7.87	7.53
S	3.53	4.24	4.09	3.45	2.96	2.89	4.39	4.03	3.80
W	1.00	1.80	1.70	1.35	1.60	1.60	1.95	1.60	1.60

(b) What should be the value of W for a drug with $S = 4.84$ and $\log A = 7.60$?

Problems

Macromolecules exhibit a range of properties and problems that illustrate a wide variety of physical chemical principles. They need to be characterized in terms of their molar mass, their size, and their shape. However, the molecules are so large and the solutions they form depart so strongly from ideality, that techniques for accommodating these departures from ideality need to be developed. Another major problem concerns the influences that determine the shapes of the molecules. We consider a range of influences in this chapter, beginning with a structureless random coil and ending with the structurally precise forces that operate in polypeptides and nucleic acids. Atoms, small molecules, and macromolecules can form large assemblies that are held together by one or more of the molecular interactions described in Chapter 18. These assemblies, which include colloids and biological membranes, exhibit some of the typical properties of molecules but have their own characteristic features.

There are macromolecules everywhere, inside us and outside us. Some are natural: they include polysaccharides such as cellulose, polypeptides such as protein enzymes, and polynucleotides such as deoxyribonucleic acid (DNA). Others are synthetic: they include **polymers** such as nylon and polystyrene that are manufactured by stringing together and (in some cases) cross-linking smaller units known as **monomers**. Life in all its forms, from its intrinsic nature to its technological interaction with its environment, is the chemistry of macromolecules.

Macromolecules give rise to special problems that include the shapes and the lengths of polymer chains, the determination of their sizes, and the large deviations from ideality of their solutions. Natural macromolecules differ in certain respects from synthetic macromolecules, particularly in their composition and the resulting structure, but the two share a number of common properties. We concentrate on these common properties here. Another level of complexity arises when small molecules aggregate into large particles in a process that is called ‘self-assembly’ and give rise to aggregates. One example is the assembly of haemoglobin from four myoglobin-like polypeptides. A similar type of aggregation gives rise to a variety of disperse phases, which include colloids. The properties of these disperse phases resemble to a certain extent the properties of solutions of macromolecules, and we describe their common attributes in the final part of this chapter.

Determination of size and shape

X-ray diffraction techniques (Chapter 20) can reveal the position of almost every heavy atom (that is, every atom other than hydrogen) even in very large molecules. However, there are several reasons why other techniques must also be used. In the first

place, the sample might be a mixture of molecules with different chain lengths and extents of cross-linking, in which case sharp X-ray images are not obtained. Even if all the molecules in the sample are identical, it might prove impossible to obtain a single crystal, which is essential for diffraction studies because only then does the electron density (which is responsible for the scattering) have a large-scale periodic variation. Furthermore, although work on proteins and DNA has shown how immensely interesting and motivating the data can be, the information is incomplete. For instance, what can be said about the shape of the molecule in its natural environment, a biological cell? What can be said about the response of its shape to changes in its environment?

19.1 Mean molar masses

A pure protein is **monodisperse**, meaning that it has a single, definite molar mass (although there may be small variations, such as one amino acid replacing another, depending on the source of the sample). A synthetic polymer, however, is **polydisperse**, in the sense that a sample is a mixture of molecules with various chain lengths and molar masses. The various techniques that are used to measure molar masses result in different types of mean values of polydisperse systems.

The mean obtained from the determination of molar mass by osmometry (Section 5.5) is the **number-average molar mass**, $\bar{M}_n$, which is the value obtained by weighting each molar mass by the number of molecules of that mass present in the sample:

$$\bar{M}_n = \frac{1}{N} \sum_i N_i M_i \quad (19.1)$$

where N_i is the number of molecules with molar mass M_i and there are N molecules in all. Viscosity measurements give the **viscosity-average molar mass**, $\bar{M}_v$, light-scattering experiments give the **weight-average molar mass**, $\bar{M}_w$, and sedimentation experiments give the **Z-average molar mass**, $\bar{M}_Z$. (The name is derived from the z-coordinate used to depict data in a procedure for determining the average.) Although such averages are often best left as empirical quantities, some may be interpreted in terms of the composition of the sample. Thus, the weight-average molar mass is the average calculated by weighting the molar masses of the molecules by the mass of each one present in the sample:

$$\bar{M}_w = \frac{1}{m} \sum_i m_i M_i \quad (19.2)$$

In this expression, m_i is the total mass of molecules of molar mass M_i and m is the total mass of the sample. Because $m_i = N_i M_i / N_A$, we can also express this average as

$$\bar{M}_w = \frac{\sum_i N_i M_i^2}{\sum_i N_i M_i} \quad (19.3)$$

This expression shows that the weight-average molar mass is proportional to the mean square molar mass. Similarly, the Z-average molar mass can be interpreted in terms of the mean cubic molar mass:

$$\bar{M}_Z = \frac{\sum_i N_i M_i^3}{\sum_i N_i M_i^2} \quad (19.4)$$

Example 19.1 Calculating number and mass averages

Determine the number-average and the weight-average molar masses for a sample of poly(vinyl chloride) from the following data:

Molar mass interval/ (kg mol ⁻¹)	Average molar mass within interval/(kg mol ⁻¹)	Mass of sample within interval/g
5–10	7.5	9.6
10–15	12.5	8.7
15–20	17.5	8.9
20–25	22.5	5.6
25–30	27.5	3.1
30–35	32.5	1.7

Method The relevant equations are eqns 19.1 and 19.2. Calculate the two averages by weighting the molar mass within each interval by the number and mass, respectively, of the molecule in each interval. Obtain the numbers in each interval by dividing the mass of the sample in each interval by the average molar mass for that interval. Because the number of molecules is proportional to the amount of substance (the number of moles), the number-weighted average can be obtained directly from the amounts in each interval.

Answer The amounts in each interval are as follows:

Interval	5–10	10–15	15–20	20–25	25–30	30–35
Molar mass/(kg mol ⁻¹)	7.5	12.5	17.5	22.5	27.5	32.5
Amount/mol	1.3	0.70	0.51	0.25	0.11	0.052
					Total:	2.92

The number-average molar mass is therefore

$$\begin{aligned}\bar{M}_n/(\text{kg mol}^{-1}) &= \frac{1}{2.92} (1.3 \times 7.5 + 0.70 \times 12.5 + 0.51 \times 17.5 + 0.25 \times 22.5 \\ &\quad + 0.11 \times 27.5 + 0.052 \times 32.5) \\ &= 13\end{aligned}$$

The weight-average molar mass is calculated directly from the data after noting that the total mass of the sample is 37.6 g:

$$\begin{aligned}\bar{M}_w/(\text{kg mol}^{-1}) &= \frac{1}{37.6} (9.6 \times 7.5 + 8.7 \times 12.5 + 8.9 \times 17.5 + 5.6 \times 22.5 \\ &\quad + 3.1 \times 27.5 + 1.7 \times 32.5) \\ &= 16\end{aligned}$$

Note the significantly different values of the two averages. In this instance, $\bar{M}_w/\bar{M}_n = 1.2$.

Self-test 19.1 Evaluate the *Z*-average molar mass of the sample. [19 kg mol⁻¹]

The ratio $\bar{M}_w/\bar{M}_n$ is called the **heterogeneity index** (or ‘polydispersity index’). In the determination of protein molar masses we expect the various averages to be the

same because the sample is monodisperse (unless there has been degradation). A synthetic polymer normally spans a range of molar masses and the different averages yield different values. Typical synthetic materials have $\bar{M}_w/\bar{M}_n \approx 4$. The term ‘monodisperse’ is conventionally applied to synthetic polymers in which this index is less than 1.1; commercial polyethylene samples might be much more heterogeneous, with a ratio close to 30. One consequence of a narrow molar mass distribution for synthetic polymers is often a higher degree of three-dimensional long-range order in the solid and therefore higher density and melting point. The spread of values is controlled by the choice of catalyst and reaction conditions. In practice, it is found that long-range order is determined more by structural factors (branching, for instance) than by molar mass.

Average molar masses may be determined by osmotic pressure of polymer solutions. The upper limit for the reliability of membrane osmometry is about 1000 kg mol^{-1} . A major problem for macromolecules of relatively low molar mass (less than about 10 kg mol^{-1}) is their ability to percolate through the membrane. One consequence of this partial permeability is that membrane osmometry tends to overestimate the average molar mass of a polydisperse mixture. Several techniques for the determination of molar mass and polydispersity that are not so limited include mass spectrometry, laser light scattering, ultracentrifugation, electrophoresis, and viscosity measurements.

19.2 Mass spectrometry

Mass spectrometry is among the most accurate techniques for the determination of molar masses. The procedure consists of ionizing the sample in the gas phase and then measuring the mass-to-charge number ratio (m/z) of all ions. Macromolecules present a challenge because it is difficult to produce gaseous ions of large species without fragmentation. However, two new techniques have emerged that circumvent this problem: **matrix-assisted laser desorption/ionization** (MALDI) and **electrospray ionization**. We shall discuss **MALDI-TOF mass spectrometry**, so called because the MALDI technique is coupled to a time-of-flight (TOF) ion detector.

Figure 19.1 shows a schematic view of a MALDI-TOF mass spectrometer. The macromolecule is first embedded in a solid matrix that often consists of an organic material such as *trans*-3-indoleacrylic acid and inorganic salts such as sodium chloride or silver trifluoroacetate. This sample is then irradiated with a pulsed laser, such as a nitrogen laser. The laser energy ejects electronically excited matrix ions, cations, and neutral macromolecules, thus creating a dense gas plume above the sample surface. The macromolecule is ionized by collisions and complexation with small cations, such as H^+ , Na^+ , and Ag^+ .

In the TOF spectrometer, the ions are accelerated over a short distance d by an electrical field of strength $\mathcal{E}$ and then travel through a drift region of length l . The time, t , required for an ion of mass m and charge number z to reach the detector at the end of the drift region is (see the *Justification*):

$$t = l \left(\frac{m}{2ze\mathcal{E}d} \right)^{1/2} \quad (19.5)$$

where e is the fundamental charge. Because d , l , and $\mathcal{E}$ are fixed for a given experiment, the time of flight, t , of the ion is a direct measure of its m/z ratio, which is given by:

$$\frac{m}{z} = 2e\mathcal{E}d \left(\frac{t}{l} \right)^2 \quad (19.6)$$

Fig. 19.1 A matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometer. A laser beam ejects macromolecules and ions from the solid matrix. The ionized macromolecules are accelerated by an electrical potential difference over a distance d and then travel through a drift region of length l . Ions with the smallest mass to charge ratio (m/z) reach the detector first.

Fig. 19.2 MALDI-TOF spectrum of a sample of poly(butylene adipate) with $\bar{M}_n = 4525 \text{ g mol}^{-1}$ (Adapted from Mudiman *et al.*, *J. Chem. Educ.*, **74**, 1288 (1997).)

Justification 19.1 The time of flight of an ion in a mass spectrometer

Consider an ion of charge ze and mass m that is accelerated from rest by an electric field of strength $\mathcal{E}$ applied over a distance d . The kinetic energy, E_K , of the ion is

$$E_K = \frac{1}{2}mv^2 = ze\mathcal{E}d$$

where v is the speed of the ion. The drift region, l , and the time of flight, t , in the mass spectrometer are both sufficiently short that we can ignore acceleration and write $v = l/t$. Then substitution into this equation gives

$$\frac{1}{2}m\left(\frac{l}{t}\right)^2 = ze\mathcal{E}d$$

Rearrangement of this equation gives eqn 19.6.

Figure 19.2 shows the MALDI-TOF mass spectrum of a polydisperse sample of poly(butylene adipate) (PBA, **1**). The MALDI technique produces mostly singly charged molecular ions that are not fragmented. Therefore, the multiple peaks in the spectrum arise from polymers of different lengths, with the intensity of each peak being proportional to the abundance of each polymer in the sample. Values of $\bar{M}_n$, $\bar{M}_w$, and the heterogeneity index can be calculated from the data. It is also possible to use the mass spectrum to verify the structure of a polymer, as shown in the following example.

Example 19.2 Interpreting the mass spectrum of a polymer

The mass spectrum in Fig. 19.2 consists of peaks spaced by 200 g mol^{-1} . The peak at 4113 g mol^{-1} corresponds to the polymer for which $n = 20$. From these data, verify that the sample consists of polymers with the general structure given by (**1**).

Method Because each peak corresponds to a different value of n , the molar mass difference, ΔM , between peaks corresponds to the molar mass, M , of the repeating unit (the group inside the brackets in **1**). Furthermore, the molar mass of the terminal groups (the groups outside the brackets in **1**) may be obtained from the molar mass of any peak by using

$$M(\text{terminal groups}) = M(\text{polymer with } n \text{ repeating units}) - n\Delta M - M(\text{cation})$$

where the last term corresponds to the molar mass of the cation that attaches to the macromolecule during ionization.

Answer The value of ΔM is consistent with the molar mass of the repeating unit shown in (**1**), which is 200 g mol^{-1} . The molar mass of the terminal group is calculated by recalling that Na^+ is the cation in the matrix:

$$M(\text{terminal group}) = 4113 \text{ g mol}^{-1} - 20(200 \text{ g mol}^{-1}) - 23 \text{ g mol}^{-1} = 90 \text{ g mol}^{-1}$$

The result is consistent with the molar mass of the $-\text{O}(\text{CH}_2)_4\text{OH}$ terminal group (89 g mol^{-1}) plus the molar mass of the $-\text{H}$ terminal group (1 g mol^{-1}).

Self-test 19.2 What would be the molar mass of the $n = 20$ polymer if silver trifluoroacetate were used instead of NaCl in the preparation of the matrix?

[4198 g mol^{-1}]

19.3 Laser light scattering

Large particles scatter light very efficiently. A familiar example is the light scattered by specks of dust in a sunbeam. Therefore, light scattering is a convenient method for the characterization of polymers, large aggregates (such as colloids), and biological systems from proteins to viruses. Unlike mass spectrometry, laser light scattering measurements may be performed in nearly intact samples; often the only preparation required is filtration of the sample.

(a) General principles of light scattering

When the oscillating electric field of electromagnetic radiation interacts with the electrons in a particle, an oscillating dipole moment develops with a magnitude proportional to the polarizability of the particle and the strength of the field (Section 18.1). Elastic light scattering is observed as the oscillating dipoles in the particle radiate at the same frequency as the frequency of the exciting electromagnetic radiation. The term *elastic* refers to the fact that the incident and scattered photons have the same frequency and hence the same energy. If the medium is perfectly homogeneous, as in a perfect crystal, the scattered waves interfere destructively in all directions except the direction of propagation of the exciting radiation. If the medium is inhomogeneous, as in an imperfect crystal or a solution of macromolecules, radiation is scattered into other directions as well.

Scattering of light by particles with diameters much smaller than the wavelength of the incident radiation is called **Rayleigh scattering** (Fig. 19.3). This type of scattering has several characteristic features.

- 1 The intensity of scattered light is proportional to λ^{-4} , so shorter wavelength radiation is scattered more intensely than longer wavelengths.
- 2 The intensity of scattered light is proportional to the molar mass of the particle.
- 3 The intensity of scattered light depends on the scattering angle θ (Fig. 19.3). In practice, data are collected at several angles to the incident laser beam (Example 19.3).
- 4 For very dilute solutions excited by plane-polarized light, the **Rayleigh ratio**, R_θ , a measure of the intensity of scattered light at a given scattering angle θ , is defined as

$$R_\theta = \frac{I}{I_0} \times \frac{r^2}{\sin^2 \phi} \quad (19.7)$$

where I is the intensity of scattered light, I_0 is the intensity of incident light, r is the distance between the sample and the detector, ϕ is the angle between the plane of polarization of the incident beam and the plane defined by the incident and scattered beams (see the inset in Fig. 19.3).

For a solution of a polymer of mass concentration c_p , the Rayleigh ratio may be written as

$$R_\theta = K P_\theta c_p \bar{M}_w, \text{ with } K = \frac{4\pi^2 n_{r,0}^2 V (dn_r/dc_p)^2}{\lambda^4 N_A} \quad (19.8)$$

Here $n_{r,0}$ is the refractive index of the pure solvent (see *Comment* 18.6 and *Appendix* 3), (dn/dc_p) is the change in refractive index of the solution with concentration of polymer, V is the volume of the sample, and N_A is Avogadro's constant. The parameter P_θ is the **structure factor**, which takes into account the fact that scattering may occur from different sites of the same molecule and interference between scattered rays becomes important when the wavelength of the incident radiation is comparable to the size of the scattering particles. When the molecule is much smaller than the wavelength of incident radiation, $P_\theta \approx 1$. However, when the size of the molecule is

Fig. 19.3 Rayleigh scattering from a sample of point-like particles. The intensity of scattered light depends on the angle θ between the incident and scattered beams. The inset shows the angle ϕ between the plane of polarization of the incident beam and the plane defined by the incident and scattered beams. In a typical experimental arrangement, $\phi = 90^\circ$.

Fig. 19.4 (a) A spherical molecule and (b) the hollow spherical shell that has the same rotational characteristics. The radius of the hollow shell is the radius of gyration of the molecule.

* More values are given in the *Data section*.

† In a poor solvent.

about one-tenth the wavelength of the incident radiation, we show in *Further information* 19.1 that

$$P_\theta \approx 1 - \frac{16\pi^2 R_g^2 \sin^2 \frac{1}{2}\theta}{3\lambda^2} \quad (19.9)$$

where R_g is the **radius of gyration** of the macromolecule, the radius of a thin hollow spherical shell of the same mass and moment of inertia as the molecule (Fig. 19.4 and Section 19.8). Table 19.1 lists some experimental values of R_g .

Illustration 19.1 Why is the sky blue whereas clouds are white?

We expect from eqn 19.9 that when the particles are very small and $P_\theta \approx 1$, the medium scatters light of shorter wavelengths much more efficiently than light of longer wavelengths. This effect accounts for the colour of a cloudless sky: the N_2 and O_2 molecules in the atmosphere are much smaller than the wavelengths of visible electromagnetic radiation, so blue light is scattered preferentially. We also see clouds because light scatters from them, but they look white, not blue. In clouds, the water molecules group together into droplets of a size comparable to the wavelength of light, and scatter cooperatively. Although blue light scatters more strongly, more molecules can contribute cooperatively when the wavelength is longer (as for red light), so the net result is uniform scattering for all wavelengths: white light scatters as white light. This paper looks white for the same reason. As a result, the scattering intensity is distorted from the form characteristic of small-particle, Rayleigh scattering, and the distortion is taken into account by values of P_θ that differ from 1.

(b) Scattering by non-ideal solutions of polymers

The preceding discussion shows that structural properties, such as size and the weight-average molar mass of a macromolecule, can be obtained from measurements of light scattering by a sample at several angles θ relative to the direction of propagation on an incident laser beam. However, eqn 19.8 applies only to ideal solutions. In practice, even relatively dilute polymer dispersions can deviate considerably from ideality. Being so large, macromolecules displace a large quantity of solvent instead of replacing individual solvent molecules with negligible disturbance. In thermodynamic terms, the displacement and reorganization of solvent molecules implies that the entropy change is especially important when a macromolecule dissolves. Furthermore, its great bulk means that a macromolecule is unable to move freely through the solution because the molecule is excluded from the regions occupied by other solute molecules. There are also significant contributions to the Gibbs energy from the enthalpy of solution, largely because solvent–solvent interactions are more favourable than the macromolecule–solvent interactions that replace them. To take deviations from ideality into account, it is common to rewrite eqn 19.8 as

$$\frac{Kc_p}{R_\theta} = \frac{1}{P_\theta \bar{M}_w} + Bc_p \quad (19.10)$$

where B is an empirical constant analogous to the osmotic virial coefficient and indicative of the effect of excluded volume.

For most solute–solvent systems there is a unique temperature (which is not always experimentally attainable) at which the effects leading to non-ideal behaviour cancel and the solution is virtually ideal. This temperature (the analogue of the Boyle

temperature for real gases) is called the **θ -temperature** (theta temperature). At this temperature, B is zero. As an example, for polystyrene in cyclohexane the θ -temperature is approximately 306 K, the exact value depending on the average molar mass of the polymer. A solution at its θ -temperature is called a **θ -solution**. Because a θ -solution behaves nearly ideally, its thermodynamic and structural properties are easier to describe even though the molar concentration is not low. In molecular terms, in a theta solution the molecules are in an unperturbed condition, whereas in other solutions expansion of the coiled molecule takes place as a result of interactions with the solvent.

Example 19.3 Determining the size of a polymer by light scattering

The following data for a sample of polystyrene in butanone were obtained at 20°C with plane-polarized light at $\lambda = 546$ nm.

$\theta/^\circ$	26.0	36.9	66.4	90.0	113.6
R_θ/m^2	19.7	18.8	17.1	16.0	14.4

In separate experiments, it was determined that $K = 6.42 \times 10^{-5} \text{ mol m}^5 \text{ kg}^{-2}$. From this information, calculate R_g and $\bar{M}_w$ for the sample. Assume that B is negligibly small and that the polymer is small enough that eqn 19.9 holds.

Method Substituting the result of eqn 19.9 into eqn 19.8 we obtain, after some rearrangement:

$$\frac{1}{R_\theta} = \frac{1}{Kc_p\bar{M}_w} + \left(\frac{16\pi^2 R_g^2}{3\lambda^2} \right) \left(\frac{1}{R_\theta} \sin^2 \frac{1}{2}\theta \right)$$

Hence, a plot of $1/R_\theta$ against $(1/R_\theta) \sin^2 \frac{1}{2}\theta$ should be a straight line with slope $16\pi^2 R_g^2/3\lambda^2$ and y -intercept $1/Kc_p\bar{M}_w$.

Answer We construct a table of values of $1/R_\theta$ and $(1/R_\theta) \sin^2 \frac{1}{2}\theta$ and plot the data (Fig. 19.5).

$10^2 \times R_\theta^{-1}/\text{m}^{-2}$	5.06	5.32	5.83	6.25	6.96
$(10^3/R_\theta) \sin^2(\frac{1}{2}\theta)/\text{m}^{-2}$	2.56	5.33	17.5	31.3	48.7

The best straight line through the data has a slope of 0.391 and a y -intercept of 5.06×10^{-2} . From these values and the value of K , we calculate $R_g = 4.71 \times 10^{-8} \text{ m} = 47.1 \text{ nm}$ and $\bar{M}_w = 987 \text{ kg mol}^{-1}$.

A more accurate method for more concentrated samples consists of conducting a series of experiments where R_θ against θ data are obtained for several c_p values. From analysis of the entire data set, the R_g , $\bar{M}_w$, and B values are obtained.

Self-test 19.3 The following data for an aqueous solution of a protein with $c_p = 2.0 \text{ kg m}^{-3}$ were obtained at 20°C with laser light at $\lambda = 532$ nm:

$\theta/^\circ$	15.0	45.0	70.0	85.0	90.0
R_θ/m^2	23.8	22.9	21.6	20.7	20.4

In a separate experiment, it was determined that $K = 2.40 \times 10^{-2} \text{ mol m}^5 \text{ kg}^{-2}$. From this information, calculate the radius of gyration and the molar mass of the protein. Assume that B is negligibly small and that the protein is small enough that eqn 19.9 holds.

$$[R_g = 39.8 \text{ nm}; M = 498 \text{ kg mol}^{-1}]$$

(c) Dynamic light scattering

A special laser scattering technique, **dynamic light scattering**, can be used to investigate the diffusion of polymers in solution. Consider two polymer molecules being irradiated by a laser beam. Suppose that at a time t the scattered waves from these particles interfere constructively at the detector, leading to a large signal. However, as the molecules move through the solution, the scattered waves may interfere destructively at another time t' and result in no signal. When this behaviour is extended to a very large number of molecules in solution, it results in fluctuations in light intensity that depend on the diffusion coefficient, D , which is a measure of the rate of molecular motion and is given by the **Stokes–Einstein relation** (which is discussed further in Section 21.9e):

$$D = \frac{kT}{f} \quad (19.11)$$

where f is the **frictional coefficient**, a measure of the forces that retard a molecule's motion. Table 19.2 lists some typical values of D . For a spherical particle of radius a in a solvent of viscosity η (see Section 19.6), the frictional coefficient is given by **Stokes's relation**:

$$f = 6\pi a \eta \quad (19.12)$$

If the molecule is not spherical, we use appropriate values of f given in Table 19.3. Hence, dynamic light scattering measurements give the diffusion coefficient and molecular size, in cases where the molecular shape is known. For dilute monodisperse systems of random coils, it has been found empirically that D is related to the molar mass M of the polymer by:

$$D = \beta_D M^{-0.6} \quad (19.13)$$

The coefficient β_D is obtained by determining D at fixed viscosity and temperature for a variety of standard samples with known molar masses. As we should expect, bulky polymers of high molar mass migrate more slowly (have a lower diffusion coefficient) through a solvent than polymers of low molar mass.

19.4 Ultracentrifugation

In a gravitational field, heavy particles settle towards the foot of a column of solution by the process called **sedimentation**. The rate of sedimentation depends on the strength of the field and on the masses and shapes of the particles. Spherical molecules (and compact molecules in general) sediment faster than rod-like and extended molecules. When the sample is at equilibrium, the particles are dispersed over a range of heights in accord with the Boltzmann distribution (because the gravitational field competes with the stirring effect of thermal motion). The spread of heights depends on the masses of the molecules, so the equilibrium distribution is another way to determine molar mass.

Sedimentation is normally very slow, but it can be accelerated by **ultracentrifugation**, a technique that replaces the gravitational field with a centrifugal field. The effect can be achieved in an ultracentrifuge, which is essentially a cylinder that can be rotated at high speed about its axis with a sample in a cell near its periphery (Fig. 19.6). Modern ultracentrifuges can produce accelerations equivalent to about 10^5 that of gravity (' $10^5 g$ '). Initially the sample is uniform, but the 'top' (innermost) boundary of the solute moves outwards as sedimentation proceeds.

(a) The rate of sedimentation

A solute particle of mass m has an effective mass $m_{\text{eff}} = bm$ on account of the buoyancy of the medium, with

$$b = 1 - \rho v_s \quad (19.14)$$

where ρ is the solution density, v_s is the partial specific volume of the solute ($v_s = (\partial V / \partial m_B)_T$, with m_B the total mass of solute), and ρv_s is the mass of solvent displaced per gram of solute. The solute particles at a distance r from the axis of a rotor spinning at an angular velocity ω experience a centrifugal force of magnitude $m_{\text{eff}} r \omega^2$. The acceleration outwards is countered by a frictional force proportional to the speed, s , of the particles through the medium. This force is written fs , where f is the frictional coefficient (Section 19.3). The particles therefore adopt a **drift speed**, a constant speed through the medium, which is found by equating the two forces $m_{\text{eff}} r \omega^2$ and fs . The forces are equal when

$$s = \frac{m_{\text{eff}} r \omega^2}{f} = \frac{bmr\omega^2}{f} \quad (19.15)$$

The drift speed depends on the angular velocity and the radius, and it is convenient to define the **sedimentation constant**, S , as

$$S = \frac{s}{r\omega^2} \quad (19.16)$$

Then, because the average molecular mass is related to the average molar mass $\bar{M}_n$ through $m = \bar{M}_n / N_A$,

$$S = \frac{b\bar{M}_n}{fN_A} \quad (19.17)$$

On substituting the Stokes relation for spherical molecules (eqn 19.12), we obtain

$$S = \frac{b\bar{M}_n}{6\pi a\eta N_A} \quad (19.18)$$

and S may be used to determine either $\bar{M}_n$ or a . Again, if the molecules are not spherical, we use the appropriate value of f given in Table 19.3. As always when dealing with macromolecules, the measurements must be carried out at a series of concentrations and then extrapolated to zero concentration to avoid the complications that arise from the interference between bulky molecules.

Fig. 19.6 (a) An ultracentrifuge head. The sample on one side is balanced by a blank diametrically opposite. (b) Detail of the sample cavity: the 'top' surface is the inner surface, and the centrifugal force causes sedimentation towards the outer surface; a particle at a radius r experiences a force of magnitude $mr\omega^2$.

Example 19.4 *Determining a sedimentation constant*

The sedimentation of the protein bovine serum albumin (BSA) was monitored at 25°C. The initial location of the solute surface was at 5.50 cm from the axis of rotation, and during centrifugation at 56 850 r.p.m. it receded as follows:

t/s	0	500	1000	2000	3000	4000	5000
r/cm	5.50	5.55	5.60	5.70	5.80	5.91	6.01

Calculate the sedimentation coefficient.

Method Equation 19.16 can be interpreted as a differential equation for $s = dr/dt$ in terms of r ; so integrate it to obtain a formula for r in terms of t . The integrated expression, an expression for r as a function of t , will suggest how to plot the data and obtain from it the sedimentation constant.

Fig. 19.7 A plot of the data in Example 19.4.

Answer Equation 19.16 may be written

$$\frac{dr}{dt} = r\omega^2 S$$

This equation integrates to

$$\ln \frac{r}{r_0} = \omega^2 S t$$

It follows that a plot of $\ln(r/r_0)$ against t should be a straight line of slope $\omega^2 S$. Use $\omega = 2\pi\nu$, where ν is in cycles per second, and draw up the following table:

t/s	0	500	1000	2000	3000	4000	5000
$10^2 \ln(r/r_0)$	0	0.905	1.80	3.57	5.31	7.19	8.87

The straight-line graph (Fig. 19.7) has slope 1.78×10^{-5} ; so $\omega^2 S = 1.79 \times 10^{-5} \text{ s}^{-1}$. Because $\omega = 2\pi \times (56\,850/60) \text{ s}^{-1} = 5.95 \times 10^3 \text{ s}^{-1}$, it follows that $S = 5.02 \times 10^{-13} \text{ s}$. The unit 10^{-13} s is sometimes called a ‘svedberg’ and denoted Sv; in this case $S = 5.02 \text{ Sv}$.

Self-test 19.4 Calculate the sedimentation constant given the following data (the other conditions being the same as above):

t/s	0	500	1000	2000	3000	4000	5000
r/cm	5.65	5.68	5.71	5.77	5.84	5.9	5.97

[3.11 Sv]

At this stage, it appears that we need to know the molecular radius a to obtain the molar mass from the value of S . Fortunately, this requirement can be avoided by drawing on the Stokes–Einstein relation (eqn 19.11) between f and the diffusion coefficient, D . The average molar mass is then:

$$\bar{M} = \frac{SRT}{bD} \quad (19.19)$$

where we are not specifying which mean molar mass because the average obtained depends on technical details of the experiment. The result in eqn 19.19 is independent of the shape of the solute molecules. It follows that we can find the molar mass by combining measurements of S and D by ultracentrifugation and dynamic light scattering, respectively.

(b) Sedimentation equilibria

The difficulty with using sedimentation rates to measure molar masses lies in the inaccuracies inherent in the determination of diffusion coefficients of polydisperse systems. This problem can be avoided by allowing the system to reach equilibrium, for the transport property D is then no longer relevant. As we show in the *Justification* below, the weight-average molar mass can be obtained from the ratio of concentrations of the macromolecules at two different radii in a centrifuge operating at angular frequency ω :

$$\bar{M}_w = \frac{2RT}{(r_2^2 - r_1^2)b\omega^2} \ln \frac{c_2}{c_1} \quad (19.20)$$

An alternative treatment of the data leads to the Z -average molar mass. The centrifuge is run more slowly in this technique than in the sedimentation rate method to avoid having all the solute pressed in a thin film against the bottom of the cell. At these slower speeds, several days may be needed for equilibrium to be reached.

Justification 19.2 *The weight-average molar mass from sedimentation experiments*

The distribution of particles is the outcome of the balance between the effect of the centrifugal force and the dispersing effect of diffusion down a concentration gradient. The kinetic energy of a particle of effective mass m at a radius r in a rotor spinning at a frequency ω is $\frac{1}{2}m\omega^2r^2$, so the total chemical potential at a radius r is $\bar{\mu}(r) = \mu(r) - \frac{1}{2}m\omega^2r^2$, where $\mu(r)$ is the contribution that depends on the concentration of solute. The condition for equilibrium is that the chemical potential is uniform, so

$$\left(\frac{\partial \bar{\mu}}{\partial r}\right)_T = \left(\frac{\partial \mu}{\partial r}\right)_T - M\omega^2r = 0$$

To evaluate the partial derivative of μ , we write

$$\left(\frac{\partial \mu}{\partial r}\right)_T = \left(\frac{\partial \mu}{\partial p}\right)_{T,c} \left(\frac{\partial p}{\partial r}\right)_{T,c} + \left(\frac{\partial \mu}{\partial c}\right)_{T,p} \left(\frac{\partial c}{\partial r}\right)_{T,p} = Mv\omega^2r\rho + RT \left(\frac{\partial \ln c}{\partial r}\right)_{T,p}$$

The first result follows from the fact that $(\partial\mu/\partial p)_T = V_m$, the partial molar volume, and $V_m = Mv$. It also makes use of the fact that the hydrostatic pressure at r is $p(r) = p(r_0) + \frac{1}{2}\rho\omega^2(r^2 - r_0^2)$, where r_0 is the radius of the surface of the liquid in the sample holder (that is, the location of its meniscus), with ρ the mass density of the solution. The concentration term stems from the expression $\mu = \mu^\circ + RT \ln c$. The condition for equilibrium is therefore

$$Mr\omega^2(1 - v\rho) - RT \left(\frac{\partial \ln c}{\partial r}\right)_{T,p} = 0$$

and therefore, at constant temperature,

$$d \ln c = \frac{Mr\omega^2(1 - v\rho)dr}{RT}$$

This expression integrates to eqn 19.20.

19.5 Electrophoresis

Many macromolecules, such as DNA, are charged and move in response to an electric field. This motion is called **electrophoresis**. Electrophoretic mobility is a result of a constant drift speed, s , reached by an ion when the driving force $ze\mathcal{E}$ (where, as usual, ze is the net charge and $\mathcal{E}$ is the field strength) is matched by the frictional force fs . The drift speed (which is treated in detail in Section 21.7) is then:

$$s = \frac{ze\mathcal{E}}{f} \quad (19.21)$$

Therefore, the mobility of a macromolecule in an electric field depends on its net charge, size (and hence molar mass), and shape. The latter two factors are implied by the dependence of s on f .

The drift speeds attained by polymers in traditional electrophoresis methods are rather low; as a result, several hours are often necessary to effect good separation of

complex mixtures. According to eqn 19.21, one way to increase the drift speed is to increase the electric field strength. However, there are limits to this strategy because very large electric fields can heat the large surfaces of an electrophoresis apparatus unevenly, leading to a non-uniform distribution of electrophoretic mobilities and poor separation.

In **capillary electrophoresis**, the sample is dispersed in a medium (such as methylcellulose) and held in a thin glass or plastic tube with diameters ranging from 20 to 100 μm . The small size of the apparatus makes it easy to dissipate heat when large electric fields are applied. Excellent separations may be effected in minutes rather than hours. Each polymer fraction emerging from the capillary can be characterized further by other techniques, such as MALDI-TOF.

IMPACT ON BIOCHEMISTRY

I19.1 Gel electrophoresis in genomics and proteomics

Advances in biotechnology are linked strongly to the development of physical techniques. The ongoing effort to characterize the entire genetic material, or **genome**, of organisms as simple as bacteria and as complex as *Homo sapiens* will lead to important new insights into the molecular mechanisms of disease, primarily through the discovery of previously unknown proteins encoded by the deoxyribonucleic acid (DNA) in genes. However, decoding genomic DNA will not always lead to accurate predictions of the amino acids present in biologically active proteins. Many proteins undergo chemical modification, such as cleavage into smaller proteins, after being synthesized in the cell. Moreover, it is known that one piece of DNA may encode more than one active protein. It follows that it is also important to describe the **proteome**, the full complement of functional proteins of an organism, by characterizing directly the proteins after they have been synthesized and processed in the cell.

The procedures of **genomics** and **proteomics**, the analysis of the genome and proteome, of complex organisms are time-consuming because of the very large number of molecules that must be characterized. For example, the human genome contains about 30 000 genes and the number of active proteins is likely to be much larger. Success in the characterization of the genome and proteome of any organism will depend on the deployment of very rapid techniques for the determination of the order in which molecular building blocks are linked covalently in DNA and proteins.

An important tool in genomics and proteomics is **gel electrophoresis**, in which biopolymers are separated on a slab of a porous gel, a semirigid dispersion of a solid in a liquid. Because the molecules must pass through the pores in the gel, the larger the macromolecule the less mobile it is in the electric field and, conversely, the smaller the macromolecule the more swiftly it moves through the pores. In this way, gel electrophoresis allows for the separation of components of a mixture according to their molar masses. Two common gel materials for the study of proteins and nucleic acids are agarose and cross-linked polyacrylamide. Agarose has large pores and is better suited for the study of large macromolecules, such as DNA and enzyme complexes. Polyacrylamide gels with varying pore sizes can be made by changing the concentration of acrylamide in the polymerization solution. In general, smaller pores form as the concentration of acrylamide is increased, making possible the separation of relatively small macromolecules by **polyacrylamide gel electrophoresis** (PAGE).

The separation of very large pieces of DNA, such as chromosomes, by conventional gel electrophoresis is not effective, making the analysis of genomic material rather difficult. Double-stranded DNA molecules are thin enough to pass through gel pores, but long and flexible DNA coils can become trapped in the pores and the result is impaired mobility along the direction of the applied electric field. This problem can be avoided with **pulsed-field electrophoresis**, in which a brief burst of the electric

field is applied first along one direction and then along a perpendicular direction. In response to the switching back and forth between field directions, the DNA coils writhe about and eventually pass through the gel pores. In this way, the mobility of the macromolecule can be related to its molar mass.

We have seen that charge also determines the drift speed. For example, proteins of the same size but different net charge travel along the slab at different speeds. One way to avoid this problem and to achieve separation by molar mass is to denature the proteins in a controlled way. Sodium dodecyl sulfate is an anionic detergent that is very useful in this respect: it denatures proteins, whatever their initial shapes, into rods by forming a complex with them. Moreover, most protein molecules bind a constant number of ions, so the net charge per protein is well regulated. Under these conditions, different proteins in a mixture may be separated according to size only. The molar mass of each constituent protein is estimated by comparing its mobility in its rod-like complex form with that of a standard sample of known molar mass. However, molar masses obtained by this method, often referred to as **SDS-PAGE** when polyacrylamide gels are used, are not as accurate as those obtained by MALDI-TOF or ultracentrifugation.

Another technique that deals with the effect of charge on drift speed takes advantage of the fact that the overall charge of proteins and other biopolymers depends on the pH of the medium. For instance, in acidic environments protons attach to basic groups and the net charge is positive; in basic media the net charge is negative as a result of proton loss. At the **isoelectric point**, the pH is such that there is no net charge on the biopolymer. Consequently, the drift speed of a biopolymer depends on the pH of the medium, with $s = 0$ at the isoelectric point (Fig. 19.8). **Isoelectric focusing** is an electrophoresis method that exploits the dependence of drift speed on pH. In this technique, a mixture of proteins is dispersed in a medium with a pH gradient along the direction of an applied electric field. Each protein in the mixture will stop moving at a position in the gradient where the pH is equal to the isoelectric point. In this manner, the protein mixture can be separated into its components.

The separation of complicated mixtures of macromolecules may be difficult by SDS-PAGE or isoelectric focusing alone. However, the two techniques can be combined in **two-dimensional (2D) electrophoresis**. In a typical experiment, a protein mixture is separated first by isoelectric focusing, yielding a pattern of bands in a gel slab such as the one shown in Fig. 19.9a. To improve the separation of closely spaced bands, the first slab is attached to a second slab and SDS-PAGE is performed with the electric field being applied in a direction that is perpendicular to the direction in which isoelectric focusing was performed. The macromolecules separate according to their molar masses along this second dimension of the experiment, and the result is that spots are spread widely over the surface of the slab, leading to enhanced separation of the mixture's components (Fig. 19.9b).

19.6 Viscosity

The formal definition of viscosity is given in Section 21.4; for now, we need to know that highly viscous liquids flow slowly and retard the motion of objects through them. The presence of a macromolecular solute increases the viscosity of a solution. The effect is large even at low concentration, because big molecules affect the fluid flow over an extensive region surrounding them. At low concentrations the viscosity, η , of the solution is related to the viscosity of the pure solvent, η_0 , by

$$\eta = \eta_0(1 + [\eta]c + \dots) \quad (19.22)$$

The **intrinsic viscosity**, $[\eta]$, is the analogue of a virial coefficient (and has dimensions of 1/concentration). It follows from eqn 19.22 that

Fig. 19.8 The plot of drift speed of the protein bovine serum albumin in water against pH. The isoelectric point of the macromolecule corresponds to the pH at which the drift speed in the presence of an electric field is zero.

Fig. 19.9 The experimental steps taken during separation of a mixture of biopolymers by two-dimensional electrophoresis. (a) Isoelectric focusing is performed on a thin gel slab, resulting in separation along the vertical direction of the illustration. (b) The first slab is attached to a second, larger slab and SDS-PAGE is performed with the electric field oriented in the horizontal direction of the illustration, resulting in further separation by molar mass. The dashed horizontal lines show how the bands in the two-dimensional gel correspond to the bands in the gel on which isoelectric focusing was performed.

Fig. 19.10 An Ostwald viscometer. The viscosity is measured by noting the time required for the liquid to drain between the two marks.

Fig. 19.11 A rotating rheometer. The torque on the inner drum is observed when the outer container is rotated.

Synoptic table 19.4* Intrinsic viscosity

	Solvent	$\theta/^\circ\text{C}$	$K/(\text{cm}^3 \text{g}^{-1})$	a
Polystyrene	Benzene	25	9.5×10^{-3}	0.74
Polyisobutylene	Benzene	23	8.3×10^{-2}	0.50
Various proteins	Guanidine hydrochloride + $\text{HSCH}_2\text{CH}_2\text{OH}$		7.2×10^{-3}	0.66

* More values are given in the *Data section*.

$$[\eta] = \lim_{c \rightarrow 0} \left(\frac{\eta - \eta_0}{c\eta_0} \right) = \lim_{c \rightarrow 0} \left(\frac{\eta/\eta_0 - 1}{c} \right) \quad (19.23)$$

Viscosities are measured in several ways. In the **Ostwald viscometer** shown in Fig. 19.10, the time taken for a solution to flow through the capillary is noted, and compared with a standard sample. The method is well suited to the determination of $[\eta]$ because the ratio of the viscosities of the solution and the pure solvent is proportional to the drainage time t and t_0 after correcting for different densities ρ and ρ_0 :

$$\frac{\eta}{\eta_0} = \frac{t}{t_0} \times \frac{\rho}{\rho_0} \quad (19.24)$$

(In practice, the two densities are only rarely significantly different.) This ratio can be used directly in eqn 19.23. Viscometers in the form of rotating concentric cylinders are also used (Fig. 19.11), and the torque on the inner cylinder is monitored while the outer one is rotated. Such **rotating rheometers** (some instruments for the measurement of viscosity are also called rheometers) have the advantage over the Ostwald viscometer that the shear gradient between the cylinders is simpler than in the capillary and effects of the kind discussed shortly can be studied more easily.

There are many complications in the interpretation of viscosity measurements. Much of the work is based on empirical observations, and the determination of molar mass is usually based on comparisons with standard, nearly monodisperse sample. Some regularities are observed that help in the determination. For example, it is found that θ solutions of macromolecules often fit the **Mark–Kuhn–Houwink–Sakurada equation**:

$$[\eta] = K\bar{M}_v^a \quad (19.25)$$

where K and a are constants that depend on the solvent and type of macromolecule (Table 19.4); the viscosity-average molar mass, $\bar{M}_v$, appears in this expression.

Example 19.5 Using intrinsic viscosity to measure molar mass

The viscosities of a series of solutions of polystyrene in toluene were measured at 25°C with the following results:

$c/(\text{g dm}^{-3})$	0	2	4	6	8	10
$\eta/(10^{-4} \text{ kg m}^{-1} \text{ s}^{-1})$	5.58	6.15	6.74	7.35	7.98	8.64

Calculate the intrinsic viscosity and estimate the molar mass of the polymer by using eqn 19.25 with $K = 3.80 \times 10^{-5} \text{ dm}^3 \text{g}^{-1}$ and $a = 0.63$.

Method The intrinsic viscosity is defined in eqn 19.23; therefore, form this ratio at the series of data points and extrapolate to $c = 0$. Interpret $\bar{M}_v$ as $\bar{M}_v/(\text{g mol}^{-1})$ in eqn 19.25.

Answer We draw up the following table:

$c/(\text{g dm}^{-3})$	0	2	4	6	8	10
η/η_0	1	1.102	1.208	1.317	1.43	1.549
$100[(\eta/\eta_0) - 1]/(c/\text{g dm}^{-3})$		5.11	5.2	5.28	5.38	5.49

The points are plotted in Fig. 19.12. The extrapolated intercept at $c = 0$ is 0.0504, so $[\eta] = 0.0504 \text{ dm}^3 \text{ g}^{-1}$. Therefore,

$$\bar{M}_v = \left(\frac{[\eta]}{K} \right)^{1/a} = 9.0 \times 10^4 \text{ g mol}^{-1}$$

Self-test 19.5 Evaluate the viscosity-average molar mass by using the second plotting technique. [90 g mol⁻¹]

In some cases, the flow is non-Newtonian in the sense that the viscosity of the solution changes as the rate of flow increases. A decrease in viscosity with increasing rate of flow indicates the presence of long rod-like molecules that are orientated by the flow and hence slide past each other more freely. In some somewhat rare cases the stresses set up by the flow are so great that long molecules are broken up, with further consequences for the viscosity.

Structure and dynamics

The concept of the ‘structure’ of a macromolecule takes on different meanings at the different levels at which we think about the arrangement of the chain or network of monomers. The term **configuration** refers to the structural features that can be changed only by breaking chemical bonds and forming new ones. Thus, the chains —A—B—C— and —A—C—B— have different configurations. The term **conformation** refers to the spatial arrangement of the different parts of a chain, and one conformation can be changed into another by rotating one part of a chain around a bond.

19.7 The different levels of structure

The **primary structure** of a macromolecule is the sequence of small molecular residues making up the polymer. The residues may form either a chain, as in polyethylene, or a more complex network in which cross-links connect different chains, as in cross-linked polyacrylamide. In a synthetic polymer, virtually all the residues are identical and it is sufficient to name the monomer used in the synthesis. Thus, the repeating unit of polyethylene is —CH₂CH₂—, and the primary structure of the chain is specified by denoting it as —(CH₂CH₂)_n—.

The concept of primary structure ceases to be trivial in the case of synthetic copolymers and biological macromolecules, for in general these substances are chains formed from different molecules. For example, proteins are **polypeptides** formed from different amino acids (about twenty occur naturally) strung together by the **peptide link**, —CONH—. The determination of the primary structure is then a highly

Fig. 19.12 The plot used for the determination of intrinsic viscosity, which is taken from the intercept at $c = 0$; see Example 19.5.

Comment 19.1

More rigorously, the repeating unit in polyethylene is —CH₂— and the substance is polymethylene. However, the advantage of regarding the repeating unit as —CH₂CH₂— and naming it after its monomer is that derivatives, —CHXCH₂—, are seen to belong to the same family.

Fig. 19.13 (a) A polymer adopts a highly organized helical conformation, an example of a secondary structure. The helix is represented as a cylinder. (b) Several helical segments connected by short random coils pack together, providing an example of tertiary structure.

Fig. 19.14 Several subunits with specific tertiary structures pack together, providing an example of quaternary structure.

complex problem of chemical analysis called **sequencing**. The **degradation** of a polymer is a disruption of its primary structure, when the chain breaks into shorter components.

The **secondary structure** of a macromolecule is the (often local) spatial arrangement of a chain. The secondary structure of an isolated molecule of polyethylene is a random coil, whereas that of a protein is a highly organized arrangement determined largely by hydrogen bonds, and taking the form of random coils, helices (Fig. 19.13a), or sheets in various segments of the molecule. The loss of secondary structure is called **denaturation**. When the hydrogen bonds in a protein are destroyed (for instance, by heating, as when cooking an egg) the structure denatures into a random coil.

The **tertiary structure** is the overall three-dimensional structure of a macromolecule. For instance, the hypothetical protein shown in Fig. 19.13b has helical regions connected by short random-coil sections. The helices interact to form a compact tertiary structure.

The **quaternary structure** of a macromolecule is the manner in which large molecules are formed by the aggregation of others. Figure 19.14 shows how four molecular subunits, each with a specific tertiary structure, aggregate together. Quaternary structure can be very important in biology. For example, the oxygen-transport protein haemoglobin consists of four subunits that work together to take up and release O_2 .

19.8 Random coils

The most likely conformation of a chain of identical units not capable of forming hydrogen bonds or any other type of specific bond is a **random coil**. Polyethylene is a simple example. The random coil model is a helpful starting point for estimating the orders of magnitude of the hydrodynamic properties of polymers and denatured proteins in solution.

The simplest model of a random coil is a **freely jointed chain**, in which any bond is free to make any angle with respect to the preceding one (Fig. 19.15). We assume that the residues occupy zero volume, so different parts of the chain can occupy the same region of space. The model is obviously an oversimplification because a bond is actually constrained to a cone of angles around a direction defined by its neighbour (Fig. 19.16). In a hypothetical one-dimensional freely jointed chain all the residues lie in a straight line, and the angle between neighbours is either 0° or 180° . The residues in a three-dimensional freely jointed chain are not restricted to lie in a line or a plane.

Fig. 19.15 A freely jointed chain is like a three-dimensional random walk, each step being in an arbitrary direction but of the same length.

Fig. 19.16 A better description is obtained by fixing the bond angle (for example, at the tetrahedral angle) and allowing free rotation about a bond direction.

(a) Measures of size

As shown in the following *Justification*, we can deduce the probability, P , that the ends of a one-dimensional freely jointed chain composed of N units of length l are a distance nl apart:

$$P = \left(\frac{2}{\pi N} \right)^{1/2} e^{-n^2/2N} \quad (19.26)$$

This function is plotted in Fig. 19.17 and can be used to calculate the probability that the ends of a three-dimensional freely jointed chain lie in the range r to $r + dr$. We write this probability as $f(r)dr$, where

$$f(r) = 4\pi \left(\frac{a}{\pi^{1/2}} \right)^3 r^2 e^{-a^2 r^2} \quad a = \left(\frac{3}{2Nl^2} \right)^{1/2} \quad (19.27)$$

In some coils, the ends may be far apart whereas in others their separation is small. Here and elsewhere we are ignoring the fact that the chain cannot be longer than Nl . Although eqn 19.29 gives a nonzero probability for $r > Nl$, the values are so small that the errors in pretending that r can range up to infinity are negligible.

An alternative interpretation of eqn 19.27 is to regard each coil in a sample as ceaselessly writhing from one conformation to another; then $f(r)dr$ is the probability that at any instant the chain will be found with the separation of its ends between r and $r + dr$.

Fig. 19.17 The probability distribution for the separation of the ends of a one-dimensional random coil. The separation of the ends is nl , where l is the bond length.

Justification 19.3 *The one-dimensional freely jointed chain*

Consider a one-dimensional freely jointed polymer. We can specify the conformation of a molecule by stating the number of bonds pointing to the right (N_R) and the number pointing to the left (N_L). The distance between the ends of the chain is $(N_R - N_L)l$, where l is the length of an individual bond. We write $n = N_R - N_L$ and the total number of bonds as $N = N_R + N_L$.

The number of ways W of forming a chain with a given end-to-end distance nl is the number of ways of having N_R right-pointing and N_L left-pointing bonds. There are $N(N-1)(N-2) \dots 1 = N!$ ways of selecting whether a step should be to the right or the left. If N_L steps are to the left, $N_R = N - N_L$ will be to the right. However, we end up at the same point for all $N_L!$ and $N_R!$ choices of which step is to the left and which to the right. Therefore

$$W = \frac{N!}{N_L!N_R!} = \frac{N!}{\{\frac{1}{2}(N+n)\}!\{\frac{1}{2}(N-n)\}!} \quad (19.28)$$

The probability that the separation is nl is

$$\begin{aligned} P &= \frac{\text{number of polymers with } N_R \text{ bonds to the right}}{\text{total number of arrangements of bonds}} \\ &= \frac{N!/N_R!(N-N_R)!}{2^N} = \frac{N!}{\{\frac{1}{2}(N+n)\}!\{\frac{1}{2}(N-n)\}!2^N} \end{aligned}$$

When the chain is compact in the sense that $n \ll N$, it is more convenient to evaluate $\ln P$: the factorials are then large and we can use Stirling's approximation (Section 16.1a) in the form

$$\ln x! \approx \ln(2\pi)^{1/2} + (x + \frac{1}{2})\ln x - x$$

The result, after quite a lot of algebra, is

$$\ln P = \ln \left(\frac{2}{\pi N} \right)^{1/2} - \frac{1}{2}(N+n+1)\ln(1+v) - \frac{1}{2}(N-n+1)\ln(1-v) \quad (19.29)$$

where $v = n/N$. For a compact coil ($v \ll 1$) we use the approximation $\ln(1 \pm v) \approx \pm v - \frac{1}{2}v^2$ and so obtain

$$\ln P \approx \ln \left(\frac{2}{\pi N} \right)^{1/2} - \frac{1}{2} N v^2$$

which rearranges into eqn 19.26.

Self-test 19.6 Provide the algebraic steps that lead from eqn 19.28 to eqn 19.29.

Fig. 19.18 The variation of the root mean square separation of the ends of a three-dimensional random coil, R_{rms} , with the number of monomers.

There are several measures of the geometrical size of a random coil. The **contour length**, R_c , is the length of the macromolecule measured along its backbone from atom to atom. For a polymer of N monomer units each of length l , the contour length is

$$R_c = Nl \quad (19.30)$$

The **root mean square separation**, R_{rms} , is a measure of the average separation of the ends of a random coil: it is the square root of the mean value of R^2 . We show in the following *Justification* that:

$$R_{\text{rms}} = N^{1/2}l \quad (19.31)$$

We see that, as the number of monomer units increases, the root mean square separation of its end increases as $N^{1/2}$ (Fig. 19.18), and consequently its volume increases as $N^{3/2}$. The result must be multiplied by a factor when the chain is not freely jointed (see below).

Justification 19.4 The root mean square separation of the ends of a freely jointed chain

In *Appendix 2* we see that the mean value $\langle X \rangle$ of a variable X with possible values x is given by

$$\langle X \rangle = \int_{-\infty}^{+\infty} x f(x) dx$$

where the function $f(x)$ is the *probability density*, a measure of the distribution of the probability values over x , and dx is an infinitesimally small interval of x values. The mean value of a function $g(X)$ can be calculated with a similar formula:

$$\langle g(X) \rangle = \int_{-\infty}^{+\infty} g(x) f(x) dx$$

To apply these concepts to the calculation of the root mean square separation of the ends of a random coil, we identify $f(r)dr$ as the probability that the ends of the chain lie in the range $R = r$ to $R = r + dr$. It follows that the general expression for the mean n th power of the end-to-end separation (a positive quantity that can vary from 0 to $+\infty$) is

$$\langle R^n \rangle = \int_0^{\infty} r^n f(r) dr$$

To calculate R_{rms} , we first determine $\langle R^2 \rangle$ by using $n = 2$ and $f(r)$ from eqn 19.27:

$$\langle R^2 \rangle = 4\pi \left(\frac{a}{\pi^{1/2}} \right)^3 \int_0^{\infty} r^4 e^{-a^2 r^2} dr = 4\pi \left(\frac{a}{\pi^{1/2}} \right)^3 \times \frac{3\pi^{1/2}}{8a^5} = \frac{3}{2a^2}$$

where we have used the standard integral

$$\int_0^{\infty} x^4 e^{-a^2 x^2} dx = \frac{3}{2a^2}$$

When we use the expression for a in eqn 19.27 we obtain:

$$\langle R^2 \rangle = \frac{3}{2} \times \left(\frac{2Nl^2}{3} \right) = Nl^2$$

The root mean square separation follows from

$$R_{\text{rms}} = \langle R^2 \rangle^{1/2} = N^{1/2}l$$

Self-test 19.7 Calculate the mean separation of the ends of a freely jointed chain of

N bonds of length l . *Hint.* You will need the standard integral $\int_0^{\infty} x^3 e^{-a^2 x^2} dx = \frac{1}{2}a^4$.

$$[\langle R \rangle = \left(\frac{8N}{3\pi} \right)^{1/2} l]$$

Another convenient measure of size is the **radius of gyration**, R_g , which we encountered in Section 19.3a. It is calculated formally from the expression:

$$R_g = \frac{1}{N} \left(\frac{1}{2} \sum_{ij} R_{ij}^2 \right)^{1/2} \quad (19.32)$$

where R_{ij} is the separation of atoms i and j . The radius of gyration of the coil also increases as $N^{1/2}$:

$$R_g = \left(\frac{N}{6} \right)^{1/2} l \quad (19.33)$$

The radius of gyration may also be calculated for other geometries. For example, a solid uniform sphere of radius R has $R_g = (\frac{3}{5})^{1/2}R$, and a long thin uniform rod of length l has $R_g = l/(12)^{1/2}$ for rotation about an axis perpendicular to the long axis.

The random coil model ignores the role of the solvent: a poor solvent will tend to cause the coil to tighten so that solute–solvent contacts are minimized; a good solvent does the opposite. Therefore, calculations based on this model are better regarded as lower bounds to the dimensions for a polymer in a good solvent and as an upper bound for a polymer in a poor solvent. The model is most reliable for a polymer in a bulk solid sample, where the coil is likely to have its natural dimensions.

(b) Conformational entropy

The random coil is the least structured conformation of a polymer chain and corresponds to the state of greatest entropy. Any stretching of the coil introduces order and reduces the entropy. Conversely, the formation of a random coil from a more extended form is a spontaneous process (provided enthalpy contributions do not interfere). As shown in the *Justification* below, we can use the same model to deduce that the change in **conformational entropy**, the statistical entropy arising from the arrangement of bonds, when a coil containing N bonds of length l is stretched or compressed by nl is

$$\Delta S = -\frac{1}{2}kN \ln\{(1+\nu)^{1+\nu}(1-\nu)^{1-\nu}\} \quad \nu = n/N \quad (19.34)$$

Fig. 19.19 The change in molar entropy of a perfect elastomer as its extension changes; $v=1$ corresponds to complete extension; $v=0$, the conformation of highest entropy, corresponds to the random coil.

This function is plotted in Fig. 19.19, and we see that minimum extension corresponds to maximum entropy.

Justification 19.5 *The conformational entropy of a freely jointed chain*

The conformational entropy of the chain is $S = k \ln W$, where W is given by eqn 19.28. Therefore,

$$S/k = \ln N! - \ln \left\{ \frac{1}{2} (N+n) \right\}! - \ln \left\{ \frac{1}{2} (N-n) \right\}!$$

Because the factorials are large (except for large extensions), we can use Stirling's approximation to obtain

$$S/k = -\ln(2\pi)^{1/2} + (N+1)\ln 2 + (N+\frac{1}{2})\ln N - \frac{1}{2} \ln \{ (N+n)^{N+n+1} (N-n)^{N-n+1} \}$$

The most probable conformation of the chain is the one with the ends close together ($n=0$), as may be confirmed by differentiation. Therefore, the maximum entropy is

$$S/k = -\ln(2\pi)^{1/2} + (N+1)\ln 2 + \frac{1}{2} \ln N$$

The change in entropy when the chain is stretched or compressed by nl is therefore the difference of these two quantities, and the resulting expression is eqn 19.34.

(c) Constrained chains

The freely jointed chain model is improved by removing the freedom of bond angles to take any value. For long chains, we can simply take groups of neighbouring bonds and consider the direction of their resultant. Although each successive individual bond is constrained to a single cone of angle θ relative to its neighbour, the resultant of several bonds lies in a random direction. By concentrating on such groups rather than individuals, it turns out that for long chains the expressions for the root mean square separation and the radius of gyration given above should be multiplied by

$$F = \left(\frac{1 - \cos \theta}{1 + \cos \theta} \right)^{1/2} \quad (19.35)$$

For tetrahedral bonds, for which $\cos \theta = -\frac{1}{3}$ (that is, $\theta = 109.5^\circ$), $F = 2^{1/2}$. Therefore:

$$R_{\text{rms}} = (2N)^{1/2} l \quad R_g = \left(\frac{N}{3} \right)^{1/2} l \quad (19.36)$$

Fig. 19.20 A random coil in three dimensions. This one contains about 200 units. The root mean square distance between the ends (R_{rms}), the mean radius, and the radius of gyration (R_g) are indicated.

Illustration 19.2 *The dimensions of a polymer chain*

Consider a polyethylene chain with $M = 56 \text{ kg mol}^{-1}$, corresponding to $N = 4000$. Because $l = 154 \text{ pm}$ for a C—C bond, we find $R_{\text{rms}} = 14 \text{ nm}$ and $R_g = 5.6 \text{ nm}$ (Fig. 19.20). This value of R_g means that, on average, the coils rotate like hollow spheres of radius 5.6 nm and mass equal to the molecular mass.

The model of a randomly coiled molecule is still an approximation, even after the bond angles have been restricted, because it does not take into account the impossibility of two or more atoms occupying the same place. Such self-avoidance tends to swell the coil, so (in the absence of solvent effects) it is better to regard R_{rms} and R_g as lower bounds to the actual values.

19.9 The structure and stability of synthetic polymers

Synthetic polymers are classified broadly as *elastomers*, *fibres*, and *plastics*, depending on their **crystallinity**, the degree of three-dimensional long-range order attained in the solid state. An **elastomer** is a flexible polymer that can expand or contract easily upon application of an external force. Elastomers are polymers with numerous cross-links that pull them back into their original shape when a stress is removed. A **perfect elastomer**, a polymer in which the internal energy is independent of the extension of the random coil, can be modelled as a freely jointed chain. We saw in Section 19.8b that the contraction of an extended chain to a random coil is spontaneous in the sense that it corresponds to an increase in entropy; the entropy change of the surroundings is zero because no energy is released when the coil forms. In the following *Justification* we also see that the restoring force, F , of a one-dimensional perfect elastomer is

$$F = \frac{kT}{2l} \ln \left(\frac{1+v}{1-v} \right) \quad v = n/N \quad (19.37a)$$

where N is the total number of bonds of length l and the polymer is stretched or compressed by nl . This function is plotted in Fig. 19.21. At low extensions, when $v \ll 1$:

$$F \approx \frac{vkT}{l} = \frac{nkT}{Nl} \quad (19.37b)$$

and the sample obeys Hooke's law: the restoring force is proportional to the displacement (which is proportional to n). For small displacements, therefore, the whole coil shakes with simple harmonic motion.

Justification 19.6 Hooke's law

The work done on an elastomer when it is extended through a distance dx is Fdx , where F is the restoring force. The change in internal energy is therefore

$$dU = TdS - pdV + Fdx$$

It follows that

$$\left(\frac{\partial U}{\partial x} \right)_{T,V} = T \left(\frac{\partial S}{\partial x} \right)_{T,V} + F$$

In a perfect elastomer, as in a perfect gas, the internal energy is independent of the dimensions (at constant temperature), so $(\partial U/\partial x)_{T,V} = 0$. The restoring force is therefore

$$F = -T \left(\frac{\partial S}{\partial x} \right)_{T,V}$$

If now we substitute eqn 19.34 into this expression (we evade problems arising from the constraint of constant volume by supposing that the sample contracts laterally as it is stretched), we obtain

$$F = -\frac{T}{l} \left(\frac{\partial S}{\partial n} \right)_{T,V} = \frac{T}{Nl} \left(\frac{\partial S}{\partial v} \right)_{T,V} = \frac{kT}{2l} \ln \left(\frac{1+v}{1-v} \right)$$

as in eqn 19.37a.

A **fibre** is a polymeric material that owes its strength to interactions between chains. One example is nylon-66 (Fig. 19.22). Under certain conditions, nylon-66 can be

Fig. 19.21 The restoring force, F , of a one-dimensional perfect elastomer. For small strains, F is linearly proportional to the extension, corresponding to Hooke's law.

Fig. 19.22 A fragment of two nylon-66 polymer chains showing the pattern of hydrogen bonds that are responsible for the cohesion between the chains.

Fig. 19.23 The variation of specific volume with temperature of a synthetic polymer. The glass transition temperature, T_g , is at the point of intersection of extrapolations of the two linear parts of the curve.

Comment 19.2

As we shall discuss further in Chapter 20, a metallic conductor is a substance with an electrical conductivity that decreases as the temperature is raised. A semiconductor is a substance with an electrical conductivity that increases as the temperature is raised.

IMPACT ON TECHNOLOGY

19.2 Conducting polymers

We have just seen how the structure of a polymer chain affects its mechanical and thermal properties. Now we consider the electrical properties of synthetic polymers.

Most of the macromolecules and self-assembled structures considered in this chapter are insulators, or very poor electrical conductors. However, a variety of newly developed macromolecular materials have electrical conductivities that rival those of silicon-based semiconductors and even metallic conductors. We examine one example in detail: **conducting polymers**, in which extensively conjugated double bonds facilitate electron conduction along the polymer chain. The Nobel Prize in chemistry was awarded in 2000 to A.J. Heeger, A.J. McDiarmid, and H. Shirakawa for their pioneering work in the synthesis and characterization of conducting polymers.

One example of a conducting polymer is polyacetylene (Fig. 19.24). Whereas the delocalized π bonds do suggest that electrons can move up and down the chain, the electrical conductivity of polyacetylene increases significantly when it is partially oxidized by I_2 and other strong oxidants. The product is a **polaron**, a partially localized cation radical that does not delocalize but rather travels through the chain, as shown in Fig. 19.24. Oxidation of the polymer by one more equivalent forms either **bipolarons**, a di-cation that moves as a unit through the chain, or **solitons**, two separate cation

Fig. 19.24 The mechanism of migration of a partially localized cation radical, or polaron, in polyacetylene.

radicals that move independently. Polarons and solitons contribute to the mechanism of charge conduction in polyacetylene.

Conducting polymers are slightly better electrical conductors than silicon semiconductors but are far worse than metallic conductors. They are currently used in a number of devices, such as electrodes in batteries, electrolytic capacitors, and sensors. Recent studies of photon emission by conducting polymers may lead to new technologies for light-emitting diodes and flat-panel displays. Conducting polymers also show promise as molecular wires that can be incorporated into nanometre-sized electronic devices.

19.10 The structure of proteins

A protein is a polypeptide composed of linked α -amino acids, $\text{NH}_2\text{CHRCOOH}$, where R is one of about 20 groups. For a protein to function correctly, it needs to have a well defined conformation. For example, an enzyme has its greatest catalytic efficiency only when it is in a specific conformation. The amino acid sequence of a protein contains the necessary information to create the active conformation of the protein from a newly synthesized random coil. However, the prediction of the conformation from the primary structure, the so-called *protein folding problem*, is extraordinarily difficult and is still the focus of much research.

(a) The Corey–Pauling rules

The origin of the secondary structures of proteins is found in the rules formulated by Linus Pauling and Robert Corey in 1951. The essential feature is the stabilization of structures by hydrogen bonds involving the peptide link. The latter can act both as a donor of the H atom (the NH part of the link) and as an acceptor (the CO part). The **Corey–Pauling rules** are as follows (Fig. 19.25):

- 1 The four atoms of the peptide link lie in a relatively rigid plane.

The planarity of the link is due to delocalization of π electrons over the O, C, and N atoms and the maintenance of maximum overlap of their p orbitals.

- 2 The N, H, and O atoms of a hydrogen bond lie in a straight line (with displacements of H tolerated up to not more than 30° from the N–O vector).

- 3 All NH and CO groups are engaged in hydrogen bonding.

The rules are satisfied by two structures. One, in which hydrogen bonding between peptide links leads to a helical structure, is a *helix*, which can be arranged as either a right- or a left-handed screw. The other, in which hydrogen bonding between peptide links leads to a planar structure, is a *sheet*; this form is the secondary structure of the protein fibroin, the constituent of silk.

(b) Conformational energy

A polypeptide chain adopts a conformation corresponding to a minimum Gibbs energy, which depends on the **conformational energy**, the energy of interaction between different parts of the chain, and the energy of interaction between the chain and surrounding solvent molecules. In the aqueous environment of biological cells, the outer surface of a protein molecule is covered by a mobile sheath of water molecules, and its interior contains pockets of water molecules. These water molecules play an important role in determining the conformation that the chain adopts through hydrophobic interactions and hydrogen bonding to amino acids in the chain.

The simplest calculations of the conformational energy of a polypeptide chain ignore entropy and solvent effects and concentrate on the total potential energy of all the

Fig. 19.25 The dimensions that characterize the peptide link (bonds in picometres). The C–NH–CO–C atoms define a plane (the C–N bond has partial double-bond character), but there is rotational freedom around the C–CO and N–C bonds.

interactions between nonbonded atoms. For example, these calculations predict that a right-handed α helix of L-amino acids is marginally more stable than a left-handed helix of the same amino acids.

To calculate the energy of a conformation, we need to make use of many of the molecular interactions described in Chapter 18, and also of some additional interactions:

1 *Bond stretching.* Bonds are not rigid, and it may be advantageous for some bonds to stretch and others to be compressed slightly as parts of the chain press against one another. If we liken the bond to a spring, then the potential energy takes the form of Hooke's law

$$V_{\text{stretch}} = \frac{1}{2}k_{\text{stretch}}(R - R_e)^2 \quad (19.38)$$

where R_e is the equilibrium bond length and k_{stretch} is the force constant, a measure of the stiffness of the bond in question.

2 *Bond bending.* An O—C—H bond angle (or some other angle) may open out or close in slightly to enable the molecule as a whole to fit together better. If the equilibrium bond angle is θ_e , we write

$$V_{\text{bend}} = \frac{1}{2}k_{\text{bend}}(\theta - \theta_e)^2 \quad (19.39)$$

where k_{bend} is the force constant, a measure of how difficult it is to change the bond angle.

Self-test 19.8 Theoretical studies have estimated that the lumiflavin isoalloazine ring system has an energy minimum at the bending angle of 15° , but that it requires only 8.5 kJ mol^{-1} to increase the angle to 30° . If there are no other compensating interactions, what is the force constant for lumiflavin bending?

$[6.27 \times 10^{-23} \text{ J deg}^{-2}, \text{ equivalent to } 37.7 \text{ J mol}^{-1} \text{ deg}^{-2}]$

Fig. 19.26 The definition of the torsional angles ψ and ϕ between two peptide units. In this case (an α -L-polypeptide) the chain has been drawn in its all-*trans* form, with $\psi = \phi = 180^\circ$.

3 *Bond torsion.* There is a barrier to internal rotation of one bond relative to another (just like the barrier to internal rotation in ethane). Because the planar peptide link is relatively rigid, the geometry of a polypeptide chain can be specified by the two angles that two neighbouring planar peptide links make to each other. Figure 19.26 shows the two angles ϕ and ψ commonly used to specify this relative orientation. The sign convention is that a positive angle means that the front atom must be rotated clockwise to bring it into an eclipsed position relative to the rear atom. For an all-*trans* form of the chain, all ϕ and ψ are 180° . A helix is obtained when all the ϕ are equal and when all the ψ are equal. For a right-handed helix, all $\phi = -57^\circ$ and all $\psi = -47^\circ$. For a left-handed helix, both angles are positive. The torsional contribution to the total potential energy is

$$V_{\text{torsion}} = A(1 + \cos 3\phi) + B(1 + \cos 3\psi) \quad (19.40)$$

in which A and B are constants of the order of 1 kJ mol^{-1} . Because only two angles are needed to specify the conformation of a helix, and they range from -180° to $+180^\circ$, the torsional potential energy of the entire molecule can be represented on a **Ramachandran plot**, a contour diagram in which one axis represents ϕ and the other represents ψ .

4 *Interaction between partial charges.* If the partial charges q_i and q_j on the atoms i and j are known, a Coulombic contribution of the form $1/r$ can be included (Section 18.3):

$$V_{\text{Coulomb}} = \frac{q_i q_j}{4\pi\epsilon r} \quad (19.41)$$

where ϵ is the permittivity of the medium in which the charges are embedded. Charges of $-0.28e$ and $+0.28e$ are assigned to N and H, respectively, and $-0.39e$ and $+0.39e$ to O and C, respectively. The interaction between partial charges does away with the need to take dipole–dipole interactions into account, for they are taken care of by dealing with each partial charge explicitly.

5 *Dispersive and repulsive interactions.* The interaction energy of two atoms separated by a distance r (which we know once ϕ and ψ are specified) can be given by the Lennard-Jones (12,6) form (Section 18.5):

$$V_{\text{LJ}} = \frac{C}{r^{12}} - \frac{D}{r^6} \quad (19.42)$$

6 *Hydrogen bonding.* In some models of structure, the interaction between partial charges is judged to take into account the effect of hydrogen bonding. In other models, hydrogen bonding is added as another interaction of the form

$$V_{\text{H bonding}} = \frac{E}{r^{12}} - \frac{F}{r^{10}} \quad (19.43)$$

The total potential energy of a given conformation (ϕ, ψ) can be calculated by summing the contributions given by eqns 19.38–19.43 for all bond angles (including torsional angles) and pairs of atoms in the molecule. The procedure is known as a **molecular mechanics** simulation and is automated in commercially available molecular modelling software. For large molecules, plots of potential energy against bond distance or bond angle often show several local minima and a global minimum (Fig. 19.27). The software packages include schemes for modifying the locations of the atoms and searching for these minima systematically.

The structure corresponding to the global minimum of a molecular mechanics simulation is a snapshot of the molecule at $T = 0$ because only the potential energy is included in the calculation; contributions to the total energy from kinetic energy are excluded. In a **molecular dynamics** simulation, the molecule is set in motion by heating it to a specified temperature, as described in Section 17.6b. The possible trajectories of all atoms under the influence of the intermolecular potentials correspond to the conformations that the molecule can sample at the temperature of the simulation. At very low temperatures, the molecule cannot overcome some of the potential energy barriers given by eqns 19.38–19.43, atomic motion is restricted, and only a few conformations are possible. At high temperatures, more potential energy barriers can be overcome and more conformations are possible. Therefore, molecular dynamics calculations are useful tools for the visualization of the flexibility of polymers.

(c) Helices and sheets

A right-handed α -helix is illustrated in Fig. 19.28. Each turn of the helix contains 3.6 amino acid residues, so the period of the helix corresponds to 5 turns (18 residues). The pitch of a single turn (the distance between points separated by 360°) is 544 pm. The N–H $\cdots$ O bonds lie parallel to the axis and link every fourth group (so residue i is linked to residues $i - 4$ and $i + 4$). All the R groups point away from the major axis of the helix.

Figure 19.29 shows the Ramachandran plots for the helical form of polypeptide chains formed from the nonchiral amino acid glycine ($R = H$) and the chiral amino acid L-alanine ($R = CH_3$). The glycine map is symmetrical, with minima of equal depth at $\phi = -80^\circ$, $\psi = +90^\circ$ and at $\phi = +80^\circ$, $\psi = -90^\circ$. In contrast, the map for L-alanine is unsymmetrical, and there are three distinct low-energy conformations (marked I, II, III). The minima of regions I and II lie close to the angles typical of right- and

Fig. 19.27 For large molecules, a plot of potential energy against the molecular geometry often shows several local minima and a global minimum.

Fig. 19.28 The polypeptide α helix, with poly-L-glycine as an example. Carbon atoms are shown in green, with nitrogen in blue, oxygen in red, and hydrogen atoms in grey. There are 3.6 residues per turn, and a translation along the helix of 150 pm per residue, giving a pitch of 540 pm. The diameter (ignoring side chains) is about 600 pm.

Fig. 19.29 Contour plots of potential energy against the torsional angles ψ and ϕ , also known as Ramachandran plots, for (a) a glycyl residue of a polypeptide chain and (b) an alanyl residue. The darker the shading is, the lower the potential energy. The glycyl diagram is symmetrical, but regions I and II in the correspond to right- and left-handed helices, are unsymmetrical, and the minimum in region I lies lower than that in region II. (After D.A. Brant and P.J. Flory, *J. Mol. Biol.* **23**, 47 (1967).)

Fig. 19.30 The two types of β -sheets: (a) antiparallel ($\phi = -139^\circ$, $\psi = 113^\circ$), in which the N—H—O atoms of the hydrogen bonds form a straight-line; (b) parallel ($\phi = -119^\circ$, $\psi = 113^\circ$) in which the N—H—O atoms of the hydrogen bonds are not perfectly aligned.

Comment 19.3

The web site contains links to sites where you may predict the secondary structure of a polypeptide by molecular mechanics simulations. There are also links to sites where you may visualize the structures of proteins and nucleic acids that have been obtained by experimental and theoretical methods.

left-handed helices, but the former has a lower minimum. This result is consistent with the observation that polypeptides of the naturally occurring L-amino acids tend to form right-handed helices.

A **β -sheet** (also called the **β -pleated sheet**) is formed by hydrogen bonding between two extended polypeptide chains (large absolute values of the torsion angles ϕ and ψ). Some of the R groups point above and some point below the sheet. Two types of structures can be distinguished from the pattern of hydrogen bonding between the constituent chains.

In an **anti-parallel β -sheet** (Fig. 19.30a), $\phi = -139^\circ$, $\psi = 113^\circ$, and the N—H—O atoms of the hydrogen bonds form a straight line. This arrangement is a consequence of the antiparallel arrangement of the chains: every N—H bond on one chain is aligned with a C—O bond from another chain. Antiparallel β -sheets are very common in proteins. In a **parallel β -sheet** (Fig. 19.30b), $\phi = -119^\circ$, $\psi = 113^\circ$, and the N—H—O atoms of the hydrogen bonds are not perfectly aligned. This arrangement is a result of the parallel arrangement of the chains: each N—H bond on one chain is aligned with a N—H bond of another chain and, as a result, each C—O bond of one chain is aligned with a C—O bond of another chain. These structures are not common in proteins.

Circular dichroism (CD) spectroscopy (Section 14.2) provides a great deal of information about the secondary structure of polypeptides. Consider a helical polypeptide. Not only are the individual monomer units chiral, but so is the helix. Therefore, we expect the α -helix to have a unique CD spectrum. Because β -sheets and random coils also have distinguishable spectral features (Fig. 19.31), circular dichroism is a very important technique for the study of protein conformation.

(d) Higher-order structures

Covalent and non-covalent interactions may cause polypeptide chains with well defined secondary structures to fold into tertiary structures. Subunits with well defined tertiary structures may interact further to form quaternary structures.

Although we do not know all the rules that govern protein folding, a few general conclusions may be drawn from X-ray diffraction studies of water-soluble natural proteins and synthetic polypeptides. In an aqueous environment, the chains fold in such a way as to place nonpolar R groups in the interior (which is often not very accessible to solvent) and charged R groups on the surface (in direct contact with the polar solvent). A wide variety of structures can result from these broad rules. Among them, a **four-helix bundle** (Fig. 19.32), which is found in proteins such as cytochrome b_{562} (an electron transport protein), forms when each helix has a nonpolar region along its length. The four nonpolar regions pack together to form a nonpolar interior.

Fig. 19.31 Representative CD spectra of polypeptides. Random coils, α -helices, and β -sheets have different CD features in the spectral region where the peptide link absorbs.

Fig. 19.32 A four-helix bundle forms from the interactions between nonpolar amino acids on the surfaces of each helix, with the polar amino acids exposed to the aqueous environment of the solvent.

Similarly, interconnected β -sheets may interact to form a β -barrel (Fig. 19.33), the interior of which is populated by nonpolar R groups and which has an exterior rich in charged residues. The retinol-binding protein of blood plasma, which is responsible for transporting vitamin A, is an example of a β -barrel structure.

Factors that promote the folding of proteins include covalent disulfide ($-\text{S}-\text{S}-$) links, Coulombic interactions between ions (which depend on the degree of protonation of groups and therefore on the pH), hydrogen bonding, van der Waals interactions, and hydrophobic interactions (Section 18.4g). The clustering of nonpolar, hydrophobic, amino acids into the interior of a protein is driven primarily by hydrophobic interactions.

19.11 The structure of nucleic acids

Nucleic acids are key components of the mechanism of storage and transfer of genetic information in biological cells. Deoxyribonucleic acid (DNA) contains the instructions for protein synthesis, which is carried out by different forms of ribonucleic acid (RNA). In this section, we discuss the main structural features of DNA and RNA.

Both DNA and RNA are *polynucleotides* (2), in which base–sugar–phosphate units are linked by phosphodiester bonds. In RNA the sugar is β -D-ribose and in DNA it is β -D-2-deoxyribose (as shown in 2). The most common bases are adenine (A, 3), cytosine (C, 4), guanine (G, 5), thymine (T, found in DNA only, 6), and uracil (U, found in RNA only, 7). At physiological pH, each phosphate group of the chain carries a

2 D-ribose ($\text{R} = \text{OH}$) and 2'-deoxy-D-Ribose ($\text{R} = \text{H}$)

Fig. 19.33 Eight anti-parallel β -sheets, each represented by a purple arrow and linked by short random coils fold together as a β -barrel. Nonpolar amino acids are in the interior of the barrel.

negative charge and the bases are deprotonated and neutral. This charge distribution leads to two important properties. One is that the polynucleotide chain is a **polyelectrolyte**, a macromolecule with many different charged sites, with a large and negative overall surface charge. The second is that the bases can interact by hydrogen bonding, as shown for A—T (8) and C—G base pairs (9). The secondary and tertiary structures of DNA and RNA arise primarily from the pattern of this hydrogen bonding between bases of one or more chains.

In DNA, two polynucleotide chains wind around each other to form a double helix (Fig. 19.34). The chains are held together by links involving A—T and C—G base pairs that lie parallel to each other and perpendicular to the major axis of the helix. The structure is stabilized further by interactions between the planar π systems of the bases. In B-DNA, the most common form of DNA found in biological cells, the helix is right-handed with a diameter of 2.0 nm and a pitch of 3.4 nm. Long stretches of DNA can fold further into a variety of tertiary structures. Two examples are shown in Fig. 19.35. Supercoiled DNA is found in the chromosome and can be visualized as the twisting of closed circular DNA (ccDNA), much like the twisting of a rubber band.

The extra —OH group in β -D-ribose imparts enough steric strain to a polynucleotide chain so that stable double helices cannot form in RNA. Therefore, RNA exists primarily as single chains that can fold into complex structures by formation of A—U and G—C base pairs. One example of this structural complexity is the structure of transfer RNA (tRNA), shown schematically in Fig. 19.36 in which base-paired regions are connected by loops and coils. Transfer RNAs help assemble polypeptide chains during protein synthesis in the cell.

Fig. 19.34 DNA double helix, in which two polynucleotide chains are linked together by hydrogen bonds between adenine (A) and thymine (T) and between cytosine (C) and guanine (G).

Fig. 19.35 A long section of DNA may form closed circular DNA (ccDNA) by covalent linkage of the two ends of the chain. Twisting of ccDNA leads to the formation of supercoiled DNA.

Fig. 19.36 Structure of a transfer RNA (tRNA).

19.12 The stability of proteins and nucleic acids

The loss of their natural conformation by proteins and nucleic acids is called **denaturation**. It can be achieved by changing the temperature or by adding chemical agents. Cooking is an example of thermal denaturation. When eggs are cooked, the protein albumin is denatured irreversibly, collapsing into a structure that resembles a random coil. One example of chemical denaturation is the ‘permanent waving’ of hair, which is a result of the reorganization of the protein keratin in hair. Disulfide cross-links between the chains of keratin render the protein and, hence hair fibres, inflexible. Chemical reduction of the disulfide bonds unravels keratin, and allows hair to be shaped. Oxidation re-forms the disulfide bonds and sets the new shape. The ‘permanence’ is only temporary, however, because the structure of newly formed hair is genetically controlled. Other means of chemically denaturing a protein include the addition of compounds that form stronger hydrogen bonds than those within a helix or sheet. One example is urea, which competes for the NH and CO groups of a polypeptide. The action of acids or bases, which can protonate or deprotonate groups involved in hydrogen bonding or change the Coulombic interactions that determine the conformation of a protein, can also result in denaturation.

Closer examination of thermal denaturation reveals some of the chemical factors that determine protein and nucleic acid stability. Thermal denaturation is similar to the melting of synthetic polymers (Section 19.9). Denaturation is a **cooperative process** in the sense that the biopolymer becomes increasingly more susceptible to denaturation once the process begins. This cooperativity is observed as a sharp step in a plot of fraction of unfolded polymer versus temperature (*Impact* I16.1). The melting temperature, T_m , is the temperature at which the fraction of unfolded polymer is 0.5 (Fig. 19.37).

A DNA molecule is held together by hydrogen bonding interactions between bases of different chains and by **base-stacking**, in which dispersion interactions bring together the planar π systems of bases. Each G—C base pair has three hydrogen bonds whereas each A—T base pair has only two. Furthermore, experiments show that stacking interactions are stronger between C—G base pairs than between A—T base pairs. It follows that two factors render DNA sequences rich in C—G base pairs more stable than sequences rich in A—T base pairs: more hydrogen bonds between the bases and stronger stacking interactions between base pairs.

Proteins are relatively unstable towards chemical and thermal denaturation. For example, $T_m = 320$ K for ribonuclease T_1 (an enzyme that cleaves RNA in the cell), which is not far above the temperature at which the enzyme must operate (close to body temperature, 310 K). More surprisingly, the Gibbs energy for the unfolding of ribonuclease T_1 at pH 7.0 and 298 K is only 19.5 kJ mol^{-1} , which is comparable to the energy required to break a single hydrogen bond (about 20 kJ mol^{-1}). Therefore, unlike DNA, the stability of a protein does not increase in a simple way with the number of hydrogen bonding interactions. While the reasons for the low stability of proteins are not known, the answer probably lies in a delicate balance of all intra- and intermolecular interactions that allow a protein to fold into its active conformation, as discussed in Section 19.10.

Fig. 19.37 A protein unfolds as the temperature of the sample increases. The sharp step in the plot of fraction of unfolded protein against temperature indicated that the transition is cooperative. The melting temperature, T_m , is the temperature at which the fraction of unfolded polymer is 0.5.

Self-assembly

Much of the material discussed in this chapter also applies to aggregates of particles that form by **self-assembly**, the spontaneous formation of complex structures of molecules or macromolecules held together by molecular interactions, such as

Coulombic, dispersion, hydrogen bonding, or hydrophobic interactions. We have already encountered a few examples of self-assembly, such as the formation of liquid crystals (*Impact I6.1*), of protein quaternary structures from two or more polypeptide chains, and of a DNA double helix from two polynucleotide chains. Now we concentrate on the specific properties of additional self-assembled systems, including small aggregates that are at the heart of detergent action and extended sheets like those forming biological cell membranes.

19.13 Colloids

A **colloid**, or **disperse phase**, is a dispersion of small particles of one material in another. In this context, ‘small’ means something less than about 500 nm in diameter (about the wavelength of visible light). In general, colloidal particles are aggregates of numerous atoms or molecules, but are too small to be seen with an ordinary optical microscope. They pass through most filter papers, but can be detected by light-scattering and sedimentation.

(a) Classification and preparation

The name given to the colloid depends on the two phases involved. A **sol** is a dispersion of a solid in a liquid (such as clusters of gold atoms in water) or of a solid in a solid (such as ruby glass, which is a gold-in-glass sol, and achieves its colour by light scattering). An **aerosol** is a dispersion of a liquid in a gas (like fog and many sprays) or a solid in a gas (such as smoke): the particles are often large enough to be seen with a microscope. An **emulsion** is a dispersion of a liquid in a liquid (such as milk).

A further classification of colloids is as **lyophilic**, or solvent attracting, and **lyophobic**, solvent repelling. If the solvent is water, the terms **hydrophilic** and **hydrophobic**, respectively, are used instead. Lyophobic colloids include the metal sols. Lyophilic colloids generally have some chemical similarity to the solvent, such as —OH groups able to form hydrogen bonds. A **gel** is a semirigid mass of a lyophilic sol in which all the dispersion medium has penetrated into the sol particles.

The preparation of aerosols can be as simple as sneezing (which produces an imperfect aerosol). Laboratory and commercial methods make use of several techniques. Material (for example, quartz) may be ground in the presence of the dispersion medium. Passing a heavy electric current through a cell may lead to the sputtering (crumbling) of an electrode into colloidal particles. Arcing between electrodes immersed in the support medium also produces a colloid. Chemical precipitation sometimes results in a colloid. A precipitate (for example, silver iodide) already formed may be dispersed by the addition of a peptizing agent (for example, potassium iodide). Clays may be peptized by alkalis, the OH[−] ion being the active agent.

Emulsions are normally prepared by shaking the two components together vigorously, although some kind of emulsifying agent usually has to be added to stabilize the product. This emulsifying agent may be a soap (the salt of a long-chain carboxylic acid) or other **surfactant** (surface active) species, or a lyophilic sol that forms a protective film around the dispersed phase. In milk, which is an emulsion of fats in water, the emulsifying agent is casein, a protein containing phosphate groups. It is clear from the formation of cream on the surface of milk that casein is not completely successful in stabilizing milk: the dispersed fats coalesce into oily droplets which float to the surface. This coagulation may be prevented by ensuring that the emulsion is dispersed very finely initially: intense agitation with ultrasonics brings this dispersion about, the product being ‘homogenized’ milk.

One way to form an aerosol is to tear apart a spray of liquid with a jet of gas. The dispersal is aided if a charge is applied to the liquid, for then electrostatic repulsions

help to blast it apart into droplets. This procedure may also be used to produce emulsions, for the charged liquid phase may be directed into another liquid.

Colloids are often purified by dialysis (*Impact I5.2*). The aim is to remove much (but not all, for reasons explained later) of the ionic material that may have accompanied their formation. A membrane (for example, cellulose) is selected that is permeable to solvent and ions, but not to the colloid particles. Dialysis is very slow, and is normally accelerated by applying an electric field and making use of the charges carried by many colloidal particles; the technique is then called **electrodialysis**.

(b) Structure and stability

Colloids are thermodynamically unstable with respect to the bulk. This instability can be expressed thermodynamically by noting that because the change in Gibbs energy, dG , when the surface area of the sample changes by $d\sigma$ at constant temperature and pressure is $dG = \gamma d\sigma$, where γ is the interfacial surface tension (Section 18.7a), it follows that $dG < 0$ if $d\sigma < 0$. The survival of colloids must therefore be a consequence of the kinetics of collapse: colloids are thermodynamically unstable but kinetically nonlabile.

At first sight, even the kinetic argument seems to fail: colloidal particles attract each other over large distances, so there is a long-range force that tends to condense them into a single blob. The reasoning behind this remark is as follows. The energy of attraction between two individual atoms i and j separated by a distance R_{ij} , one in each colloidal particle, varies with their separation as $1/R_{ij}^6$ (Section 18.4). The sum of all these pairwise interactions, however, decreases only as approximately $1/R^2$ (the precise variation depending on the shape of the particles and their closeness), where R is the separation of the centres of the particles. The sum has a much longer range than the $1/R^6$ dependence characteristic of individual particles and small molecules.

Several factors oppose the long-range dispersion attraction. For example, there may be a protective film at the surface of the colloid particles that stabilizes the interface and cannot be penetrated when two particles touch. Thus the surface atoms of a platinum sol in water react chemically and are turned into $-\text{Pt}(\text{OH})_3\text{H}_3$, and this layer encases the particle like a shell. A fat can be emulsified by a soap because the long hydrocarbon tails penetrate the oil droplet but the carboxylate head groups (or other hydrophilic groups in synthetic detergents) surround the surface, form hydrogen bonds with water, and give rise to a shell of negative charge that repels a possible approach from another similarly charged particle.

(c) The electrical double layer

A major source of kinetic nonlability of colloids is the existence of an electric charge on the surfaces of the particles. On account of this charge, ions of opposite charge tend to cluster nearby, and an ionic atmosphere is formed, just as for ions (Section 5.9).

We need to distinguish two regions of charge. First, there is a fairly immobile layer of ions that adhere tightly to the surface of the colloidal particle, and which may include water molecules (if that is the support medium). The radius of the sphere that captures this rigid layer is called the **radius of shear** and is the major factor determining the mobility of the particles. The electric potential at the radius of shear relative to its value in the distant, bulk medium is called the **zeta potential**, ζ , or the **electrokinetic potential**. Second, the charged unit attracts an oppositely charged atmosphere of mobile ions. The inner shell of charge and the outer ionic atmosphere is called the **electrical double layer**.

The theory of the stability of lyophobic dispersions was developed by B. Derjaguin and L. Landau and independently by E. Verwey and J.T.G. Overbeek, and is known as

the **DLVO theory**. It assumes that there is a balance between the repulsive interaction between the charges of the electric double layers on neighbouring particles and the attractive interactions arising from van der Waals interactions between the molecules in the particles. The potential energy arising from the repulsion of double layers on particles of radius a has the form

$$V_{\text{repulsion}} = + \frac{Aa^2\zeta^2}{R} e^{-s/r_D} \quad (19.44)$$

where A is a constant, ζ is the **zeta potential**,¹ R is the separation of centres, s is the separation of the surfaces of the two particles ($s = R - 2a$ for spherical particles of radius a), and r_D is the thickness of the double layer. This expression is valid for small particles with a thick double layer ($a \ll r_D$). When the double layer is thin ($r_D \ll a$), the expression is replaced by

$$V_{\text{repulsion}} = \frac{1}{2}Aa\zeta^2 \ln(1 + e^{-s/r_D}) \quad (19.45)$$

In each case, the thickness of the double layer can be estimated from an expression like that derived for the thickness of the ionic atmosphere in the Debye–Hückel theory (eqn 5.80):

$$r_D = \left(\frac{\epsilon RT}{2\rho F^2 I b^\oplus} \right)^{1/2} \quad (19.46)$$

where I is the ionic strength of the solution, ρ its mass density, and $b^\oplus = 1 \text{ mol kg}^{-1}$. The potential energy arising from the attractive interaction has the form

$$V_{\text{attraction}} = -\frac{B}{s} \quad (19.47)$$

where B is another constant. The variation of the total potential energy with separation is shown in Fig. 19.38.

At high ionic strengths, the ionic atmosphere is dense and the potential shows a secondary minimum at large separations. Aggregation of the particles arising from the stabilizing effect of this secondary minimum is called **flocculation**. The flocculated material can often be redispersed by agitation because the well is so shallow. **Coagulation**, the irreversible aggregation of distinct particles into large particles, occurs when the separation of the particles is so small that they enter the primary minimum of the potential energy curve and van der Waals forces are dominant.

The ionic strength is increased by the addition of ions, particularly those of high charge type, so such ions act as flocculating agents. This increase is the basis of the empirical **Schulze–Hardy rule**, that hydrophobic colloids are flocculated most efficiently by ions of opposite charge type and high charge number. The Al^{3+} ions in alum are very effective, and are used to induce the congealing of blood. When river water containing colloidal clay flows into the sea, the salt water induces flocculation and coagulation, and is a major cause of silting in estuaries. Metal oxide sols tend to be positively charged whereas sulfur and the noble metals tend to be negatively charged.

The primary role of the electric double layer is to confer kinetic non-lability. Colliding colloidal particles break through the double layer and coalesce only if the collision is sufficiently energetic to disrupt the layers of ions and solvating molecules, or if thermal motion has stirred away the surface accumulation of charge. This disruption may occur at high temperatures, which is one reason why sols precipitate

Fig. 19.38 The potential energy of interaction as a function of the separation of the centres of the two particles and its variation with the ratio of the particle size to the thickness a of the electric double layer r_D . The regions labelled coagulation and flocculation show the dips in the potential energy curves where these processes occur.

¹ The actual potential is that of the surface of the particles; there is some danger in identifying it with the zeta potential. See the references in *Further reading*.

when they are heated. The protective role of the double layer is the reason why it is important not to remove all the ions when a colloid is being purified by dialysis, and why proteins coagulate most readily at their isoelectric point.

19.14 Micelles and biological membranes

Surfactant molecules or ions can cluster together as **micelles**, which are colloid-sized clusters of molecules, for their hydrophobic tails tend to congregate, and their hydrophilic heads provide protection (Fig. 19.39).

(a) Micelle formation

Micelles form only above the **critical micelle concentration** (CMC) and above the **Krafft temperature**. The CMC is detected by noting a pronounced change in physical properties of the solution, particularly the molar conductivity (Fig. 19.40). There is no abrupt change in properties at the CMC; rather, there is a transition region corresponding to a range of concentrations around the CMC where physical properties vary smoothly but nonlinearly with the concentration. The hydrocarbon interior of a micelle is like a droplet of oil. Nuclear magnetic resonance shows that the hydrocarbon tails are mobile, but slightly more restricted than in the bulk. Micelles are important in industry and biology on account of their solubilizing function: matter can be transported by water after it has been dissolved in their hydrocarbon interiors. For this reason, micellar systems are used as detergents, for organic synthesis, froth flotation, and petroleum recovery.

Non-ionic surfactant molecules may cluster together in clumps of 1000 or more, but ionic species tend to be disrupted by the electrostatic repulsions between head groups and are normally limited to groups of less than about 100. The micelle population is often polydisperse, and the shapes of the individual micelles vary with concentration. Spherical micelles do occur, but micelles are more commonly flattened spheres close to the CMC.

Under certain experimental conditions, a **liposome** may form, with an inward pointing inner surface of molecules surrounded by an outward pointing outer layer (Fig. 19.41). Liposomes may be used to carry nonpolar drug molecules in blood. In concentrated solutions micelles formed from surfactant molecules may take the form of long cylinders and stack together in reasonably close-packed (hexagonal) arrays. These orderly arrangements of micelles are called **lyotropic mesomorphs** and, more colloquially, 'liquid crystalline phases'.

The enthalpy of micelle formation reflects the contributions of interactions between micelle chains within the micelles and between the polar head groups and the surrounding medium. Consequently, enthalpies of micelle formation display no readily discernible pattern and may be positive (endothermic) or negative (exothermic). Many non-ionic micelles form endothermically, with ΔH of the order of 10 kJ per mole of surfactant. That such micelles do form above the CMC indicates that the entropy change accompanying their formation must then be positive, and measurements suggest a value of about $+140 \text{ J K}^{-1} \text{ mol}^{-1}$ at room temperature. The fact that the entropy change is positive even though the molecules are clustering together shows that hydrophobic interactions (Section 18.*) are important in the formation of micelles.

(b) Membrane formation

Some micelles at concentrations well above the CMC form extended parallel sheets, called **lamellar micelles**, two molecules thick. The individual molecules lie perpendicular to the sheets, with hydrophilic groups on the outside in aqueous solution and

Fig. 19.39 A schematic version of a spherical micelle. The hydrophilic groups are represented by spheres and the hydrophobic hydrocarbon chains are represented by the stalks; these stalks are mobile.

Fig. 19.40 The typical variation of some physical properties of an aqueous solution of sodium dodecylsulfate close to the critical micelle concentration (CMC).

The web site contains links to databases of thermodynamic properties of lipids.

on the inside in nonpolar media. Such lamellar micelles show a close resemblance to biological membranes, and are often a useful model on which to base investigations of biological structures.

Although lamellar micelles are convenient models of cell membranes, actual membranes are highly sophisticated structures. The basic structural element of a membrane is a phospholipid, such as phosphatidyl choline (**10**), which contains long hydrocarbon chains (typically in the range C_{14} – C_{24}) and a variety of polar groups, such as $-\text{CH}_2\text{CH}_2\text{N}(\text{CH}_3)_3^+$ in (**10**). The hydrophobic chains stack together to form an extensive bilayer about 5 nm across. The lipid molecules form layers instead of micelles because the hydrocarbon chains are too bulky to allow packing into nearly spherical clusters.

The bilayer is a highly mobile structure, as shown by EPR studies with spin-labelled phospholipids (*Impact* I15.2). Not only are the hydrocarbon chains ceaselessly twisting and turning in the region between the polar groups, but the phospholipid and cholesterol molecules migrate over the surface. It is better to think of the membrane as a viscous fluid rather than a permanent structure, with a viscosity about 100 times that of water. In common with diffusional behaviour in general (see Section 21.*), the average distance a phospholipid molecule diffuses is proportional to the square-root of the time; more precisely, for a molecule confined to a two-dimensional plane, the average distance travelled in a time t is equal to $(4Dt)^{1/2}$. Typically, a phospholipid molecule migrates through about $1\text{ }\mu\text{m}$ (the diameter of a cell) in about 1 min.

All lipid bilayers undergo a transition from a state of high to low chain mobility at a temperature that depends on the structure of the lipid. To visualize the transition, we consider what happens to a membrane as we lower its temperature (Fig. 19.42). There is sufficient energy available at normal temperatures for limited bond rotation to occur and the flexible chains writhe. However, the membrane is still highly organized in the sense that the bilayer structure does not come apart and the system is best described as a liquid crystal (Fig. 19.42a). At lower temperatures, the amplitudes of the writhing motion decrease until a specific temperature is reached at which motion is largely frozen. The membrane is said to exist as a gel (Fig. 19.42b). Biological membranes exist as liquid crystals at physiological temperatures.

Phase transitions in membranes are often observed as ‘melting’ from gel to liquid crystal by differential scanning calorimetry (*Impact* I2.1). The data show relations between the structure of the lipid and the melting temperature. For example, the melting temperature increases with the length of the hydrophobic chain of the lipid. This correlation is reasonable, as we expect longer chains to be held together more strongly by hydrophobic interactions than shorter chains. It follows that stabilization of the gel phase in membranes of lipids with long chains results in relatively high melting temperatures. On the other hand, any structural elements that prevent alignment of the hydrophobic chains in the gel phase lead to low melting temperatures. Indeed, lipids containing unsaturated chains, those containing some $\text{C}=\text{C}$ bonds, form membranes

Fig. 19.42 A depiction of the variation with temperature of the flexibility of hydrocarbon chains in a lipid bilayer. (a) At physiological temperature, the bilayer exists as a liquid crystal, in which some order exists but the chains writhe. (b) At a specific temperature, the chains are largely frozen and the bilayer is said to exist as a gel.

with lower melting temperatures than those formed from lipids with fully saturated chains, those consisting of C—C bonds only.

Interspersed among the phospholipids of biological membranes are sterols, such as cholesterol (11), which is largely hydrophobic but does contain a hydrophilic —OH group. Sterols, which are present in different proportions in different types of cells, prevent the hydrophobic chains of lipids from ‘freezing’ into a gel and, by disrupting the packing of the chains, spread the melting point of the membrane over a range of temperatures.

Self-test 19.9 Organisms are capable of biosynthesizing lipids of different composition so that cell membranes have melting temperatures close to the ambient temperature. Why do bacterial and plant cells grown at low temperatures synthesize more phospholipids with unsaturated chains than do cells grown at higher temperatures?

[Insertion of lipids with unsaturated chains lowers the plasma membrane’s melting temperature to a value that is close to the lower ambient temperature.]

Peripheral proteins are proteins attached to the bilayer. **Integral proteins** are proteins immersed in the mobile but viscous bilayer. These proteins may span the depth of the bilayer and consist of tightly packed α helices or, in some cases, β sheets containing hydrophobic residues that sit comfortably within the hydrocarbon region of the bilayer. There are two views of the motion of integral proteins in the bilayer. In the **fluid mosaic model** shown in Fig. 19.43 the proteins are mobile, but their diffusion coefficients are much smaller than those of the lipids. In the **lipid raft model**, a number of lipid and cholesterol molecules form ordered structures, or ‘rafts’, that envelop proteins and help carry them to specific parts of the cell.

The mobility of the bilayer enables it to flow round a molecule close to the outer surface, to engulf it, and incorporate it into the cell by the process of *endocytosis*. Alternatively, material from the cell interior wrapped in cell membrane may coalesce with the cell membrane itself, which then withdraws and ejects the material in the process of *exocytosis*. The function of the proteins embedded in the bilayer, though, is to act as devices for transporting matter into and out of the cell in a more subtle manner. By providing hydrophilic channels through an otherwise alien hydrophobic environment, some proteins act as **ion channels** and **ion pumps** (Impact I21.2).

19.15 Surface films

The compositions of surface layers have been investigated by the simple but technically elegant procedure of slicing thin layers off the surfaces of solutions and analysing their compositions. The physical properties of surface films have also been investigated. Surface films one molecule thick, such as that formed by a surfactant, are called **monolayers**. When a monolayer has been transferred to a solid support, it is called a **Langmuir–Blodgett film**, after Irving Langmuir and Katherine Blodgett, who developed experimental techniques for studying them.

(a) Surface pressure

The principal apparatus used for the study of surface monolayers is a **surface film balance** (Fig. 19.44). This device consists of a shallow trough and a barrier that can be moved along the surface of the liquid in the trough, and hence compress any monolayer on the surface. The **surface pressure**, π , the difference between the surface

11 Cholesterol

Fig. 19.43 In the fluid mosaic model of a biological cell membrane, integral proteins diffuse through the lipid bilayer. In the alternative lipid raft model, a number of lipid and cholesterol molecules envelop and transport the protein around the membrane.

Fig. 19.44 A schematic diagram of the apparatus used to measure the surface pressure and other characteristics of a surface film. The surfactant is spread on the surface of the liquid in the trough, and then compressed horizontally by moving the compression barrier towards the mica float. The latter is connected to a torsion wire, so the difference in force on either side of the float can be monitored.

Fig. 19.45 The variation of surface pressure with the area occupied by each surfactant molecule. The collapse pressures are indicated by the horizontal dotted lines.

 $\text{C}_{17}\text{H}_{35}\text{COOH}$

13 Isostearic acid,
 $\text{C}_{17}\text{H}_{35}\text{COOH}$

14 Tri-*p*-cresylphosphate

tension of the pure solvent and the solution ($\pi = \gamma^* - \gamma$) is measured by using a torsion wire attached to a strip of mica that rests on the surface and pressing against one edge of the monolayer. The parts of the apparatus that are in touch with liquids are coated in polytetrafluoroethylene to eliminate effects arising from the liquid–solid interface. In an actual experiment, a small amount (about 0.01 mg) of the surfactant under investigation is dissolved in a volatile solvent and then poured on to the surface of the water; the compression barrier is then moved across the surface and the surface pressure exerted on the mica bar is monitored.

Some typical results are shown in Fig. 19.45. One parameter obtained from the isotherms is the area occupied by the molecules when the monolayer is closely packed. This quantity is obtained from the extrapolation of the steepest part of the isotherm to the horizontal axis. As can be seen from the illustration, even though stearic acid (12) and isostearic acid (13) are chemically very similar (they differ only in the location of a methyl group at the end of a long hydrocarbon chain), they occupy significantly different areas in the monolayer. Neither, though, occupies as much area as the tri-*p*-cresyl phosphate molecule (14), which is like a wide bush rather than a lanky tree.

The second feature to note from Fig. 19.45 is that the tri-*p*-cresyl phosphate isotherm is much less steep than the stearic acid isotherms. This difference indicates that the tri-*p*-cresyl phosphate film is more compressible than the stearic acid films, which is consistent with their different molecular structures.

A third feature of the isotherms is the **collapse pressure**, the highest surface pressure. When the monolayer is compressed beyond the point represented by the collapse pressure, the monolayer buckles and collapses into a film several molecules thick. As can be seen from the isotherms in Fig. 19.45, stearic acid has a high collapse pressure, but that of tri-*p*-cresyl phosphate is significantly smaller, indicating a much weaker film.

(b) The thermodynamics of surface layers

A surfactant is active at the interface between two phases, such as at the interface between hydrophilic and hydrophobic phases. A surfactant accumulates at the interface, and modifies its surface tension and hence the surface pressure. To establish the relation between the concentration of surfactant at a surface and the change in surface tension it brings about, we consider two phases α and β in contact and suppose that the system consists of several components J , each one present in an overall amount n_J . If the components were distributed uniformly through the two phases right up to the interface, which is taken to be a plane of surface area σ , the total Gibbs energy, G , would be the sum of the Gibbs energies of both phases, $G = G(\alpha) + G(\beta)$. However, the components are not uniformly distributed because one may accumulate at the interface. As a result, the sum of the two Gibbs energies differs from G by an amount called the **surface Gibbs energy**, $G(\sigma)$:

$$G(\sigma) = G - \{G(\alpha) + G(\beta)\} \quad (19.48)$$

Similarly, if it is supposed that the concentration of a species J is uniform right up to the interface, then from its volume we would conclude that it contains an amount $n_J(\alpha)$ of J in phase α and an amount $n_J(\beta)$ in phase β . However, because a species may accumulate at the interface, the total amount of J differs from the sum of these two amounts by $n_J(\sigma) = n_J - \{n_J(\alpha) + n_J(\beta)\}$. This difference is expressed in terms of the **surface excess**, Γ_J :

$$\Gamma_J = \frac{n_J(\sigma)}{\sigma} \quad (19.49)$$

The surface excess may be either positive (an accumulation of J at the interface) or negative (a deficiency there).

The relation between the change in surface tension and the composition of a surface (as expressed by the surface excess) was derived by Gibbs. In the following *Justification* we derive the **Gibbs isotherm**, between the changes in the chemical potentials of the substances present in the interface and the change in surface tension:

$$d\gamma = - \sum_j \Gamma_j d\mu_j \quad (19.50)$$

Justification 19.7 *The Gibbs isotherm*

A general change in G is brought about by changes in T , p , and the n_j :

$$dG = -SdT + Vdp + \gamma d\sigma + \sum_j \mu_j dn_j$$

When this relation is applied to G , $G(\alpha)$, and $G(\beta)$ we find

$$dG(\sigma) = -S(\sigma)dT + \gamma d\sigma + \sum_j \mu_j dn_j(\sigma)$$

because at equilibrium the chemical potential of each component is the same in every phase, $\mu_j(\alpha) = \mu_j(\beta) = \mu_j(\sigma)$. Just as in the discussion of partial molar quantities (Section 5.1), the last equation integrates at constant temperature to

$$G(\sigma) = \gamma\sigma + \sum_j \mu_j n_j(\sigma)$$

We are seeking a connection between the change of surface tension $d\gamma$ and the change of composition at the interface. Therefore, we use the argument that in Section 5.1 led to the Gibbs–Duhem equation (eqn 5.12b), but this time we compare the expression

$$dG(\sigma) = \gamma d\sigma + \sum_j \mu_j dn_j(\sigma)$$

(which is valid at constant temperature) with the expression for the same quantity but derived from the preceding equation:

$$dG(\sigma) = \gamma d\sigma + \sigma d\gamma + \sum_j \mu_j dn_j(\sigma) + \sum_j n_j(\sigma) d\mu_j$$

The comparison implies that, at constant temperature,

$$\sigma d\gamma + \sum_j n_j(\sigma) d\mu_j = 0$$

Division by σ then gives eqn 19.50.

Now consider a simplified model of the interface in which the ‘oil’ and ‘water’ phases are separated by a geometrically flat surface. This approximation implies that only the surfactant, S , accumulates at the surface, and hence that Γ_{oil} and Γ_{water} are both zero. Then the Gibbs isotherm equation becomes

$$d\gamma = -\Gamma_S d\mu_S \quad (19.51)$$

For dilute solutions,

$$d\mu_S = RT \ln c \quad (19.52)$$

where c is the molar concentration of the surfactant. It follows that

$$d\gamma = RT \Gamma_S \frac{dc}{c}$$

at constant temperature, or

$$\left(\frac{\partial \gamma}{\partial c} \right)_T = - \frac{RT \Gamma_S}{c} \quad (19.53)$$

If the surfactant accumulates at the interface, its surface excess is positive and eqn 19.53 implies that $(\partial \gamma / \partial c)_T < 0$. That is, the surface tension decreases when a solute accumulates at a surface. Conversely, if the concentration dependence of γ is known, then the surface excess may be predicted and used to infer the area occupied by each surfactant molecule on the surface.

Fig. 19.46 Self-assembled monolayers of alkylthiols formed on to a gold surface by reaction of the thiol groups with the surface and aggregation of the alkyl chains.

IMPACT ON NANOSCIENCE

I19.3 Nanofabrication with self-assembled monolayers

Nanofabrication is the synthesis of *nanodevices*, nanometre-sized assemblies of atoms and molecules that can be used in nanotechnological applications, such as those discussed in *Impact I9.2*. Here we see how molecular self-assembly can be used as the basis for nanofabrication on surfaces. Of current interest are **self-assembled monolayers** (SAMs), ordered molecular aggregates that form a monolayer of material on a surface. To understand the formation of SAMs, consider exposing molecules such as alkyl thiols RSH , where R represents an alkyl chain, to an $\text{Au}(0)$ surface. The thiols react with the surface, forming $\text{RS}^-\text{Au}(\text{I})$ adducts:

If R is a sufficiently long chain, van der Waals interactions between the adsorbed RS units lead to the formation of a highly ordered monolayer on the surface, as shown in Fig. 19.46. It is observed that the Gibbs energy of formation of SAMs increases with the length of the alkyl chain, with each methylene group contributing $400\text{--}4000 \text{ J mol}^{-1}$ to the overall Gibbs energy of formation.

The atomic force microscope (*Impact I9.1*) can be used to manipulate SAMs into specific shapes on a surface by digging the microscope tip through the alkyl chains, bringing it into contact with the surface and then moving SAMs around the surface. In one application of the technique, enzymes were bound to patterned SAMs. The experiment shows that it is possible to form nanometre-sized reactors that take advantage of the catalytic properties of enzymes (which we explore in Chapter 23).

Checklist of key ideas

☐ 1. A polymer is a compound formed by linking together small molecules. Many proteins (specifically protein enzymes) are monodisperse; a synthetic polymer is polydisperse. ☐ 2. The number-average molar mass, $\bar{M}_n$, is the value obtained by weighting each molar mass by the number of molecules of that mass present in the sample; the weight-average molar mass, $\bar{M}_w$, is the average calculated by weighting the molar masses of the molecules by the mass of each one present in the sample; the Z-average molar mass, $\bar{M}_Z$, is the average molar mass obtained from sedimentation measurements. ☐ 3. The heterogeneity index of a polymer sample is $\bar{M}_w/\bar{M}_n$. ☐ 4. Techniques for the determination of the mean molar masses of macromolecules include mass spectrometry (as MALDI), ultracentrifugation, laser light scattering, and viscometry. ☐ 5. The least structured model of a macromolecule is as a random coil; for a freely jointed random coil of contour length Nl, the root mean square separation is $N^{1/2}l$ and the radius of gyration is $R_g = (N/6)^{1/2}l$. ☐ 6. The conformational entropy is the statistical entropy arising from the arrangement of bonds in a random coil. ☐ 7. The primary structure of a biopolymer is the sequence of its monomer units. ☐ 8. The secondary structure of a protein is the spatial arrangement of the polypeptide chain and includes the α-helix and β-sheet.	☐ 9. Helical and sheet-like polypeptide chains are folded into a tertiary structure by bonding influences between the residues of the chain. ☐ 10. Some macromolecules have a quaternary structure as aggregates of two or more polypeptide chains. ☐ 11. Synthetic polymers are classified as elastomers, fibres, and plastics. ☐ 12. A perfect elastomer is a polymer in which the internal energy is independent of the extension of the random coil; for small extensions a random coil model obeys a Hooke's law restoring force. ☐ 13. Synthetic polymers undergo a transition from a state of high to low chain mobility at the glass transition temperature, T_g. ☐ 14. The melting temperature of a polymer is the temperature at which three-dimensional order is lost. ☐ 15. A mesophase is a bulk phase that is intermediate in character between a solid and a liquid. ☐ 16. A disperse system is a dispersion of small particles of one material in another. ☐ 17. Colloids are classified as lyophilic (solvent attracting, specifically hydrophilic for water) and lyophobic (solvent repelling, specifically hydrophobic). ☐ 18. A surfactant is a species that accumulates at the interface of two phases or substances and modifies the properties of the surface.

- 19. The radius of shear is the radius of the sphere that captures the rigid layer of charge attached to a colloid particle.
- 20. The zeta potential is the electric potential at the radius of shear relative to its value in the distant, bulk medium.
- 21. The inner shell of charge and the outer atmosphere jointly constitute the electric double layer.
- 22. Many colloid particles are thermodynamically unstable but kinetically non-labile.
- 23. Flocculation is the reversible aggregation of colloidal particles; coagulation is the irreversible aggregation of colloidal particles.
- 24. The Schultze–Hardy rule states that hydrophobic colloids are flocculated most efficiently by ions of opposite charge type and high charge number.
- 25. A micelle is a colloid-sized cluster of molecules that forms at the critical micelle concentration (CMC) and at the Krafft temperature.
- 26. A liposome is a vesicle with an inward pointing inner surface of molecules surrounded by an outward pointing outer layer.
- 27. A lamellar micelle is an extended layer of molecules two molecules thick.
- 28. A monolayer, a single layer of molecules on a surface. A Langmuir–Blodgett film is a monolayer that has been transferred to a solid support.
- 29. Surface pressure is the difference between the surface tension of the pure solvent and the solution: $\pi = \gamma^* - \gamma$.
- 30. The collapse pressure is the highest surface pressure sustained by a surface film.

Further information

Further information 19.1 The Rayleigh ratio

Here we outline the key steps in the derivation of eqn 19.8 for the Rayleigh ratio. You are encouraged to consult sources in the *Further reading* section for additional details.

The ratio of the intensity of the light scattered by a sample to the intensity of the incident light is (see *Further reading*):

$$\frac{I}{I_0} = \frac{\pi^2 \alpha^2 \sin^2 \phi}{\epsilon_r^2 \lambda^4 r^2} \quad (19.54)$$

where r is the distance between the sample and the detector and ϕ is the angle of observation relative to the z -axis ($\phi = 90^\circ$ in Fig. 19.3). It follows from eqn 19.7 that

$$R_\theta = \frac{\pi^2 \alpha^2}{\epsilon_r^2 \lambda^4}$$

The relation between the polarizability and the refractive index, n_r , of a solution is (see *Appendix 3* for a qualitative explanation and *Further reading* for quantitative details)

$$n_r^2 - n_{r,0}^2 = \frac{\mathcal{N} \alpha}{\epsilon_r} \quad (19.55)$$

where $n_{r,0}$ is the refractive index of the solvent and $\mathcal{N}$ is the number density of polymer molecules. Because $\mathcal{N} = c_p N_A / M$ (where c_p is the mass concentration of the polymer and M is its molar mass), we have:

$$\alpha = \frac{\epsilon_r M}{c_p N_A} (n_r^2 - n_{r,0}^2)$$

For a dilute solution, n_r differs little from $n_{r,0}$ and we can write:

$$n_r = n_{r,0} + \left(\frac{dn_r}{dc_p} \right) c_p + \dots$$

It follows that

$$n_r^2 \approx n_{r,0}^2 + 2n_{r,0} \left(\frac{dn_r}{dc_p} \right) c_p$$

and therefore that

$$\alpha = \frac{2\varepsilon_r n_{r,0} M}{N_A} \left(\frac{dn_r}{dc_p} \right) \quad (19.56)$$

The Rayleigh ratio for scattering by a single molecule now becomes

$$R_\theta = \frac{4\pi^2 n_{r,0}^2 M^2}{\lambda^4 N_A^2} \left(\frac{dn_r}{dc_p} \right)^2 \quad (19.57)$$

For a sample of N molecules, we multiply the expression above by $N = c_p N_A V/M$ and, after substituting $\tilde{M}_w$ for M , obtain

$$R_\theta = K c_p \tilde{M}_w \quad K = \frac{4\pi^2 n_{r,0}^2 V (dn_r/dc_p)^2}{\lambda^4 N_A} \quad (19.58)$$

Equation 19.8 follows after we multiply the right-hand side of this equation by the structure factor P_θ .

Now we derive expressions for the structure factor. If the molecule is regarded as composed of a number of atoms i at distances R_i from a convenient point, interference occurs between the radiation scattered by each pair. The scattering from all the particles is then calculated by allowing for contributions from all possible orientations of each pair

of atoms in each molecule. If there are N atoms in the macromolecule, and if all are assumed to have the same scattering power, then it is possible to show that (see *Further reading*)

$$P_\theta = \frac{1}{N^2} \sum_{ij} \frac{\sin sR_{ij}}{sR_{ij}}, \quad s = \frac{4\pi}{\lambda} \sin \frac{1}{2}\theta \quad (19.59)$$

where R_{ij} is the separation of atoms i and j , and λ is the wavelength of the incident radiation.

When the molecule is much smaller than the wavelength of the incident radiation in the sense that $sR_{ij} \ll 1$ (for example, if $R = 5$ nm, and $\lambda = 500$ nm, all the sR_{ij} are about 0.1), we can use the expansion $\sin x = x - \frac{1}{6}x^3 + \dots$ to write

$$\sin sR_{ij} = sR_{ij} - \frac{1}{6}(sR_{ij})^3 + \dots$$

and then

$$P_\theta = \frac{1}{N^2} \sum_{ij} \left\{ 1 - \frac{1}{6}(sR_{ij})^2 + \dots \right\} = 1 - \frac{s^2}{6N^2} \sum_{ij} R_{ij}^2 + \dots$$

The sum over the squares of the separations gives the radius of gyration of the molecule (through eqn 19.32). Therefore

$$P_\theta \approx 1 - \frac{1}{3}s^2 R_g^2 = 1 - \frac{16\pi^2 R_g^2 \sin^2 \frac{1}{2}\theta}{3\lambda^2}$$

which is eqn 19.9.

Discussion questions

19.1 Distinguish between number-average, weight-average, and Z -average molar masses. Discuss experimental techniques that can measure each of these properties.

19.2 Suggest reasons why the techniques described in the preceding question produce different mass averages.

19.3 Distinguish between contour length, root mean square separation, and radius of gyration of a random coil.

19.4 Identify the terms in and limit the generality of the following expressions: (a) $\Delta S = -\frac{1}{2}kN \ln\{(1+\nu)^{1+\nu}(1-\nu)^{1-\nu}\}$, (b) $R_{rms} = (2N)^{1/2}l$, and (c) $R_g = (N/6)^{1/2}l$.

19.5 Distinguish between molecular mechanics and molecular dynamics calculations. Why are these methods generally more popular in the field of

polymer chemistry than the quantum mechanical procedures discussed in Chapter 11?

19.6 It is observed that the critical micelle concentration of sodium dodecyl sulfate in aqueous solution decreases as the concentration of added sodium chloride increases. Explain this effect.

19.7 Explain the physical origins of surface activity by surfactant molecules.

19.8 Discuss the physical origins of the surface Gibbs energy.

19.9 Self-assembled monolayers (SAMs) are receiving more attention than Langmuir–Blodgett (LB) films as starting points for nanofabrication. How do SAMs differ from LB films and why are SAMs more useful than LB films in nanofabrication work?

Exercises

19.1a Calculate the number-average molar mass and the mass-average molar mass of a mixture of equal amounts of two polymers, one having $M = 62$ kg mol⁻¹ and the other $M = 78$ kg mol⁻¹.

19.1b Calculate the number-average molar mass and the mass-average molar mass of a mixture of two polymers, one having $M = 62$ kg mol⁻¹ and the other $M = 78$ kg mol⁻¹, with their amounts (numbers of moles) in the ratio 3:2.

19.2a The radius of gyration of a long chain molecule is found to be 7.3 nm. The chain consists of C—C links. Assume the chain is randomly coiled and estimate the number of links in the chain.

19.2b The radius of gyration of a long chain molecule is found to be 18.9 nm. The chain consists of links of length 450 pm. Assume the chain is randomly coiled and estimate the number of links in the chain.

19.3a A solution consists of solvent, 30 per cent by mass, of a dimer with $M = 30$ kg mol⁻¹ and its monomer. What average molar mass would be obtained from measurement of (a) osmotic pressure, (b) light scattering?

19.3b A solution consists of 25 per cent by mass of a trimer with $M = 22$ kg mol⁻¹ and its monomer. What average molar mass would be obtained from measurement of: (a) osmotic pressure, (b) light scattering?

19.4a Evaluate the rotational correlation time, $\tau_R = 4\pi a^3 \eta / 3kT$, for serum albumin in water at 25°C on the basis that it is a sphere of radius 3.0 nm. What is the value for a CCl_4 molecule in carbon tetrachloride at 25°C? (Viscosity data in Table 21.4 in the *Data section* at the end of this volume; take $a(\text{CCl}_4) = 250$ pm.)

19.4b Evaluate the rotational correlation time, $\tau_R = 4\pi a^3 \eta / 3kT$, for a synthetic polymer in water at 20°C on the basis that it is a sphere of radius 4.5 nm.

19.5a What is the relative rate of sedimentation for two spherical particles of the same density, but which differ in radius by a factor of 10?

19.5b What is the relative rate of sedimentation for two spherical particles with densities 1.10 g cm^{-3} and 1.18 g cm^{-3} and which differ in radius by a factor of 8.4, the former being the larger? Use $\rho = 0.794 \text{ g cm}^{-3}$ for the density of the solution.

19.6a Human haemoglobin has a specific volume of $0.749 \times 10^{-3} \text{ m}^3 \text{ kg}^{-1}$, a sedimentation constant of 4.48 Sv, and a diffusion coefficient of $6.9 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$. Determine its molar mass from this information.

19.6b A synthetic polymer has a specific volume of $8.01 \times 10^{-4} \text{ m}^3 \text{ kg}^{-1}$, a sedimentation constant of 7.46 Sv, and a diffusion coefficient of $7.72 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$. Determine its molar mass from this information.

19.7a Find the drift speed of a particle of radius 20 μm and density 1750 kg m^{-3} which is settling from suspension in water (density 1000 kg m^{-3}) under the influence of gravity alone. The viscosity of water is $8.9 \times 10^{-4} \text{ kg m}^{-1} \text{ s}^{-1}$.

19.7b Find the drift speed of a particle of radius 15.5 μm and density 1250 kg m^{-3} which is settling from suspension in water (density 1000 kg m^{-3}) under the influence of gravity alone. The viscosity of water is $8.9 \times 10^{-4} \text{ kg m}^{-1} \text{ s}^{-1}$.

19.8a At 20°C the diffusion coefficient of a macromolecule is found to be $8.3 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$. Its sedimentation constant is 3.2 Sv in a solution of density 1.06 g cm^{-3} . The specific volume of the macromolecule is $0.656 \text{ cm}^3 \text{ g}^{-1}$. Determine the molar mass of the macromolecule.

19.8b At 20°C the diffusion coefficient of a macromolecule is found to be $7.9 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$. Its sedimentation constant is 5.1 Sv in a solution of density 997 kg m^{-3} . The specific volume of the macromolecule is $0.721 \text{ cm}^3 \text{ g}^{-1}$. Determine the molar mass of the macromolecule.

19.9a The data from a sedimentation equilibrium experiment performed at 300 K on a macromolecular solute in aqueous solution show that a graph of $\ln c$ against r^2 is a straight line with a slope of 729 cm^{-2} . The rotational rate of the centrifuge was 50 000 r.p.m. The specific volume of the solute is $0.61 \text{ cm}^3 \text{ g}^{-1}$. Calculate the molar mass of the solute.

19.9b The data from a sedimentation equilibrium experiment performed at 293 K on a macromolecular solute in aqueous solution show that a graph of $\ln c$ against $(r/\text{cm})^2$ is a straight line with a slope of 821. The rotation rate of the centrifuge was 1080 Hz. The specific volume of the solute is $7.2 \times 10^{-4} \text{ m}^3 \text{ kg}^{-1}$. Calculate the molar mass of the solute.

19.10a Calculate the radial acceleration (as so many g) in a cell placed at 6.0 cm from the centre of rotation in an ultracentrifuge operating at 80 000 r.p.m.

19.10b Calculate the radial acceleration (as so many g) in a cell placed at 5.50 cm from the centre of rotation in an ultracentrifuge operating at 1.32 kHz.

19.11a A polymer chain consists of 700 segments, each 0.90 nm long. If the chain were ideally flexible, what would be the r.m.s. separation of the ends of the chain?

19.11b A polymer chain consists of 1200 segments, each 1.125 nm long. If the chain were ideally flexible, what would be the r.m.s. separation of the ends of the chain?

19.12a Calculate the contour length (the length of the extended chain) and the root mean square separation (the end-to-end distance) for polyethylene with a molar mass of 280 kg mol^{-1} .

19.12b Calculate the contour length (the length of the extended chain) and the root mean square separation (the end-to-end distance) for polypropylene of molar mass 174 kg mol^{-1} .

Problems*

Numerical problems

19.1 In a sedimentation experiment the position of the boundary as a function of time was found to be as follows:

t/min	15.5	29.1	36.4	58.2
r/cm	5.05	5.09	5.12	5.19

The rotation rate of the centrifuge was 45 000 r.p.m. Calculate the sedimentation constant of the solute.

19.2 Calculate the speed of operation (in r.p.m.) of an ultracentrifuge needed to obtain a readily measurable concentration gradient in a sedimentation equilibrium experiment. Take that gradient to be a concentration at the bottom of the cell about five times greater than at the top. Use $r_{\text{top}} = 5.0 \text{ cm}$, $r_{\text{bott}} = 7.0 \text{ cm}$, $M \approx 10^5 \text{ g mol}^{-1}$, $\rho v_s \approx 0.75$, $T = 298 \text{ K}$.

19.3 The concentration dependence of the viscosity of a polymer solution is found to be as follows:

$c/(\text{g dm}^{-3})$	1.32	2.89	5.73	9.17
$\eta/(\text{g m}^{-1} \text{ s}^{-1})$	1.08	1.20	1.42	1.73

The viscosity of the solvent is $0.985 \text{ g m}^{-1} \text{ s}^{-1}$. What is the intrinsic viscosity of the polymer?

19.4 The times of flow of dilute solutions of polystyrene in benzene through a viscometer at 25°C are given in the table below. From these data, calculate the molar mass of the polystyrene samples. Since the solutions are dilute, assume that the densities of the solutions are the same as those of pure benzene. $\eta(\text{benzene}) = 0.601 \times 10^{-3} \text{ kg m}^{-1} \text{ s}^{-1}$ (0.601 cP) at 25°C.

$c/(\text{g dm}^{-3})$	0	2.22	5.00	8.00	10.00
t/s	208.2	248.1	303.4	371.8	421.3

19.5 The viscosities of solutions of polyisobutylene in benzene were measured at 24°C (the θ temperature for the system) with the following results:

$c/(\text{g}/10^2 \text{ cm}^3)$	0	0.2	0.4	0.6	0.8	1.0
$\eta/(10^{-3} \text{ kg m}^{-1} \text{ s}^{-1})$	0.647	0.690	0.733	0.777	0.821	0.865

Use the information in Table 19.4 to deduce the molar mass of the polymer.

19.6‡ Polystyrene in cyclohexane at 34.5°C forms a θ solution, with an intrinsic viscosity related to the molar mass by $[\eta] = KM^a$. The following data

* Problems denoted with the symbol ‡ were supplied by Charles Trapp and Carmen Giunta.

on polystyrene in cyclohexane are taken from L.J. Fetters, N. Hadjichristidis, J.S. Lindner, and J.W. Mays (*J. Phys. Chem. Ref. Data* **23**, 619 (1994)):

$M/(\text{kg mol}^{-1})$	10.0	19.8	106	249	359	860	1800	5470	9720	56 800
$[\eta]/(\text{cm}^3 \text{g}^{-1})$	8.90	11.9	28.1	44.0	51.2	77.6	113.9	195	275	667

Determine the parameters K and a . What is the molar mass of a polystyrene that forms a θ solution in cyclohexane with $[\eta] = 100 \text{ cm}^3 \text{g}^{-1}$?

19.74 Standard polystyrene solutions of known average molar masses continue to be used as for the calibration of many methods of characterizing polymer solutions. M. Kolinsky and J. Janca (*J. Polym. Sci., Polym. Chem.* **12**, 1181 (1974)) studied polystyrene in tetrahydrofuran (THF) for use in calibrating a gel permeation chromatograph. Their results for the intrinsic viscosity, $[\eta]$, as a function of average molar mass at 25°C are given in the table below. (a) Obtain the Mark–Houwink constants that fit these data. (b) Compare your values to those in Table 19.4 and Example 19.5. How might you explain the differences?

$\bar{M}_v/(\text{kg mol}^{-1})$	5.0	10.3	19.85	51	98.2	173	411	867
$[\eta]/(\text{cm}^3 \text{g}^{-1})$	5.2	8.8	14.0	27.6	43.6	67.0	125.0	206.7

19.8 The concentration dependence of the osmotic pressure of solutions of a macromolecule at 20°C was found to be as follows:

$c/(\text{g dm}^{-3})$	1.21	2.72	5.08	6.60
Π/Pa	134	321	655	898

Determine the molar mass of the macromolecule and the osmotic virial coefficient.

19.9 The osmotic pressure of a fraction of poly(vinyl chloride) in a ketone solvent was measured at 25°C . The density of the solvent (which is virtually equal to the density of the solution) was 0.798 g cm^{-3} . Calculate the molar mass and the osmotic virial coefficient, B , of the fraction from the following data:

$c/(\text{g}/10^2 \text{ cm}^3)$	0.200	0.400	0.600	0.088	1.000
h/cm	0.48	1.2	1.86	2.76	3.88

19.10 The following table lists the glass transition temperatures, T_g , of several polymers. Discuss the reasons why the structure of the monomer unit has an effect on the value of T_g .

Polymer	Poly(oxymethylene)	Polyethylene	Poly(vinyl chloride)	Polystyrene
Structure	$-(\text{OCH}_2)_n-$	$-(\text{CH}_2\text{CH}_2)_n-$	$-(\text{CH}_2-\text{CHCl})_n-$	$-(\text{CH}_2-\text{CH}(\text{C}_6\text{H}_5))_n-$
T_g/K	198	253	354	381

Theoretical problems

19.11 In formamide as solvent, poly(γ -benzyl-L-glutamate) is found by light scattering experiments to have a radius of gyration proportional to M ; in contrast, polystyrene in butanone has R_g proportional to $M^{1/2}$. Present arguments to show that the first polymer is a rigid rod whereas the second is a random coil.

19.12 The *kinematic viscosity*, ν , of a fluid is defined as η/ρ , where ρ is the mass density. What are the SI units of kinematic viscosity? Confirm that the drainage times through a narrow tube are governed by the kinematic viscosity by referring to the Poiseuille equation for fluid flow (eqn 21.25) and hence confirm eqn 19.24.

19.13 A polymerization process produced a Gaussian distribution of polymers in the sense that the proportion of molecules having a molar mass in the range M to $M + dM$ was proportional to $e^{-(M-\bar{M})^2/2\gamma dM}$. What is the number average molar mass when the distribution is narrow?

19.14 Show how eqn 19.26 for a one-dimensional freely jointed chain can be used to derive eqn 19.27 for a three-dimensional freely-jointed chain. *Hint.* Write the probability that the ends lie in the range n_x to $n_x + dn_x$ as $dP_x = P dn_x$, with P given in eqn 19.26, and similarly for the other two dimensions.

Multiply these probabilities together, and integrate $dn_x dn_y dn_z$ over a shell of thickness dn . Don't count negative integers (that is, divide the volume of the shell by 8, corresponding to the all-positive octant of values).

19.15 Use eqn 19.27 to deduce expressions for (a) the root mean square separation of the ends of the chain, (b) the mean separation of the ends, and (c) their most probable separation. Evaluate these three quantities for a fully flexible chain with $N = 4000$ and $l = 154 \text{ pm}$.

19.16 Construct a two-dimensional random walk by using a random number generating routine with mathematical software or electronic spreadsheet. Construct a walk of 50 and 100 steps. If there are many people working on the problem, investigate the mean and most probable separations in the plots by direct measurement. Do they vary as $N^{1/2}$?

19.17 Evaluate the radius of gyration, R_g , of (a) a solid sphere of radius a , (b) a long straight rod of radius a and length l . Show that in the case of a solid sphere of specific volume v_s , $R_g/\text{nm} \approx 0.056902 \times \{(v_s/\text{cm}^3 \text{g}^{-1})(M/\text{g mol}^{-1})\}^{1/3}$. Evaluate R_g for a species with $M = 100 \text{ kg mol}^{-1}$, $v_s = 0.750 \text{ cm}^3 \text{g}^{-1}$, and, in the case of the rod, of radius 0.50 nm .

19.18 The effective radius, a , of a random coil is related to its radius of gyration, R_g , by $a = \gamma R_g$, with $\gamma = 0.85$. Deduce an expression for the osmotic virial coefficient, B , in terms of the number of chain units for (a) a freely jointed chain, (b) a chain with tetrahedral bond angles. Evaluate B for $l = 154 \text{ pm}$ and $N = 4000$. Estimate B for a randomly coiled polyethylene chain of arbitrary molar mass, M , and evaluate it for $M = 56 \text{ kg mol}^{-1}$. Use $B = \frac{1}{2} N_A v_p$, where v_p is the excluded volume due to a single molecule.

19.19 Radius of gyration is defined in eqn 19.32. Show that an equivalent definition is that R_g is the average root mean square distance of the atoms or groups (all assumed to be of the same mass), that is, that $R_g^2 = (1/N) \sum_j R_j^2$, where R_j is the distance of atom j from the centre of mass.

19.20 Consider the thermodynamic description of stretching rubber. The observables are the tension, t , and length, l (the analogues of p and V for gases). Because $dw = tdl$, the basic equation is $dU = TdS + tdl$. (The term $p dV$ is supposed negligible throughout.) If $G = U - TS - tl$, find expressions for dG and dA , and deduce the Maxwell relations

$$\left(\frac{\partial S}{\partial l}\right)_T = -\left(\frac{\partial t}{\partial T}\right)_l \quad \left(\frac{\partial S}{\partial t}\right)_T = -\left(\frac{\partial l}{\partial T}\right)_t$$

Go on to deduce the equation of state for rubber,

$$\left(\frac{\partial U}{\partial l}\right)_T = t - \left(\frac{\partial t}{\partial T}\right)_l$$

19.21 On the assumption that the tension required to keep a sample at a constant length is proportional to the temperature ($t = aT$, the analogue of $p \propto T$), show that the tension can be ascribed to the dependence of the entropy on the length of the sample. Account for this result in terms of the molecular nature of the sample.

Applications: to biochemistry and technology

19.22 In this problem you will use molecular mechanics software of your instructor's choice to gain some appreciation for the complexity of the calculations that lead to plots such as those in Fig. 19.29. Our model for the protein is the dipeptide (15) in which the terminal methyl groups replace the rest of the polypeptide chain. (a) Draw three initial conformers of the dipeptide with $R = \text{H}$: one with $\phi = +75^\circ$, $\psi = -65^\circ$, a second with $\phi = \psi = +180^\circ$, and a third with $\phi = +65^\circ$, $\psi = +35^\circ$. Use a molecular mechanics routine to optimize the geometry of each conformer and measure the total potential energy and the final ϕ and ψ angles in each case. (Although any force field will work satisfactorily, the AMBER force field is strongly recommended, as it is optimized for calculations on biopolymers.) Did all of the initial conformers converge to the same final conformation? If not, what do these

15

final conformers represent? Rationalize any observed differences in total potential energy of the final conformers. (b) Use the approach in part (a) to investigate the case $R = \text{CH}_3$, with the same three initial conformers as starting points for the calculations. Rationalize any similarities and differences between the final conformers of the dipeptides with $R = \text{H}$ and $R = \text{CH}_3$.

19.23 Calculate the excluded volume in terms of the molecular volume on the basis that the molecules are spheres of radius a . Evaluate the osmotic virial coefficient in the case of bushy stunt virus, $a = 14.0 \text{ nm}$, and haemoglobin, $a = 3.2 \text{ nm}$ (see Problem 19.18). Evaluate the percentage deviation of the Rayleigh ratios of $1.00 \text{ g}/(100 \text{ cm}^3)$ solutions of bushy stunt virus ($M = 1.07 \times 10^4 \text{ kg mol}^{-1}$) and haemoglobin ($M = 66.5 \text{ kg mol}^{-1}$) from the ideal solution values. In eqn 19.8, let $P_\theta = 1$ and assume that both solutions have the same K value.

19.24 Use the information below and the expression for R_g of a solid sphere quoted in the Problem 19.17, to classify the species below as globular or rod-like.

	$M/(\text{g mol}^{-1})$	$v_s/(\text{cm}^3 \text{ g}^{-1})$	R_g/nm
Serum albumin	66×10^3	0.752	2.98
Bushy stunt virus	10.6×10^6	0.741	12.0
DNA	4×10^6	0.556	117.0

19.25 Suppose that a rod-like DNA molecule of length 250 nm undergoes a conformational change to a closed-circular (cc) form. (a) Use the information in Problem 19.24 and an incident wavelength $\lambda = 488 \text{ nm}$ to calculate the ratio of scattering intensities by each of these conformations, $I_{\text{rod}}/I_{\text{cc}}$, when $\theta = 20^\circ$, 45° , and 90° . (b) Suppose that you wish to use light scattering as a technique for the study of conformational changes in DNA molecules. Based on your answer to part (a), at which angle would you conduct the experiments? Justify your choice.

19.26 In an ultracentrifugation experiment at 20°C on bovine serum albumin the following data were obtained: $\rho = 1.001 \text{ g cm}^{-3}$, $v_s = 1.112 \text{ cm}^3 \text{ g}^{-1}$, $\omega/2\pi = 322 \text{ Hz}$,

r/cm	5.0	5.1	5.2	5.3	5.4
$c/(\text{mg cm}^{-3})$	0.536	0.284	0.148	0.077	0.039

Evaluate the molar mass of the sample.

19.27 Sedimentation studies on haemoglobin in water gave a sedimentation constant $S = 4.5 \text{ Sv}$ at 20°C . The diffusion coefficient is $6.3 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$ at the same temperature. Calculate the molar mass of haemoglobin using $v_s = 0.75 \text{ cm}^3 \text{ g}^{-1}$ for its partial specific volume and $\rho = 0.998 \text{ g cm}^{-3}$ for the density of the solution. Estimate the effective radius of the haemoglobin molecule given that the viscosity of the solution is $1.00 \times 10^{-3} \text{ kg m}^{-1} \text{ s}^{-1}$.

19.28 The rate of sedimentation of a recently isolated protein was monitored at 20°C and with a rotor speed of $50\,000 \text{ r.p.m.}$ The boundary receded as follows:

t/s	0	300	600	900	1200	1500	1800
r/cm	6.127	6.153	6.179	6.206	6.232	6.258	6.284

Calculate the sedimentation constant and the molar mass of the protein on the basis that its partial specific volume is $0.728 \text{ cm}^3 \text{ g}^{-1}$ and its diffusion coefficient is $7.62 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$ at 20°C , the density of the solution then being

0.9981 g cm^{-3} . Suggest a shape for the protein given that the viscosity of the solution is $1.00 \times 10^{-3} \text{ kg m}^{-1} \text{ s}^{-1}$ at 20°C .

19.29 For some proteins, the isoelectric point must be obtained by extrapolation because the macromolecule might not be stable over a very wide pH range. Estimate the pH of the isoelectric point from the following data for a protein:

pH	4.5	5.0	5.5	6.0
Drift speed/ $(\mu\text{m s}^{-1})$	-0.10	-0.20	-0.30	-0.35

19.30 Here we use concepts developed in Chapter 16 and this chapter to enhance our understanding of closed-circular and supercoiled DNA. (a) The average end-to-end distance of a flexible polymer (such as a fully denatured polypeptide or a strand of DNA) is $N^{1/2}l$, where N is the number of groups (residues or bases) and l is the length of each group. Initially, therefore, one end of the polymer can be found anywhere within a sphere of radius $N^{1/2}l$ centred on the other end. When the ends join to form a circle, they are confined to a volume of radius l . What is the change in molar entropy? Plot the function you derive as a function of N . (b) The energy necessary to twist ccDNA by i turns is $\epsilon_i = ki^2$, with k an empirical constant and i being negative or positive depending on the sense of the twist. For example, one twist ($i = \pm 1$) makes ccDNA resemble the number 8. (i) Show that the distribution of the populations $p_i = n_i/N$ of ccDNA molecules with i turns at a specified temperature has the form of a Gaussian function. (ii) Plot the expression you derived in part (a) for several values of the temperature. Does the curve have a maximum? If so, at what value of i ? Comment on variations of the shape of the curve with temperature. (iii) Calculate p_0, p_1, p_5 , and p_{10} at 298 K .

19.31 The melting temperature of a DNA molecule can be determined by differential scanning calorimetry (Impact I2.1). The following data were obtained in aqueous solutions containing the specified concentration c_{salt} of an soluble ionic solid for a series of DNA molecules with varying base pair composition, with f the fraction of G—C base pairs:

	$c_{\text{salt}} = 1.0 \times 10^{-2} \text{ mol dm}^{-3}$				
f	0.375	0.509	0.589	0.688	0.750
T_m/K	339	344	348	351	354
	$c_{\text{salt}} = 0.15 \text{ mol dm}^{-3}$				
f	0.375	0.509	0.589	0.688	0.750
T_m/K	359	364	368	371	374

(a) Estimate the melting temperature of a DNA molecule containing 40.0 per cent G—C base pairs in both samples. *Hint.* Begin by plotting T_m against fraction of G—C base pairs and examining the shape of the curve. (b) Do the data show an effect of concentration of ions in solution on the melting temperature of DNA? If so, provide a molecular interpretation for the effect you observe.

19.32 The fluidity of a lipid bilayer dispersed in aqueous solution depends on temperature and there are two important melting transitions. One transition is from a 'solid crystalline' state in which the hydrophobic chains are packed together tightly (hence move very little) to a 'liquid crystalline state', in which there is increased but still limited movement of the of the chains. The second transition, which occurs at a higher temperature than the first, is from the liquid crystalline state to a liquid state, in which the hydrophobic interactions holding the aggregate together are largely disrupted. (a) It is observed that the transition temperatures increase with the hydrophobic chain length and decrease with the number of C=C bonds in the chain. Explain these observations. (b) What effect is the inclusion of cholesterol likely to have on the transition temperatures of a lipid bilayer? Justify your answer.

19.33 Polystyrene is a synthetic polymer with the structure $-(\text{CH}_2-\text{CH}(\text{C}_6\text{H}_5))_n-$. A batch of polydisperse polystyrene was prepared by initiating the polymerization with *t*-butyl radicals. As a result, the *t*-butyl group is

expected to be covalently attached to the end of the final products. A sample from this batch was embedded in an organic matrix containing silver trifluoroacetate and the resulting MALDI-TOF spectrum consisted of a large number of peaks separated by 104 g mol⁻¹, with the most intense peak at 25 578 g mol⁻¹. Comment on the purity of this sample and determine the number of (CH₂—CH(C₆H₅)) units in the species that gives rise to the most intense peak in the spectrum .

19.34 A manufacturer of polystyrene beads claims that they have an average molar mass of 250 kg mol⁻¹. Solutions of these beads are studied by a physical chemistry student by dilute solution viscometry with an Ostwald viscometer in both the ‘good’ solvent toluene and the theta solvent cyclohexane. The drainage times, *t*_D, as a function of concentration for the two solvents are given in the table below. (a) Fit the data to the virial equation for viscosity,

$$\eta = \eta^*(1 + [\eta]c + k'[\eta]^2c^2 + \dots)$$

where *k'* is called the *Huggins constant* and is typically in the range 0.35–0.40. From the fit, determine the intrinsic viscosity and the Huggins constant. (b) Use the empirical Mark–Kuhn–Houwink–Sakurada equation (eqn 19.25) to determine the molar mass of polystyrene in the two solvents. For theta solvents, *a* = 0.5 and *K* = 8.2 × 10⁻⁵ dm³ g⁻¹ for cyclohexane; for the good solvent toluene *a* = 0.72 and *K* = 1.15 × 10⁻⁵ dm³ g⁻¹. (c) According to a general theory proposed by Kirkwood and Riseman, the root mean square end-to-end distance of a polymer chain in solution is related to $[\eta]$ by $[\eta] = \Phi \langle r^2 \rangle^{3/2} / M$, where Φ is a universal constant with the value 2.84 × 10²⁶ when $[\eta]$ is expressed in cubic decimetres per gram and the distance is in metres. Calculate this quantity for each solvent. (d) From the molar masses calculate

the average number of styrene (C₆H₅CH=CH₂) monomer units, $\langle n \rangle$, (e) Calculate the length of a fully stretched, planar zigzag configuration, taking the C—C distance as 154 pm and the CCC bond angle to be 109°. (f) Use eqn 19.33 to calculate the radius of gyration, *R*_g. Also calculate $\langle r^2 \rangle^{1/2} = n^{1/2}$. Compare this result with that predicted by the Kirkwood–Riseman theory: which gives the better fit? (g) Compare your values for *M* to the results of Problem 19.33. Is there any reason why they should or should not agree? Is the manufacturer’s claim valid?

<i>c</i> /(g dm ⁻³ toluene)	0	1.0	3.0	5.0
<i>t</i> _D /s	8.37	9.11	10.72	12.52
<i>c</i> /(g dm ⁻³ cyclohexane)	0	1.0	1.5	2.0
<i>t</i> _D /s	8.32	8.67	8.85	9.03

19.35‡ The determination of the average molar masses of conducting polymers is an important part of their characterization. S. Holdcroft (*J. Polym. Sci., Polym. Phys.* **29**, 1585 (1991)) has determined the molar masses and Mark–Houwink constants for the electronically conducting polymer, poly(3-hexylthiophene) (P3HT) in tetrahydrofuran (THF) at 25°C by methods similar to those used for nonconducting polymers. The values for molar mass and intrinsic viscosity in the table below are adapted from their data. Determine the constants in the Mark–Kuhn–Houwink–Sakurada equation from these results and compare to the values obtained in your solution to Problem 19.7 .

$\bar{M}_v$ /(kg mol ⁻¹)	3.8	11.1	15.3	58.8
$[\eta]$ /(cm ³ g ⁻¹)	6.23	17.44	23.73	85.28

Materials 2: the solid state

20

First, we see how to describe the regular arrangement of atoms in crystals and the symmetry of their arrangement. Then we consider the basic principles of X-ray diffraction and see how the diffraction pattern can be interpreted in terms of the distribution of electron density in a unit cell. X-ray diffraction leads to information about the structures of metallic, ionic, and molecular solids, and we review some typical results and their rationalization in terms of atomic and ionic radii. With structures established, we move on to the properties of solids, and see how their mechanical, electrical, optical, and magnetic properties stem from the properties of their constituent atoms and molecules.

The solid state includes most of the materials that make modern technology possible. It includes the wide varieties of steel that are used in architecture and engineering, the semiconductors and metallic conductors that are used in information technology and power distribution, the ceramics that increasingly are replacing metals, and the synthetic and natural polymers that are used in the textile industry and in the fabrication of many of the common objects of the modern world. The properties of solids stem, of course, from the arrangement and properties of the constituent atoms, and one of the challenges of this chapter is to see how a wide range of bulk properties, including rigidity, electrical conductivity, and optical and magnetic properties stem from the properties of atoms. One crucial aspect of this link is the pattern in which the atoms (and molecules) are stacked together, and we start this chapter with an examination of how the structures of solids are described and determined.

Crystal lattices

Early in the history of modern science it was suggested that the regular external form of crystals implied an internal regularity of their constituents. In this section we see how to describe the arrangement of atoms inside crystals.

20.1 Lattices and unit cells

A crystal is built up from regularly repeating ‘structural motifs’, which may be atoms, molecules, or groups of atoms, molecules, or ions. A **space lattice** is the pattern formed by points representing the locations of these motifs (Fig. 20.1). The space lattice is, in effect, an abstract scaffolding for the crystal structure. More formally, a space lattice is a three-dimensional, infinite array of points, each of which is surrounded in an identical way by its neighbours, and which defines the basic structure of the crystal. In some cases there may be a structural motif centred on each lattice

Problems

Fig. 20.1 Each lattice point specifies the location of a structural motif (for example, a molecule or a group of molecules). The crystal lattice is the array of lattice points; the crystal structure is the collection of structural motifs arranged according to the lattice.

Fig. 20.2 A unit cell is a parallel-sided (but not necessarily rectangular) figure from which the entire crystal structure can be constructed by using only translations (not reflections, rotations, or inversions).

Fig. 20.3 A unit cell can be chosen in a variety of ways, as shown here. It is conventional to choose the cell that represents the full symmetry of the lattice. In this rectangular lattice, the rectangular unit cell would normally be adopted.

point, but that is not necessary. The crystal structure itself is obtained by associating with each lattice point an identical structural motif.

The **unit cell** is an imaginary parallelepiped (parallel-sided figure) that contains one unit of the translationally repeating pattern (Fig. 20.2). A unit cell can be thought of as the fundamental region from which the entire crystal may be constructed by purely translational displacements (like bricks in a wall). A unit cell is commonly formed by joining neighbouring lattice points by straight lines (Fig. 20.3). Such unit cells are called **primitive**. It is sometimes more convenient to draw larger **non-primitive unit cells** that also have lattice points at their centres or on pairs of opposite faces. An infinite number of different unit cells can describe the same lattice, but the one with sides that have the shortest lengths and that are most nearly perpendicular to one another is normally chosen. The lengths of the sides of a unit cell are denoted a , b , and c , and the angles between them are denoted α , β , and γ (Fig. 20.4).

Unit cells are classified into seven **crystal systems** by noting the rotational symmetry elements they possess. A *cubic unit cell*, for example, has four threefold axes in a tetrahedral array (Fig. 20.5). A *monoclinic unit cell* has one twofold axis; the unique

Comment 20.1

A *symmetry operation* is an action (such as a rotation, reflection, or inversion) that leaves an object looking the same after it has been carried out. There is a corresponding *symmetry element* for each symmetry operation, which is the point, line, or plane with respect to which the symmetry operation is performed. For instance, an *n-fold rotation* (the symmetry operation) about an *n-fold axis of symmetry* (the corresponding symmetry element) is a rotation through $360^\circ/n$. See Chapter 12 for a more detailed discussion of symmetry.

Fig. 20.4 The notation for the sides and angles of a unit cell. Note that the angle α lies in the plane (b, c) and perpendicular to the axis a .

Fig. 20.5 A unit cell belonging to the cubic system has four threefold axes, denoted C_3 , arranged tetrahedrally. The insert shows the threefold symmetry.

axis is by convention the b axis (Fig. 20.6). A *triclinic unit cell* has no rotational symmetry, and typically all three sides and angles are different (Fig. 20.7). Table 20.1 lists the **essential symmetries**, the elements that must be present for the unit cell to belong to a particular crystal system.

There are only 14 distinct space lattices in three dimensions. These **Bravais lattices** are illustrated in Fig. 20.8. It is conventional to portray these lattices by primitive unit cells in some cases and by non-primitive unit cells in others. A **primitive unit cell** (with lattice points only at the corners) is denoted P. A **body-centred unit cell** (I) also has a lattice point at its centre. A **face-centred unit cell** (F) has lattice points at its corners and also at the centres of its six faces. A **side-centred unit cell** (A, B, or C) has lattice points at its corners and at the centres of two opposite faces. For simple structures, it is often convenient to choose an atom belonging to the structural motif, or the

Fig. 20.6 A unit belonging to the monoclinic system has a twofold axis (denoted C_2 and shown in more detail in the insert).

Fig. 20.8 The fourteen Bravais lattices. The points are lattice points, and are not necessarily occupied by atoms. P denotes a primitive unit cell (R is used for a trigonal lattice), I a body-centred unit cell, F a face-centred unit cell, and C (or A or B) a cell with lattice points on two opposite faces.

Fig. 20.7 A triclinic unit cell has no axes of rotational symmetry.

Table 20.1 The seven crystal systems

System	Essential symmetries
Triclinic	None
Monoclinic	One C_2 axis
Orthorhombic	Three perpendicular C_2 axes
Rhombohedral	One C_3 axis
Tetragonal	One C_4 axis
Hexagonal	One C_6 axis
Cubic	Four C_3 axes in a tetrahedral arrangement

Fig. 20.9 Some of the planes that can be drawn through the points of a rectangular space lattice and their corresponding Miller indices (hkl): (a) (110), (b) (230), (c) ($\bar{1}10$), and (d) (010).

centre of a molecule, as the location of a lattice point or the vertex of a unit cell, but that is not a necessary requirement.

20.2 The identification of lattice planes

The spacing of the planes of lattice points in a crystal is an important quantitative aspect of its structure. However, there are many different sets of planes (Fig. 20.9), and we need to be able to label them. Two-dimensional lattices are easier to visualize than three-dimensional lattices, so we shall introduce the concepts involved by referring to two dimensions initially, and then extend the conclusions by analogy to three dimensions.

(a) The Miller indices

Consider a two-dimensional rectangular lattice formed from a unit cell of sides a , b (as in Fig. 20.9). Each plane in the illustration (except the plane passing through the origin) can be distinguished by the distances at which it intersects the a and b axes. One way to label each set of parallel planes would therefore be to quote the smallest intersection distances. For example, we could denote the four sets in the illustration as $(1a, 1b)$, $(\frac{1}{2}a, \frac{1}{3}b)$, $(-1a, 1b)$, and $(\infty a, 1b)$. However, if we agree to quote distances along the axes as multiples of the lengths of the unit cell, then we can label the planes more simply as $(1, 1)$, $(\frac{1}{2}, \frac{1}{3})$, $(-1, 1)$, and $(\infty, 1)$. If the lattice in Fig. 20.9 is the top view of a three-dimensional orthorhombic lattice in which the unit cell has a length c in the z -direction, all four sets of planes intersect the z -axis at infinity. Therefore, the full labels are $(1, 1, \infty)$, $(\frac{1}{2}, \frac{1}{3}, \infty)$, $(-1, 1, \infty)$, and $(\infty, 1, \infty)$.

The presence of fractions and infinity in the labels is inconvenient. They can be eliminated by taking the reciprocals of the labels. As we shall see, taking reciprocals turns out to have further advantages. The **Miller indices**, (hkl), are the reciprocals of intersection distances (with fractions cleared by multiplying through by an appropriate factor, if taking the reciprocal results in a fraction). For example, the $(1, 1, \infty)$ planes in Fig. 20.9a are the (110) planes in the Miller notation. Similarly, the $(\frac{1}{2}, \frac{1}{3}, \infty)$ planes are denoted (230). Negative indices are written with a bar over the number, and Fig. 20.9c shows the ($\bar{1}10$) planes. The Miller indices for the four sets of planes in Fig. 20.9 are therefore (110), (230), ($\bar{1}10$), and (010). Figure 20.10 shows a three-dimensional representation of a selection of planes, including one in a lattice with non-orthogonal axes.

The notation (hkl) denotes an *individual* plane. To specify a *set* of parallel planes we use the notation $\{hkl\}$. Thus, we speak of the (110) plane in a lattice, and the set of all $\{110\}$ planes that lie parallel to the (110) plane. A helpful feature to remember is that, the smaller the absolute value of h in $\{hkl\}$, the more nearly parallel the set of planes is to the a axis (the $\{h00\}$ planes are an exception). The same is true of k and the b axis and l and the c axis. When $h = 0$, the planes intersect the a axis at infinity, so the $\{0kl\}$

Fig. 20.10 Some representative planes in three dimensions and their Miller indices. Note that a 0 indicates that a plane is parallel to the corresponding axis, and that the indexing may also be used for unit cells with non-orthogonal axes.

planes are parallel to the a axis. Similarly, the $\{h0l\}$ planes are parallel to b and the $\{hk0\}$ planes are parallel to c .

(b) The separation of planes

The Miller indices are very useful for expressing the separation of planes. The separation of the $\{hk0\}$ planes in the square lattice shown in Fig. 20.11 is given by

$$\frac{1}{d_{hk0}^2} = \frac{h^2 + k^2}{a^2} \quad \text{or} \quad d_{hk0} = \frac{a}{(h^2 + k^2)^{1/2}} \quad (20.1)$$

By extension to three dimensions, the separation of the $\{hkl\}$ planes of a cubic lattice is given by

$$\frac{1}{d_{hkl}^2} = \frac{h^2 + k^2 + l^2}{a^2} \quad \text{or} \quad d_{hkl} = \frac{a}{(h^2 + k^2 + l^2)^{1/2}} \quad (20.2)$$

The corresponding expression for a general orthorhombic lattice is the generalization of this expression:

$$\frac{1}{d_{hkl}^2} = \frac{h^2}{a^2} + \frac{k^2}{b^2} + \frac{l^2}{c^2} \quad (20.3)$$

Fig. 20.11 The dimensions of a unit cell and their relation to the plane passing through the lattice points.

Fig. 20.12 The separation of the $\{220\}$ planes is half that of the $\{110\}$ planes. In general, (the separation of the planes $\{nh,nk,nl\}$ is n times smaller than the separation of the $\{hkl\}$ planes.

Example 20.1 Using the Miller indices

Calculate the separation of (a) the $\{123\}$ planes and (b) the $\{246\}$ planes of an orthorhombic unit cell with $a = 0.82$ nm, $b = 0.94$ nm, and $c = 0.75$ nm.

Method For the first part, simply substitute the information into eqn 20.3. For the second part, instead of repeating the calculation, note that if all three Miller indices are multiplied by n , then their separation is reduced by that factor (Fig. 20.12):

$$\frac{1}{d_{nh,nk,nl}^2} = \frac{(nh)^2}{a^2} + \frac{(nk)^2}{b^2} + \frac{(nl)^2}{c^2} = n^2 \left(\frac{h^2}{a^2} + \frac{k^2}{b^2} + \frac{l^2}{c^2} \right) = \frac{n^2}{d_{hkl}^2}$$

which implies that

$$d_{nh,nk,nl} = \frac{d_{hkl}}{n}$$

Answer Substituting the indices into eqn 20.3 gives

$$\frac{1}{d_{123}^2} = \frac{1^2}{(0.82 \text{ nm})^2} + \frac{2^2}{(0.94 \text{ nm})^2} + \frac{3^2}{(0.75 \text{ nm})^2} = 0.22 \text{ nm}^{-2}$$

Hence, $d_{123} = 0.21$ nm. It then follows immediately that d_{246} is one-half this value, or 0.11 nm.

A note on good practice It is always sensible to look for analytical relations between quantities rather than to evaluate expressions numerically each time for that emphasizes the relations between quantities (and avoids unnecessary work).

Self-test 20.1 Calculate the separation of (a) the $\{133\}$ planes and (b) the $\{399\}$ planes in the same lattice. [0.19 nm, 0.063 nm]

Fig. 20.13 When two waves are in the same region of space they interfere. Depending on their relative phase, they may interfere (a) constructively, to give an enhanced amplitude, or (b) destructively, to give a smaller amplitude. The component waves are shown in green and blue and the resultant in purple.

Fig. 20.14 X-rays are generated by directing an electron beam on to a cooled metal target. Beryllium is transparent to X-rays (on account of the small number of electrons in each atom) and is used for the windows.

20.3 The investigation of structure

A characteristic property of waves is that they interfere with one another, giving a greater displacement where peaks or troughs coincide and a smaller displacement where peaks coincide with troughs (Fig. 20.13). According to classical electromagnetic theory, the intensity of electromagnetic radiation is proportional to the square of the amplitude of the waves. Therefore, the regions of constructive or destructive interference show up as regions of enhanced or diminished intensities. The phenomenon of **diffraction** is the interference caused by an object in the path of waves, and the pattern of varying intensity that results is called the **diffraction pattern**. Diffraction occurs when the dimensions of the diffracting object are comparable to the wavelength of the radiation.

(a) X-ray diffraction

Wilhelm Röntgen discovered X-rays in 1895. Seventeen years later, Max von Laue suggested that they might be diffracted when passed through a crystal, for by then he had realized that their wavelengths are comparable to the separation of lattice planes. This suggestion was confirmed almost immediately by Walter Friedrich and Paul Knipping and has grown since then into a technique of extraordinary power. The bulk of this section will deal with the determination of structures using X-ray diffraction. The mathematical procedures necessary for the determination of structure from X-ray diffraction data are enormously complex, but such is the degree of integration of computers into the experimental apparatus that the technique is almost fully automated, even for large molecules and complex solids. The analysis is aided by molecular modelling techniques, which can guide the investigation towards a plausible structure.

X-rays are electromagnetic radiation with wavelengths of the order of 10^{-10} m. They are typically generated by bombarding a metal with high-energy electrons (Fig. 20.14). The electrons decelerate as they plunge into the metal and generate radiation with a continuous range of wavelengths called **Bremsstrahlung**.¹ Superimposed on the

¹ *Bremse* is German for deceleration, *Strahlung* for ray.

continuum are a few high-intensity, sharp peaks (Fig. 20.15). These peaks arise from collisions of the incoming electrons with the electrons in the inner shells of the atoms. A collision expels an electron from an inner shell, and an electron of higher energy drops into the vacancy, emitting the excess energy as an X-ray photon (Fig. 20.16). If the electron falls into a K shell (a shell with $n = 1$), the X-rays are classified as **K -radiation**, and similarly for transitions into the L ($n = 2$) and M ($n = 3$) shells. Strong, distinct lines are labelled K_α , K_β , and so on. Increasingly, X-ray diffraction makes use of the radiation available from synchrotron sources (*Further information* 13.1), for its high intensity greatly enhances the sensitivity of the technique.

von Laue's original method consisted of passing a broad-band beam of X-rays into a single crystal, and recording the diffraction pattern photographically. The idea behind the approach was that a crystal might not be suitably orientated to act as a diffraction grating for a single wavelength but, whatever its orientation, diffraction would be achieved for at least one of the wavelengths if a range of wavelengths was used. There is currently a resurgence of interest in this approach because synchrotron radiation spans a range of X-ray wavelengths.

An alternative technique was developed by Peter Debye and Paul Scherrer and independently by Albert Hull. They used monochromatic radiation and a powdered sample. When the sample is a powder, at least some of the crystallites will be orientated so as to give rise to diffraction. In modern powder diffractometers the intensities of the reflections are monitored electronically as the detector is rotated around the sample in a plane containing the incident ray (Fig. 20.17). Powder diffraction techniques are used to identify a sample of a solid substance by comparison of the positions of the diffraction lines and their intensities with diffraction patterns stored in a large data bank. Powder diffraction data are also used to determine phase diagrams, for different solid phases result in different diffraction patterns, and to determine the relative amounts of each phase present in a mixture. The technique is also used for the initial determination of the dimensions and symmetries of unit cells.

Fig. 20.15 The X-ray emission from a metal consists of a broad, featureless Bremsstrahlung background, with sharp transitions superimposed on it. The label K indicates that the radiation comes from a transition in which an electron falls into a vacancy in the K shell of the atom.

Comment 20.2

The web site contains links to databases of X-ray diffraction patterns.

Fig. 20.16 The processes that contribute to the generation of X-rays. An incoming electron collides with an electron (in the K shell), and ejects it. Another electron (from the L shell in this illustration) falls into the vacancy and emits its excess energy as an X-ray photon.

Fig. 20.17 X-ray powder photographs of (a) NaCl, (b) KCl and the indexed reflections. The smaller number of lines in (b) is a consequence of the similarity of the K^+ and Cl^- scattering factors, as discussed later in the chapter.

Fig. 20.18 A four-circle diffractometer. The settings of the orientations (ϕ , χ , θ , and Ω) of the components is controlled by computer; each (hkl) reflection is monitored in turn, and their intensities are recorded.

Fig. 20.19 The conventional derivation of Bragg's law treats each lattice plane as a reflecting the incident radiation. The path lengths differ by $AB + BC$, which depends on the glancing angle, θ . Constructive interference (a 'reflection') occurs when $AB + BC$ is equal to an integer number of wavelengths.

The method developed by the Braggs (William and his son Lawrence, who later jointly won the Nobel Prize) is the foundation of almost all modern work in X-ray crystallography. They used a single crystal and a monochromatic beam of X-rays, and rotated the crystal until a reflection was detected. There are many different sets of planes in a crystal, so there are many angles at which a reflection occurs. The complete set of data consists of the list of angles at which reflections are observed and their intensities.

Single-crystal diffraction patterns are measured by using a **four-circle diffractometer** (Fig. 20.18). The computer linked to the diffractometer determines the unit cell dimensions and the angular settings of the diffractometer's four circles that are needed to observe any particular intensity peak in the diffraction pattern. The computer controls the settings, and moves the crystal and the detector for each one in turn. At each setting, the diffraction intensity is measured, and background intensities are assessed by making measurements at slightly different settings. Computing techniques are now available that lead not only to automatic indexing but also to the automated determination of the shape, symmetry, and size of the unit cell. Moreover, several techniques are now available for sampling large amounts of data, including area detectors and image plates, which sample whole regions of diffraction patterns simultaneously.

(b) Bragg's law

An early approach to the analysis of diffraction patterns produced by crystals was to regard a lattice plane as a semi-transparent mirror, and to model a crystal as stacks of reflecting lattice planes of separation d (Fig. 20.19). The model makes it easy to calculate the angle the crystal must make to the incoming beam of X-rays for constructive interference to occur. It has also given rise to the name **reflection** to denote an intense beam arising from constructive interference.

Consider the reflection of two parallel rays of the same wavelength by two adjacent planes of a lattice, as shown in Fig. 20.19. One ray strikes point D on the upper plane but the other ray must travel an additional distance AB before striking the plane immediately below. Similarly, the reflected rays will differ in path length by a distance BC . The net path length difference of the two rays is then

$$AB + BC = 2d \sin \theta$$

where θ is the **glancing angle**. For many glancing angles the path-length difference is not an integer number of wavelengths, and the waves interfere largely destructively. However, when the path-length difference is an integer number of wavelengths ($AB + BC = n\lambda$), the reflected waves are in phase and interfere constructively. It follows that a reflection should be observed when the glancing angle satisfies **Bragg's law**:

$$n\lambda = 2d \sin \theta \quad (20.4)$$

Reflections with $n = 2, 3, \dots$ are called second-order, third-order, and so on; they correspond to path-length differences of 2, 3, $\dots$ wavelengths. In modern work it is normal to absorb the n into d , to write the Bragg law as

$$\lambda = 2d \sin \theta \quad (20.5)$$

and to regard the n th-order reflection as arising from the $\{nh, nk, nl\}$ planes (see Example 20.1).

The primary use of Bragg's law is in the determination of the spacing between the layers in the lattice for, once the angle θ corresponding to a reflection has been determined, d may readily be calculated.

Example 20.2 Using Bragg's law

A first-order reflection from the {111} planes of a cubic crystal was observed at a glancing angle of 11.2° when $\text{Cu}(K_\alpha)$ X-rays of wavelength 154 pm were used. What is the length of the side of the unit cell?

Method The separation of the planes can be determined from Bragg's law. Because the crystal is cubic, the separation is related to the length of the side of the unit cell, a , by eqn 20.2, which may therefore be solved for a .

Answer According to eqn 20.5, the {111} planes responsible for the diffraction have separation

$$d_{111} = \frac{\lambda}{2 \sin \theta}$$

The separation of the {111} planes of a cubic lattice of side a is given by eqn 20.2 as

$$d_{111} = \frac{a}{3^{1/2}}$$

Therefore,

$$a = \frac{3^{1/2} \lambda}{2 \sin \theta} = \frac{3^{1/2} \times (154 \text{ pm})}{2 \sin 11.2^\circ} = 687 \text{ pm}$$

Self-test 20.2 Calculate the angle at which the same crystal will give a reflection from the {123} planes. [24.8°]

Some types of unit cell give characteristic and easily recognizable patterns of lines. For example, in a cubic lattice of unit cell dimension a the spacing is given by eqn 20.2, so the angles at which the { hkl } planes give first-order reflections are given by

$$\sin \theta = (h^2 + k^2 + l^2)^{1/2} \frac{\lambda}{2a}$$

The reflections are then predicted by substituting the values of h , k , and l :

{ hkl }	{100}	{110}	{111}	{200}	{210}	{211}	{220}	{300}	{221}	{310}	...
$h^2+k^2+l^2$	1	2	3	4	5	6	8	9	9	10	...

Notice that 7 (and 15, ...) is missing because the sum of the squares of three integers cannot equal 7 (or 15, ...). Therefore the pattern has absences that are characteristic of the cubic P lattice.

Self-test 20.3 Normally, experimental procedures measure 2θ rather than θ itself. A diffraction examination of the element polonium gave lines at the following values of 2θ (in degrees) when 71.0 pm Mo X-rays were used: 12.1, 17.1, 21.0, 24.3, 27.2, 29.9, 34.7, 36.9, 38.9, 40.9, 42.8. Identify the unit cell and determine its dimensions. [cubic P; $a = 337 \text{ pm}$]

(c) Scattering factors

To prepare the way to discussing modern methods of structural analysis we need to note that the scattering of X-rays is caused by the oscillations an incoming electromagnetic

Fig. 20.20 The variation of the scattering factor of atoms and ions with atomic number and angle. The scattering factor in the forward direction (at $\theta=0$, and hence at $(\sin \theta)/\lambda=0$) is equal to the number of electrons present in the species.

wave generates in the electrons of atoms, and heavy atoms give rise to stronger scattering than light atoms. This dependence on the number of electrons is expressed in terms of the **scattering factor**, f , of the element. If the scattering factor is large, then the atoms scatter X-rays strongly. The scattering factor of an atom is related to the electron density distribution in the atom, $\rho(r)$, by

$$f = 4\pi \int_0^\infty \rho(r) \frac{\sin kr}{kr} r^2 dr \quad k = \frac{4\pi}{\lambda} \sin \theta \quad (20.6)$$

The value of f is greatest in the forward direction and smaller for directions away from the forward direction (Fig. 20.20). The detailed analysis of the intensities of reflections must take this dependence on direction into account (in single crystal studies as well as for powders). We show in the *Justification* below that, in the forward direction (for $\theta=0$), f is equal to the total number of electrons in the atom.

Justification 20.1 The forward scattering factor

As $\theta \rightarrow 0$, so $k \rightarrow 0$. Because $\sin x = x - \frac{1}{6}x^3 + \dots$,

$$\lim_{x \rightarrow 0} \frac{\sin x}{x} = \lim_{x \rightarrow 0} \frac{x - \frac{1}{6}x^3 + \dots}{x} = \lim_{x \rightarrow 0} (1 - \frac{1}{6}x^2 + \dots) = 1$$

The factor $(\sin kr)/kr$ is therefore equal to 1 for forward scattering. It follows that in the forward direction

$$f = 4\pi \int_0^\infty \rho(r) r^2 dr$$

The integral over the electron density ρ (the number of electrons in an infinitesimal region divided by the volume of the region) multiplied by the volume element $4\pi r^2 dr$ is the total number of electrons, N_e , in the atom. Hence, in the forward direction, $f = N_e$. For example, the scattering factors of Na^+ , K^+ , and Cl^- are 8, 18, and 18, respectively.

The scattering factor is smaller in nonforward directions because $(\sin kr)/kr < 1$ for $\theta > 0$, so the integral is smaller than the value calculated above.

(d) The electron density

The problem we now address is how to interpret the data from a diffractometer in terms of the detailed structure of a crystal. To do so, we must go beyond Bragg's law.

If a unit cell contains several atoms with scattering factors f_j and coordinates (x_j, y_j, z_j) , then we show in the *Justification* below that the overall amplitude of a wave diffracted by the $\{hkl\}$ planes is given by

$$F_{hkl} = \sum_j f_j e^{i\phi_{hkl}(j)} \quad \text{where} \quad \phi_{hkl}(j) = 2\pi(hx_j + ky_j + lz_j) \quad (20.7)$$

The sum is over all the atoms in the unit cell. The quantity F_{hkl} is called the **structure factor**.

Justification 20.2 The structure factor

We begin by showing that, if in the unit cell there is an A atom at the origin and a B atom at the coordinates (x, y, z) , where x , y , and z lie in the range 0 to 1, then the phase difference, ϕ , between the hkl reflections of the A and B atoms is $\phi_{hkl} = 2\pi(hx + ky + lz)$.

Fig. 20.21 Diffraction from a crystal containing two kinds of atoms. (a) For a (100) reflection from the A planes, there is a phase difference of 2π between waves reflected by neighbouring planes. (b) For a (200) reflection, the phase difference is 4π . The reflection from a B plane at a fractional distance xa from an A plane has a phase that is x times these phase differences.

Consider the crystal shown schematically in Fig. 20.21. The reflection corresponds to two waves from adjacent A planes, the phase difference of the waves being 2π . If there is a B atom at a fraction x of the distance between the two A planes, then it gives rise to a wave with a phase difference $2\pi x$ relative to an A reflection. To see this conclusion, note that, if $x = 0$, there is no phase difference; if $x = \frac{1}{2}$ the phase difference is π ; if $x = 1$, the B atom lies where the lower A atom is and the phase difference is 2π . Now consider a (200) reflection. There is now a $2 \times 2\pi$ difference between the waves from the two A layers, and if B were to lie at $x = 0.5$ it would give rise to a wave that differed in phase by 2π from the wave from the upper A layer. Thus, for a general fractional position x , the phase difference for a (200) reflection is $2 \times 2\pi x$. For a general $(h00)$ reflection, the phase difference is therefore $h \times 2\pi x$. For three dimensions, this result generalizes to eqn 20.7.

The A and B reflections interfere destructively when the phase difference is π , and the total intensity is zero if the atoms have the same scattering power. For example, if the unit cells are cubic I with a B atom at $x = y = z = \frac{1}{2}$, then the A,B phase difference is $(h + k + l)\pi$. Therefore, all reflections for odd values of $h + k + l$ vanish because the waves are displaced in phase by π . Hence the diffraction pattern for a cubic I lattice can be constructed from that for the cubic P lattice (a cubic lattice without points at the centre of its unit cells) by striking out all reflections with odd values of $h + k + l$. Recognition of these **systematic absences** in a powder spectrum immediately indicates a cubic I lattice (Fig. 20.22).

If the amplitude of the waves scattered from A is f_A at the detector, that of the waves scattered from B is $f_B e^{i\phi_{hkl}}$, with ϕ_{hkl} the phase difference given in eqn 20.7. The total amplitude at the detector is therefore

$$F_{hkl} = f_A + f_B e^{i\phi_{hkl}}$$

Because the intensity is proportional to the square modulus of the amplitude of the wave, the intensity, I_{hkl} at the detector is

$$I_{hkl} \propto F_{hkl}^* F_{hkl} = (f_A + f_B e^{-i\phi_{hkl}})(f_A + f_B e^{i\phi_{hkl}})$$

This expression expands to

$$I_{hkl} \propto f_A^2 + f_B^2 + f_A f_B (e^{i\phi_{hkl}} + e^{-i\phi_{hkl}}) = f_A^2 + f_B^2 + 2f_A f_B \cos \phi_{hkl}$$

The cosine term either adds to or subtracts from $f_A^2 + f_B^2$ depending on the value of ϕ_{hkl} , which in turn depends on h , k , and l and x , y , and z . Hence, there is a variation in the intensities of the lines with different hkl .

Fig. 20.22 The powder diffraction patterns and the systematic absences of three versions of a cubic cell. Comparison of the observed pattern with patterns like these enables the unit cell to be identified. The locations of the lines give the cell dimensions.

Fig. 20.23 The location of the atoms for the structure factor calculation in Example 20.3. The purple circles are Na^+ ; the green circles are Cl^- .

Example 20.3 Calculating a structure factor

Calculate the structure factors for the unit cell in Fig. 20.23.

Method The structure factor is defined by eqn 20.7. To use this equation, consider the ions at the locations specified in Fig. 20.23. Write f^+ for the Na^+ scattering factor and f^- for the Cl^- scattering factor. Note that ions in the body of the cell contribute to the scattering with a strength f . However, ions on faces are shared between two cells (use $\frac{1}{2}f$), those on edges by four cells (use $\frac{1}{4}f$), and those at corners by eight cells (use $\frac{1}{8}f$). Two useful relations are

$$e^{i\pi} = -1 \quad \cos \phi = \frac{1}{2}(e^{i\phi} + e^{-i\phi})$$

Answer From eqn 20.7, and summing over the coordinates of all 27 atoms in the illustration:

$$F_{hkl} = f^+ \left(\frac{1}{8} + \frac{1}{8} e^{2\pi i l} + \dots + \frac{1}{2} e^{2\pi i (\frac{1}{2}h + \frac{1}{2}k + l)} \right) + f^- \left(e^{2\pi i (\frac{1}{2}h + \frac{1}{2}k + \frac{1}{2}l)} + \frac{1}{4} e^{2\pi i (\frac{1}{2}h)} + \dots + \frac{1}{4} e^{2\pi i (\frac{1}{2}h + l)} \right)$$

To simplify this 27-term expression, we use

$$e^{2\pi i h} = e^{2\pi i k} = e^{2\pi i l} = 1$$

because h , k , and l are all integers:

$$F_{hkl} = f^+ \{ 1 + \cos(h+k)\pi + \cos(h+l)\pi + \cos(k+l)\pi \} + f^- \{ (-1)^{h+k+l} + \cos k\pi + \cos l\pi + \cos h\pi \}$$

Then, because $\cos h\pi = (-1)^h$,

$$F_{hkl} = f^+ \{ 1 + (-1)^{h+k} + (-1)^{h+l} + (-1)^{l+k} \} + f^- \{ (-1)^{h+k+l} + (-1)^h + (-1)^k + (-1)^l \}$$

Now note that:

$$\text{if } h, k, \text{ and } l \text{ are all even, } F_{hkl} = f^+ \{ 1 + 1 + 1 + 1 \} + f^- \{ 1 + 1 + 1 + 1 \} = 4(f^+ + f^-)$$

$$\text{if } h, k, \text{ and } l \text{ are all odd, } F_{hkl} = 4(f^+ - f^-)$$

$$\text{if one index is odd and two are even, or vice versa, } F_{hkl} = 0$$

The hkl all-odd reflections are less intense than the hkl all-even. For $f^+ = f^-$, which is the case for identical atoms in a cubic P arrangement, the hkl all-odd have zero intensity, corresponding to the ‘systematic absences’ of cubic P unit cells.

Self-test 20.4 Which reflections cannot be observed for a cubic I lattice?

$$[\text{for } h + k + l \text{ odd, } F_{hkl} = 0]$$

The intensity of the (hkl) reflection is proportional to $|F_{hkl}|^2$, so in principle we can determine the structure factors experimentally by taking the square root of the corresponding intensities (but see below). Then, once we know all the structure factors F_{hkl} , we can calculate the electron density distribution, $\rho(\mathbf{r})$, in the unit cell by using the expression

$$\rho(\mathbf{r}) = \frac{1}{V} \sum_{hkl} F_{hkl} e^{-2\pi i(hx + ky + lz)} \quad (20.8)$$

where V is the volume of the unit cell. Equation 20.8 is called a **Fourier synthesis** of the electron density.

Example 20.4 Calculating an electron density by Fourier synthesis

Consider the $\{h00\}$ planes of a crystal extending indefinitely in the x -direction. In an X-ray analysis the structure factors were found as follows:

h :	0	1	2	3	4	5	6	7	8	9
F_h	16	-10	2	-1	7	-10	8	-3	2	-3
h :	10	11	12	13	14	15				
F_h	6	-5	3	-2	2	-3				

(and $F_{-h} = F_h$). Construct a plot of the electron density projected on to the x -axis of the unit cell.

Method Because $F_{-h} = F_h$, it follows from eqn 20.8 that

$$\begin{aligned} V\rho(x) &= \sum_{h=-\infty}^{\infty} F_h e^{-2\pi i h x} = F_0 + \sum_{h=1}^{\infty} (F_h e^{-2\pi i h x} + F_{-h} e^{2\pi i h x}) \\ &= F_0 + \sum_{h=1}^{\infty} F_h (e^{-2\pi i h x} + e^{2\pi i h x}) = F_0 + 2 \sum_{h=1}^{\infty} F_h \cos 2\pi h x \end{aligned}$$

and we evaluate the sum (truncated at $h = 15$) for points $0 \leq x \leq 1$ using mathematical software.

Answer The results are plotted in Fig. 20.24 (blue line). The positions of three atoms can be discerned very readily. The more terms there are included, the more accurate the density plot. Terms corresponding to high values of h (short wavelength cosine terms in the sum) account for the finer details of the electron density; low values of h account for the broad features.

Self-test 20.5 Use mathematical software to experiment with different structure factors (including changing signs as well as amplitudes). For example, use the same values of F_h as above, but with positive signs for $h \geq 6$.

[Fig. 20.24 (purple line)]

Fig. 20.24 The plot of the electron density calculated in Example 20.4 (blue) and Self-test 20.5 (purple).

Exploration If you do not have access to mathematical software, perform the calculations suggested in Self-test 20.5 by using the interactive applets found in the text's web site.

(e) The phase problem

A problem with the procedure outlined above is that the observed intensity I_{hkl} is proportional to the square modulus $|F_{hkl}|^2$, so we cannot say whether we should use $+|F_{hkl}|$ or $-|F_{hkl}|$ in the sum in eqn 20.8. In fact, the difficulty is more severe for non-centrosymmetric unit cells because, if we write F_{hkl} as the complex number $|F_{hkl}|e^{i\alpha}$, where α is the phase of F_{hkl} and $|F_{hkl}|$ is its magnitude, then the intensity lets us determine $|F_{hkl}|$ but tells us nothing of its phase, which may lie anywhere from 0 to 2π . This ambiguity is called the **phase problem**; its consequences are illustrated by comparing the two plots in Fig. 20.24. Some way must be found to assign phases to the structure factors, for otherwise the sum for ρ cannot be evaluated and the method would be useless.

The phase problem can be overcome to some extent by a variety of methods. One procedure that is widely used for inorganic materials with a reasonably small number of atoms in a unit cell and for organic molecules with a small number of heavy atoms is the **Patterson synthesis**. Instead of the structure factors F_{hkl} , the values of $|F_{hkl}|^2$, which can be obtained without ambiguity from the intensities, are used in an expression that resembles eqn 20.8:

Fig. 20.25 The Patterson synthesis corresponding to the pattern in (a) is the pattern in (b). The distance and orientation of each spot from the origin gives the orientation and separation of one atom–atom separation in (a). Some of the typical distances and their contribution to (b) are shown as R_1 , etc.

$$P(\mathbf{r}) = \frac{1}{V} \sum_{hkl} |F_{hkl}|^2 e^{-2\pi i(hx + ky + lz)} \quad (20.9)$$

The outcome of a Patterson synthesis is a map of the vector separations of the atoms (the distances and directions between atoms) in the unit cell. Thus, if atom A is at the coordinates (x_A, y_A, z_A) and atom B is at (x_B, y_B, z_B) , then there will be a peak at $(x_A - x_B, y_A - y_B, z_A - z_B)$ in the Patterson map. There will also be a peak at the negative of these coordinates, because there is a vector from B to A as well as a vector from A to B. The height of the peak in the map is proportional to the product of the atomic numbers of the two atoms, $Z_A Z_B$. For example, if the unit cell has the structure shown in Fig. 20.25a, the Patterson synthesis would be the map shown in Fig. 20.25b, where the location of each spot relative to the origin gives the separation and relative orientation of each pair of atoms in the original structure.

Heavy atoms dominate the scattering because their scattering factors are large, of the order of their atomic numbers, and their locations may be deduced quite readily. The sign of F_{hkl} can now be calculated from the locations of the heavy atoms in the unit cell, and to a high probability the phase calculated for them will be the same as the phase for the entire unit cell. To see why this is so, we have to note that a structure factor of a centrosymmetric cell has the form

$$F = (\pm)f_{\text{heavy}} + (\pm)f_{\text{light}} + (\pm)f_{\text{light}} + \dots \quad (20.10)$$

where f_{heavy} is the scattering factor of the heavy atom and f_{light} the scattering factors of the light atoms. The f_{light} are all much smaller than f_{heavy} , and their phases are more or less random if the atoms are distributed throughout the unit cell. Therefore, the net effect of the f_{light} is to change F only slightly from f_{heavy} , and we can be reasonably confident that F will have the same sign as that calculated from the location of the heavy atom. This phase can then be combined with the observed $|F|$ (from the reflection intensity) to perform a Fourier synthesis of the full electron density in the unit cell, and hence to locate the light atoms as well as the heavy atoms.

Modern structural analyses make extensive use of **direct methods**. Direct methods are based on the possibility of treating the atoms in a unit cell as being virtually randomly distributed (from the radiation's point of view), and then using statistical techniques to compute the probabilities that the phases have a particular value. It is possible to deduce relations between some structure factors and sums (and sums of squares) of others, which have the effect of constraining the phases to particular values (with high probability, so long as the structure factors are large). For example, the **Sayre probability relation** has the form

$$\text{sign of } F_{h+h', k+k', l+l'} \text{ is probably equal to } (\text{sign of } F_{hkl}) \times (\text{sign of } F_{h'k'l'}) \quad (20.11)$$

For example, if F_{122} and F_{232} are both large and negative, then it is highly likely that F_{354} , provided it is large, will be positive.

(f) Structure refinement

In the final stages of the determination of a crystal structure, the parameters describing the structure (atom positions, for instance) are adjusted systematically to give the best fit between the observed intensities and those calculated from the model of the structure deduced from the diffraction pattern. This process is called **structure refinement**. Not only does the procedure give accurate positions for all the atoms in the unit cell, but it also gives an estimate of the errors in those positions and in the bond lengths and angles derived from them. The procedure also provides information on the vibrational amplitudes of the atoms.

IMPACT ON BIOCHEMISTRY

I20.1 X-ray crystallography of biological macromolecules

X-ray crystallography is the deployment of X-ray diffraction techniques for the determination of the location of all the atoms in molecules as complicated as biopolymers. Bragg's law helps us understand the features of one of the most seminal X-ray images of all time, the characteristic X-shaped pattern obtained by Rosalind Franklin and Maurice Wilkins from strands of DNA and used by James Watson and Francis Crick in their construction of the double-helix model of DNA (Fig. 20.26). To interpret this image by using the Bragg law we have to be aware that it was obtained by using a fibre consisting of many DNA molecules oriented with their axes parallel to the axis of the fibre, with X-rays incident from a perpendicular direction. All the molecules in the fibre are parallel (or nearly so), but are randomly distributed in the perpendicular directions; as a result, the diffraction pattern exhibits the periodic structure parallel to the fibre axis superimposed on a general background of scattering from the distribution of molecules in the perpendicular directions.

There are two principal features in Fig. 20.26: the strong 'meridional' scattering upward and downward by the fibre and the X-shaped distribution at smaller scattering angles. Because scattering through large angles occurs for closely spaced features (from $\lambda = 2d \sin \theta$, if d is small, then θ must be large to preserve the equality), we can infer that the meridional scattering arises from closely spaced components and that the inner X-shaped pattern arises from features with a longer periodicity. Because the meridional pattern occurs at a distance of about 10 times that of the innermost spots of the X-pattern, the large-scale structure is about 10 times bigger than the small-scale structure. From the geometry of the instrument, the wavelength of the radiation, and Bragg's law, we can infer that the periodicity of the small-scale feature is 340 pm whereas that of the large-scale feature is 3400 pm (that is, 3.4 nm).

To see that the cross is characteristic of a helix, look at Fig. 20.27. Each turn of the helix defines two planes, one orientated at an angle α to the horizontal and the other at $-\alpha$. As a result, to a first approximation, a helix can be thought of as consisting of an array of planes at an angle α together with an array of planes at an angle $-\alpha$ with a separation within each set determined by the pitch of the helix. Thus, a DNA molecule is like two arrays of planes, each set corresponding to those treated in the derivation of Bragg's law, with a perpendicular separation $d = p \cos \alpha$, where p is the pitch of the helix, each canted at the angles $\pm\alpha$ to the horizontal. The diffraction spots from one set of planes therefore occur at an angle α to the vertical, giving one leg of the X, and those of the other set occur at an angle $-\alpha$, giving rise to the other leg of the X. The

Fig. 20.26 The X-ray diffraction pattern obtained from a fibre of B-DNA. The black dots are the reflections, the points of maximum constructive interference, that are used to determine the structure of the molecule. (Adapted from an illustration that appears in J.P. Glusker and K.N. Trueblood, *Crystal structure analysis: A primer*. Oxford University Press (1972).)

Fig. 20.27 The origin of the X pattern characteristic of diffraction by a helix. (a) A helix can be thought of as consisting of an array of planes at an angle α together with an array of planes at an angle $-\alpha$. (b) The diffraction spots from one set of planes appear at an angle α to the vertical, giving one leg of the X, and those of the other set appear at an angle $-\alpha$, giving rise to the other leg of the X. The lower half of the X appears because the helix has up-down symmetry in this arrangement. (c) The sequence of spots outward along a leg of the X corresponds to first-, second-, ... order diffraction ($n = 1, 2, \dots$).

Fig. 20.28 The effect of the internal structure of the helix on the X-ray diffraction pattern. (a) The residues of the macromolecule are represented by points. (b) Parallel planes passing through the residues are perpendicular to the axis of the molecule. (c) The planes give rise to strong diffraction with an angle that allows us to determine the layer spacing h from $\lambda = 2h \sin \theta$.

experimental arrangement has up–down symmetry, so the diffraction pattern repeats to produce the lower half of the X. The sequence of spots outward along a leg corresponds to first-, second-, . . . order diffraction ($n = 1, 2, \dots$ in eqn 20.4). Therefore from the X-ray pattern, we see at once that the molecule is helical and we can measure the angle α directly, and find $\alpha = 40^\circ$. Finally, with the angle α and the pitch p determined, we can determine the radius r of the helix from $\tan \alpha = p/4r$, from which it follows that $r = (3.4 \text{ nm})/(4 \tan 40^\circ) = 1.0 \text{ nm}$.

To derive the relation between the helix and the cross-like pattern we have ignored the detailed structure of the helix, the fact that it is a periodic array of nucleotide bases, not a smooth wire. In Fig. 20.28 we represent the bases by points, and see that there is an additional periodicity of separation h , forming planes that are perpendicular to the axis to the molecule (and the fibre). These planes give rise to the strong meridional diffraction with an angle that allows us to determine the layer spacing from Bragg's law in the form $\lambda = 2h \sin \theta$ as $h = 340 \text{ pm}$.

The success of modern biochemistry in explaining such processes as DNA replication, protein biosynthesis, and enzyme catalysis is a direct result of developments in preparatory, instrumental, and computational procedures that have led to the determination of large numbers of structures of biological macromolecules by techniques based on X-ray diffraction. Most work is now done not on fibres but on crystals, in which the large molecules lie in orderly ranks. A technique that works well for charged proteins consists of adding large amounts of a salt, such as $(\text{NH}_4)_2\text{SO}_4$, to a buffer solution containing the biopolymer. The increase in the ionic strength of the solution decreases the solubility of the protein to such an extent that the protein precipitates, sometimes as crystals that are amenable to analysis by X-ray diffraction. Other common strategies for inducing crystallization involve the gradual removal of solvent from a biopolymer solution, either by *dialysis* (Impact I5.2) or *vapour diffusion*. In one implementation of the vapour diffusion method, a single drop of biopolymer solution hangs above an aqueous solution (the reservoir), as shown in Fig. 20.29. If the reservoir solution is more concentrated in a non-volatile solute (for example, a salt) than is the biopolymer solution, then solvent will evaporate slowly from the drop until the vapour pressure of water in the closed container reaches a constant, equilibrium value. At the same time, the concentration of biopolymer in the drop increases gradually until crystals begin to form.

Special techniques are used to crystallize hydrophobic proteins, such as those spanning the bilayer of a cell membrane. In such cases, surfactant molecules, which like phospholipids contain polar head groups and hydrophobic tails, are used to encase the protein molecules and make them soluble in aqueous buffer solutions. Dialysis or vapour diffusion may then be used to induce crystallization.

After suitable crystals are obtained, X-ray diffraction data are collected and analysed as described in the previous sections. The three-dimensional structures of a very

Fig. 20.29 In a common implementation of the vapour diffusion method of biopolymer crystallization, a single drop of biopolymer solution hangs above a reservoir solution that is very concentrated in a non-volatile solute. Solvent evaporates from the more dilute drop until the vapour pressure of water in the closed container reaches a constant equilibrium value. In the course of evaporation (denoted by the downward arrows), the biopolymer solution becomes more concentrated and, at some point, crystals may form.

Fig. 20.30 Light-induced isomerization of a protein-bound phenolate ion in the photoactive yellow protein of the bacterium *Ectothiorhodospira halophila*.

large number of biological polymers have been determined in this way. However, the techniques discussed so far give only static pictures and are not useful in studies of dynamics and reactivity. This limitation stems from the fact that the Bragg rotation method requires stable crystals that do not change structure during the lengthy data acquisition times required. However, special time-resolved X-ray diffraction techniques have become available in recent years and it is now possible to make exquisitely detailed measurements of atomic motions during chemical and biochemical reactions.

Time-resolved X-ray diffraction techniques make use of synchrotron sources, which can emit intense polychromatic pulses of X-ray radiation with pulse widths varying from 100 ps to 200 ps ($1 \text{ ps} = 10^{-12} \text{ s}$). Instead of the Bragg method, the Laue method is used because many reflections can be collected simultaneously, rotation of the sample is not required, and data acquisition times are short. However, good diffraction data cannot be obtained from a single X-ray pulse and reflections from several pulses must be averaged together. In practice, this averaging dictates the time resolution of the experiment, which is commonly tens of microseconds or less.

An example of the power of time-resolved X-ray crystallography is the elucidation of structural changes that accompany the activation by light of the photoactive yellow protein of the bacterium *Ectothiorhodospira halophila*. Within 1 ns after absorption of a photon of 446 nm light, a protein-bound phenolate ion undergoes *trans*–*cis* isomerization to form the intermediate shown in Fig. 20.30. A series of rearrangements then follows, which includes the ejection of the ion from its binding site deep in the protein, its return to the site, and re-formation of the *cis* conformation. The physiological outcome of this cycle is a *negative phototactic response*, or movement of the organism away from light. Time-resolved X-ray diffraction studies in the nanosecond to millisecond ranges identified a number of structural changes that follow electronic excitation of the phenolate ion with a laser pulse: isomerization, ejection, protonation of the exposed ion, and a number of amino acid motions.

20.4 Neutron and electron diffraction

According to the de Broglie relation (eqn 8.12, $\lambda = h/p$), particles have wavelengths and may therefore undergo diffraction. Neutrons generated in a nuclear reactor and then slowed to thermal velocities have wavelengths similar to those of X-rays and may also be used for diffraction studies. For instance, a neutron generated in a reactor and slowed to thermal velocities by repeated collisions with a moderator (such as graphite) until it is travelling at about 4 km s^{-1} has a wavelength of about 100 pm. In practice, a range of wavelengths occurs in a neutron beam, but a monochromatic beam can be selected by diffraction from a crystal, such as a single crystal of germanium.

Example 20.5 Calculating the typical wavelength of thermal neutrons

Calculate the typical wavelength of neutrons that have reached thermal equilibrium with their surroundings at 373 K.

Method We need to relate the wavelength to the temperature. There are two linking steps. First, the de Broglie relation expresses the wavelength in terms of the linear momentum. Then the linear momentum can be expressed in terms of the kinetic energy, the mean value of which is given in terms of the temperature by the equipartition theorem (see Section 17.3).

Answer From the equipartition principle, we know that the mean translational kinetic energy of a neutron at a temperature T travelling in the x -direction is $E_K = \frac{1}{2}kT$. The kinetic energy is also equal to $p^2/2m$, where p is the momentum of the neutron and m is its mass. Hence, $p = (mkT)^{1/2}$. It follows from the de Broglie relation $\lambda = h/p$ that the neutron's wavelength is

$$\lambda = \frac{h}{(mkT)^{1/2}}$$

Therefore, at 373 K,

$$\begin{aligned}\lambda &= \frac{6.626 \times 10^{-34} \text{ J s}}{\{(1.675 \times 10^{-27} \text{ kg}) \times (1.381 \times 10^{-23} \text{ J K}^{-1}) \times (373 \text{ K})\}^{1/2}} \\ &= \frac{6.626 \times 10^{-34} \text{ J s}}{(1.675 \times 1.381 \times 373 \times 10^{-50})^{1/2} (\text{kg}^2 \text{ m}^2 \text{ s}^{-2})^{1/2}} \\ &= 2.26 \times 10^{-10} \text{ m} = 226 \text{ pm}\end{aligned}$$

where we have used $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$.

Self-test 20.6 Calculate the temperature needed for the average wavelength of the neutrons to be 100 pm. [$1.90 \times 10^3 \text{ K}$]

Fig. 20.31 If the spins of atoms at lattice points are orderly, as in this material, where the spins of one set of atoms are aligned antiparallel to those of the other set, neutron diffraction detects two interpenetrating simple cubic lattices on account of the magnetic interaction of the neutron with the atoms, but X-ray diffraction would see only a single bcc lattice.

Neutron diffraction differs from X-ray diffraction in two main respects. First, the scattering of neutrons is a nuclear phenomenon. Neutrons pass through the extra-nuclear electrons of atoms and interact with the nuclei through the ‘strong force’ that is responsible for binding nucleons together. As a result, the intensity with which neutrons are scattered is independent of the number of electrons and neighbouring elements in the periodic table may scatter neutrons with markedly different intensities. Neutron diffraction can be used to distinguish atoms of elements such as Ni and Co that are present in the same compound and to study order–disorder phase transitions in FeCo. A second difference is that neutrons possess a magnetic moment due to their spin. This magnetic moment can couple to the magnetic fields of atoms or ions in a crystal (if the ions have unpaired electrons) and modify the diffraction pattern. One consequence is that neutron diffraction is well suited to the investigation of magnetically ordered lattices in which neighbouring atoms may be of the same element but have different orientations of their electronic spin (Fig. 20.31).

Electrons accelerated through a potential difference of 40 kV have wavelengths of about 6 pm, and so are also suitable for diffraction studies. However, their main application is to the study of surfaces, and we postpone their discussion until Chapter 25.

Crystal structure

The bonding within a solid may be of various kinds. Simplest of all (in principle) are elemental metals, where electrons are delocalized over arrays of identical cations and bind them together into a rigid but ductile and malleable whole.

20.5 Metallic solids

Most metallic elements crystallize in one of three simple forms, two of which can be explained in terms of hard spheres packing together in the closest possible arrangement.

(a) Close packing

Figure 20.32 shows a **close-packed** layer of identical spheres, one with maximum utilization of space. A close-packed three-dimensional structure is obtained by stacking such close-packed layers on top of one another. However, this stacking can be done in different ways, which result in close-packed **polytypes**, or structures that are identical in two dimensions (the close-packed layers) but differ in the third dimension.

In all polytypes, the spheres of second close-packed layer lie in the depressions of the first layer (Fig. 20.33). The third layer may be added in either of two ways. In one, the spheres are placed so that they reproduce the first layer (Fig. 20.34a), to give an ABA pattern of layers. Alternatively, the spheres may be placed over the gaps in the first layer (Fig. 20.34b), so giving an ABC pattern. Two polytypes are formed if the two stacking patterns are repeated in the vertical direction. If the ABA pattern is repeated, to give the sequence of layers ABABAB . . . , the spheres are **hexagonally close-packed**

Fig. 20.32 The first layer of close-packed spheres used to build a three-dimensional close-packed structure.

Fig. 20.33 The second layer of close-packed spheres occupies the dips of the first layer. The two layers are the AB component of the close-packed structure.

(a)

(b)

Fig. 20.34 (a) The third layer of close-packed spheres might occupy the dips lying directly above the spheres in the first layer, resulting in an ABA structure, which corresponds to hexagonal close-packing. (b) Alternatively, the third layer might lie in the dips that are not above the spheres in the first layer, resulting in an ABC structure, which corresponds to cubic close-packing

Fig. 20.35 A fragment of the structure shown in Fig. 20.34 revealing the (a) hexagonal (b) cubic symmetry. The tints on the spheres are the same as for the layers in Fig. 20.34.

Fig. 20.36 The calculation of the packing fraction of an ccp unit cell.

Table 20.2 The crystal structures of some elements

Structure	Element
hcp*	Be, Cd, Co, He, Mg, Sc, Ti, Zn
fcc* (ccp, cubic F)	Ag, Al, Ar, Au, Ca, Cu, Kr, Ne, Ni, Pd, Pb, Pt, Rh, Rn, Sr, Xe
bcc (cubic I)	Ba, Cs, Cr, Fe, K, Li, Mn, Mo, Rb, Na, Ta, W, V
cubic P	Po

* Close-packed structures.

(hcp). Alternatively, if the ABC pattern is repeated, to give the sequence ABCABC . . . , the spheres are **cubic close-packed** (ccp). We can see the origins of these names by referring to Fig. 20.35. The ccp structure gives rise to a face-centred unit cell, so may also be denoted cubic F (or fcc, for face-centred cubic).² It is also possible to have random sequences of layers; however, the hcp and ccp polytypes are the most important. Table 20.2 lists some elements possessing these structures.

The compactness of close-packed structures is indicated by their **coordination number**, the number of atoms immediately surrounding any selected atom, which is 12 in all cases. Another measure of their compactness is the **packing fraction**, the fraction of space occupied by the spheres, which is 0.740 (see the following *Justification*). That is, in a close-packed solid of identical hard spheres, only 26.0 per cent of the volume is empty space. The fact that many metals are close-packed accounts for their high densities.

Justification 20.3 The packing fraction

To calculate a packing fraction of a ccp structure, we first calculate the volume of a unit cell, and then calculate the total volume of the spheres that fully or partially occupy it. The first part of the calculation is a straightforward exercise in geometry. The second part involves counting the fraction of spheres that occupy the cell.

Refer to Fig. 20.36. Because a diagonal of any face passes completely through one sphere and halfway through two other spheres, its length is $4R$. The length of a side is therefore $8^{1/2}R$ and the volume of the unit cell is $8^{3/2}R^3$. Because each cell contains the equivalent of $6 \times \frac{1}{2} + 8 \times \frac{1}{8} = 4$ spheres, and the volume of each sphere is $\frac{4}{3}\pi R^3$, the total occupied volume is $\frac{16}{3}\pi R^3$. The fraction of space occupied is therefore $\frac{16}{3}\pi R^3 / 8^{3/2}R^3 = \frac{16}{3}\pi / 8^{3/2}$, or 0.740. Because an hcp structure has the same coordination number, its packing fraction is the same. The packing fractions of structures that are not close-packed are calculated similarly (see Exercises 20.14 and 20.17 and Problem 20.24).

(b) Less closely packed structures

As shown in Table 20.2, a number of common metals adopt structures that are less than close-packed. The departure from close packing suggests that factors such as specific covalent bonding between neighbouring atoms are beginning to influence the structure and impose a specific geometrical arrangement. One such arrangement results in a cubic I (bcc, for body-centred cubic) structure, with one sphere at the centre of a cube formed by eight others. The coordination number of a bcc structure is

² Strictly speaking, ccp refers to a close-packed arrangement whereas fcc refers to the lattice type of the common representation of ccp. However, this distinction is rarely made.

only 8, but there are six more atoms not much further away than the eight nearest neighbours. The packing fraction of 0.68 is not much smaller than the value for a close-packed structure (0.74), and shows that about two-thirds of the available space is actually occupied.

20.6 Ionic solids

Two questions arise when we consider ionic solids: the relative locations adopted by the ions and the energetics of the resulting structure.

(a) Structure

When crystals of compounds of monatomic ions (such as NaCl and MgO) are modelled by stacks of hard spheres it is essential to allow for the different ionic radii (typically with the cations smaller than the anions) and different charges. The **coordination number** of an ion is the number of nearest neighbours of opposite charge; the structure itself is characterized as having (n_+, n_-) **coordination**, where n_+ is the coordination number of the cation and n_- that of the anion.

Even if, by chance, the ions have the same size, the problems of ensuring that the unit cells are electrically neutral makes it impossible to achieve 12-coordinate close-packed ionic structures. As a result, ionic solids are generally less dense than metals. The best packing that can be achieved is the (8,8)-coordinate **caesium-chloride structure** in which each cation is surrounded by eight anions and each anion is surrounded by eight cations (Fig. 20.37). In this structure, an ion of one charge occupies the centre of a cubic unit cell with eight counter ions at its corners. The structure is adopted by CsCl itself and also by CsI, CsCN (with some distortion), and CuZn.

When the radii of the ions differ more than in CsCl, even eight-coordinate packing cannot be achieved. One common structure adopted is the (6,6)-coordinate **rock-salt structure** typified by NaCl (Fig. 20.38). In this structure, each cation is surrounded by six anions and each anion is surrounded by six cations. The rock-salt structure can be pictured as consisting of two interpenetrating slightly expanded cubic F (fcc) arrays, one composed of cations and the other of anions. This structure is adopted by NaCl itself and also by several other MX compounds, including KBr, AgCl, MgO, and ScN.

The switch from the caesium-chloride structure to the rock-salt structure is related to the value of the **radius ratio**, γ :

$$\gamma = \frac{r_{\text{smaller}}}{r_{\text{larger}}} \quad [20.12]$$

The two radii are those of the larger and smaller ions in the crystal. The **radius-ratio rule** states that the caesium-chloride structure should be expected when $\gamma > 3^{1/2} - 1 = 0.732$ and that the rock-salt structure should be expected when $2^{1/2} - 1 = 0.414 < \gamma < 0.732$. For $\gamma < 0.414$, the most efficient packing leads to four-coordination of the type exhibited by the sphalerite (or zinc blende) form of ZnS (Fig. 20.39). The rule is derived by considering the geometrical problem of packing the maximum number of hard spheres of one radius around a hard sphere of a different radius. The deviation of a structure from that expected on the basis of the radius-ratio rule is often taken to be an indication of a shift from ionic towards covalent bonding; however, a major source of unreliability is the arbitrariness of ionic radii and their variation with coordination number.

Ionic radii are derived from the distance between centres of adjacent ions in a crystal. However, we need to apportion the total distance between the two ions by defining the radius of one ion and then inferring the radius of the other ion. One scale that is widely used is based on the value 140 pm for the radius of the O^{2-} ion (Table 20.3).

Fig. 20.37 The caesium-chloride structure consists of two interpenetrating simple cubic arrays of ions, one of cations and the other of anions, so that each cube of ions of one kind has a counter-ion at its centre.

Fig. 20.38 The rock-salt (NaCl) structure consists of two mutually interpenetrating slightly expanded face-centred cubic arrays of ions. The entire assembly shown here is the unit cell.

Fig. 20.39 The structure of the sphalerite form of ZnS showing the location of the Zn atoms in the tetrahedral holes formed by the array of S atoms. (There is an S atom at the centre of the cube inside the tetrahedron of Zn atoms.)

† Coordination number.

**Fig. 20.40** A line of alternating cations and anions used in the calculation of the Madelung constant in one dimension.

Other scales are also available (such as one based on F^- for discussing halides), and it is essential not to mix values from different scales. Because ionic radii are so arbitrary, predictions based on them must be viewed cautiously.

(b) Energetics

The **lattice energy** of a solid is the difference in potential energy of the ions packed together in a solid and widely separated as a gas. The lattice energy is always positive; a high lattice energy indicates that the ions interact strongly with one another to give a tightly bonded solid. The **lattice enthalpy**, ΔH_L , is the change in standard molar enthalpy for the process

and its equivalent for other charge types and stoichiometries. The lattice enthalpy is equal to the lattice energy at $T = 0$; at normal temperatures they differ by only a few kilojoules per mole, and the difference is normally neglected.

Each ion in a solid experiences electrostatic attractions from all the other oppositely charged ions and repulsions from all the other like-charged ions. The total Coulombic potential energy is the sum of all the electrostatic contributions. Each cation is surrounded by anions, and there is a large negative contribution from the attraction of the opposite charges. Beyond those nearest neighbours, there are cations that contribute a positive term to the total potential energy of the central cation. There is also a negative contribution from the anions beyond those cations, a positive contribution from the cations beyond them, and so on to the edge of the solid. These repulsions and attractions become progressively weaker as the distance from the central ion increases, but the net outcome of all these contributions is a lowering of energy.

First, consider a simple one-dimensional model of a solid consisting of a long line of uniformly spaced alternating cations and anions, with d the distance between their centres, the sum of the ionic radii (Fig. 20.40). If the charge numbers of the ions have the same absolute value ($+1$ and -1 , or $+2$ and -2 , for instance), then $z_1 = +z$, $z_2 = -z$, and $z_1 z_2 = -z^2$. The potential energy of the central ion is calculated by summing all the terms, with negative terms representing attractions to oppositely charged ions and positive terms representing repulsions from like-charged ions. For the interaction with ions extending in a line to the right of the central ion, the lattice energy is

$$\begin{aligned} E_p &= \frac{1}{4\pi\epsilon_0} \times \left(-\frac{z^2 e^2}{d} + \frac{z^2 e^2}{2d} - \frac{z^2 e^2}{3d} + \frac{z^2 e^2}{4d} - \dots \right) \\ &= -\frac{z^2 e^2}{4\pi\epsilon_0 d} \left(1 - \frac{1}{2} + \frac{1}{3} - \frac{1}{4} + \dots \right) \\ &= -\frac{z^2 e^2}{4\pi\epsilon_0 d} \times \ln 2 \end{aligned}$$

We have used the relation $1 - \frac{1}{2} + \frac{1}{3} - \frac{1}{4} + \dots = \ln 2$. Finally, we multiply E_p by 2 to obtain the total energy arising from interactions on each side of the ion and then multiply by Avogadro's constant, N_A , to obtain an expression for the lattice energy per mole of ions. The outcome is

$$E_p = -2 \ln 2 \times \frac{z^2 N_A e^2}{4\pi\epsilon_0 d}$$

with $d = r_{\text{cation}} + r_{\text{anion}}$. This energy is negative, corresponding to a net attraction. The calculation we have just performed can be extended to three-dimensional arrays of ions with different charges:

$$E_p = -A \times \frac{|z_1 z_2| N_A e^2}{4\pi\epsilon_0 d} \quad (20.13)$$

The factor A is a positive numerical constant called the **Madelung constant**; its value depends on how the ions are arranged about one another. For ions arranged in the same way as in sodium chloride, $A = 1.748$. Table 20.4 lists Madelung constants for other common structures.

There are also repulsions arising from the overlap of the atomic orbitals of the ions and the role of the Pauli principle. These repulsions are taken into account by supposing that, because wavefunctions decay exponentially with distance at large distances from the nucleus, and repulsive interactions depend on the overlap of orbitals, the repulsive contribution to the potential energy has the form

$$E_p^* = N_A C' e^{-d/d^*} \quad (20.14)$$

with C' and d^* constants; the latter is commonly taken to be 34.5 pm. The total potential energy is the sum of E_p and E_p^* , and passes through a minimum when $d(E_p + E_p^*)/dd = 0$ (Fig. 20.41). A short calculation leads to the following expression for the minimum total potential energy (see Exercise 20.21a):

$$E_{p,\min} = -\frac{N_A |z_A z_B| e^2}{4\pi\epsilon_0 d} \left(1 - \frac{d^*}{d} \right) A \quad (20.15)$$

This expression is called the **Born–Mayer equation**. Provided we ignore zero-point contributions to the energy, we can identify the negative of this potential energy with the lattice energy. We see that large lattice energies are expected when the ions are highly charged (so $|z_A z_B|$ is large) and small (so d is small).

Experimental values of the lattice enthalpy (the enthalpy, rather than the energy) are obtained by using a **Born–Haber cycle**, a closed path of transformations starting and ending at the same point, one step of which is the formation of the solid compound from a gas of widely separated ions. A typical cycle, for potassium chloride, is shown in Fig. 20.42. It consists of the following steps (for convenience, starting at the elements):

	$\Delta H/(\text{kJ mol}^{-1})$	
1. Sublimation of K(s)	+89	[dissociation enthalpy of K(s)]
2. Dissociation of $\frac{1}{2} \text{Cl}_2(\text{g})$	+122	$[\frac{1}{2} \times \text{dissociation enthalpy of Cl}_2(\text{g})]$
3. Ionization of K(g)	+418	[ionization enthalpy of K(g)]
4. Electron attachment to Cl(g)	−349	[electron gain enthalpy of Cl(g)]
5. Formation of solid from gas	$-\Delta H_L/(\text{kJ mol}^{-1})$	
6. Decomposition of compound	+437	[negative of enthalpy of formation of KCl(s)]

Because the sum of these enthalpy changes is equal to zero, we can infer from

$$89 + 122 + 418 - 349 - \Delta H_L/(\text{kJ mol}^{-1}) + 437 = 0$$

that $\Delta H_L = +717 \text{ kJ mol}^{-1}$. Some lattice enthalpies obtained in this way are listed in Table 20.5. As can be seen from the data, the trends in values are in general accord with the predictions of the Born–Mayer equation. Agreement is typically taken to imply that the ionic model of bonding is valid for the substance; disagreement implies that there is a covalent contribution to the bonding.

Comment 20.4

Allotropes are distinct forms of an element that differ in the way that atoms are linked. For example, oxygen has two allotropes: O_2 and O_3 (ozone).

Fig. 20.43 A fragment of the structure of diamond. Each C atom is tetrahedrally bonded to four neighbours. This framework-like structure results in a rigid crystal.

Fig. 20.45 In a single-walled nanotube (SWNT), sp^2 -hybridized carbon atoms form hexagonal rings that grow as tubes with diameters between 1 and 2 nm and lengths of several micrometres.

20.7 Molecular solids and covalent networks

X-ray diffraction studies of solids reveal a huge amount of information, including interatomic distances, bond angles, stereochemistry, and vibrational parameters. In this section we can do no more than hint at the diversity of types of solids found when molecules pack together or atoms link together in extended networks.

In **covalent network solids**, covalent bonds in a definite spatial orientation link the atoms in a network extending through the crystal. The demands of directional bonding, which have only a small effect on the structures of many metals, now override the geometrical problem of packing spheres together, and elaborate and extensive structures may be formed. Examples include silicon, red phosphorus, boron nitride, and—very importantly—diamond, graphite, and carbon nanotubes, which we discuss in detail.

Diamond and graphite are two allotropes of carbon. In diamond each sp^3 -hybridized carbon is bonded tetrahedrally to its four neighbours (Fig. 20.43). The network of strong C—C bonds is repeated throughout the crystal and, as a result, diamond is the hardest known substance.

In graphite, σ bonds between sp^2 -hybridized carbon atoms form hexagonal rings which, when repeated throughout a plane, give rise to sheets (Fig. 20.44). Because the sheets can slide against each other when impurities are present, graphite is used widely as a lubricant.

Carbon nanotubes are thin cylinders of carbon atoms that are both mechanically strong and highly conducting (see *Impact* I20.2). They are synthesized by condensing a carbon plasma either in the presence or absence of a catalyst. The simplest structural motif is called a *single-walled nanotube* (SWNT) and is shown in Fig. 20.45. In a SWNT, sp^2 -hybridized carbon atoms form hexagonal rings reminiscent of the structure of the carbon sheets found in graphite. The tubes have diameters between 1 and 2 nm and lengths of several micrometres. The features shown in Fig. 20.45 have been confirmed by direct visualization with scanning tunnelling microscopy (*Impact* I9.1). A *multi-walled nanotube* (MWNT) consists of several concentric SWNTs and its diameter varies between 2 and 25 nm.

Molecular solids, which are the subject of the overwhelming majority of modern structural determinations, are held together by van der Waals interactions (Chapter 18). The observed crystal structure is Nature's solution to the problem of condensing objects of various shapes into an aggregate of minimum energy (actually, for $T > 0$, of

Fig. 20.44 Graphite consists of flat planes of hexagons of carbon atoms lying above one another. (a) The arrangement of carbon atoms in a sheet; (b) the relative arrangement of neighbouring sheets. When impurities are present, the planes can slide over one another easily.

Fig. 20.46 A fragment of the crystal structure of ice (ice-I). Each O atom is at the centre of a tetrahedron of four O atoms at a distance of 276 pm. The central O atom is attached by two short O—H bonds to two H atoms and by two long hydrogen bonds to the H atoms of two of the neighbouring molecules. Overall, the structure consists of planes of hexagonal puckered rings of H_2O molecules (like the chair form of cyclohexane).

minimum Gibbs energy). The prediction of the structure is a very difficult task, but software specifically designed to explore interaction energies can now make reasonably reliable predictions. The problem is made more complicated by the role of hydrogen bonds, which in some cases dominate the crystal structure, as in ice (Fig. 20.46), but in others (for example, in phenol) distort a structure that is determined largely by the van der Waals interactions.

The properties of solids

In this section we consider how the bulk properties of solids, particularly their mechanical, electrical, optical, and magnetic properties, stem from the properties of their constituent atoms. The rational fabrication of modern materials depends crucially on an understanding of this link.

20.8 Mechanical properties

The fundamental concepts for the discussion of the mechanical properties of solids are stress and strain. The **stress** on an object is the applied force divided by the area to which it is applied. The **strain** is the resulting distortion of the sample. The general field of the relations between stress and strain is called **rheology**.

Stress may be applied in a number of different ways. Thus, **uniaxial stress** is a simple compression or extension in one direction (Fig. 20.47); **hydrostatic stress** is a stress applied simultaneously in all directions, as in a body immersed in a fluid. A **pure shear** is a stress that tends to push opposite faces of the sample in opposite directions. A sample subjected to a small stress typically undergoes **elastic deformation** in the sense that it recovers its original shape when the stress is removed. For low stresses, the strain is linearly proportional to the stress. The response becomes nonlinear at high stresses but may remain elastic. Above a certain threshold, the strain becomes **plastic** in the sense that recovery does not occur when the stress is removed. Plastic deformation occurs when bond breaking takes place and, in pure metals, typically takes place through the agency of dislocations. Brittle solids, such as ionic solids, exhibit sudden fracture as the stress focused by cracks causes them to spread catastrophically.

The response of a solid to an applied stress is commonly summarized by a number of coefficients of proportionality known as ‘moduli’:

Comment 20.5

The web site contains links to databases of properties of materials, such as metals and polymers.

Fig. 20.47 Types of stress applied to a body. (a) Uniaxial stress, (b) shear stress, (c) hydrostatic pressure.

Fig. 20.48 (a) Normal stress and the resulting strain. (b) Shear stress. Poisson's ratio indicates the extent to which a body changes shape when subjected to a uniaxial stress.

$$\text{Young's modulus: } E = \frac{\text{normal stress}}{\text{normal strain}} \quad [20.16a]$$

$$\text{Bulk modulus: } K = \frac{\text{pressure}}{\text{fractional change in volume}} \quad [20.16b]$$

$$\text{Shear modulus: } G = \frac{\text{shear stress}}{\text{shear strain}} \quad [20.16c]$$

where 'normal stress' refers to stretching and compression of the material, as shown in Fig. 20.48a and 'shear stress' refers to the stress depicted in Fig. 20.48b. The bulk modulus is the inverse of the isothermal compressibility, κ , first encountered in Section 2.11 (eqn 2.44, $\kappa = -(\partial V / \partial p)_T / V$). A third ratio indicates how the sample changes its shape:

$$\text{Poisson's ratio: } \nu_p = \frac{\text{transverse strain}}{\text{normal strain}} \quad [20.17]$$

The moduli are interrelated:

$$G = \frac{E}{2(1 + \nu_p)} \quad K = \frac{E}{3(1 - 2\nu_p)} \quad (20.18)$$

We can use thermodynamic arguments to discover the relation of the moduli to the molecular properties of the solid. Thus, in the *Justification* below, we show that, if neighbouring molecules interact by a Lennard-Jones potential, then the bulk modulus and the compressibility of the solid are related to the Lennard-Jones parameter ϵ (the depth of the potential well) by

$$K = \frac{8N_A \epsilon}{V_m} \quad \kappa = \frac{V_m}{8N_A \epsilon} \quad (20.19)$$

We see that the bulk modulus is large (the solid stiff) if the potential well represented by the Lennard-Jones potential is deep and the solid is dense (its molar volume small).

Justification 20.4 *The relation between compressibility and molecular interactions*

First, we combine the definition of $K = 1/\kappa$, with the thermodynamic relation $p = -(\partial U / \partial V)_T$ (this is eqn 3.45), to obtain

$$K = V \left(\frac{\partial^2 U}{\partial V^2} \right)_T$$

This expression shows that the bulk modulus (and through eqn 20.18, the other two moduli) depends on the curvature of a plot of the internal energy against volume. To develop this conclusion, we note that the variation of internal energy with volume can be expressed in terms of its variation with a lattice parameter, R , such as the length of the side of a unit cell.

$$\frac{\partial U}{\partial V} = \frac{\partial U}{\partial R} \frac{\partial R}{\partial V}$$

and so

$$\frac{\partial^2 U}{\partial V^2} = \frac{\partial U}{\partial R} \frac{\partial^2 R}{\partial V^2} + \frac{\partial^2 U}{\partial V \partial R} \frac{\partial R}{\partial V} = \frac{\partial U}{\partial R} \frac{\partial^2 R}{\partial V^2} + \frac{\partial^2 U}{\partial R^2} \left(\frac{\partial R}{\partial V} \right)^2$$

To calculate K at the equilibrium volume of the sample, we set $R = R_0$ and recognize that $\partial U / \partial R = 0$ at equilibrium, so

$$K = V \left(\frac{\partial^2 U}{\partial R^2} \right)_{T,0} \left(\frac{\partial R}{\partial V} \right)_{T,0}^2$$

where the 0 denotes that the derivatives are evaluated at the equilibrium dimensions of the unit cell by setting $R = R_0$ after the derivative has been calculated. At this point we can write $V = aR^3$, where a is a constant that depends on the crystal structure, which implies that $\partial R / \partial V = 1/(3aR^2)$. Then, if the internal energy is given by a pairwise Lennard-Jones (12,6)-potential, eqn 18.31, we can write

$$\left(\frac{\partial^2 U}{\partial R^2} \right)_{T,0} = \frac{72nN_A \epsilon}{R_0^2} \quad (20.20)$$

where n is the amount of substance in the sample of volume V_0 . It then follows that

$$K = \frac{72nN_A \epsilon}{9aR^3} = \frac{8nN_A \epsilon}{V_0} = \frac{8N_A \epsilon}{V_m}$$

where we have used $V_m = V_0/n$, which is the first of eqn 20.19. Its reciprocal is κ .

Comment 20.6

To obtain the result in eqn 20.20, we have used the fact that, at equilibrium, $R = R_0$ and $\sigma^6/R_0^6 = \frac{1}{2}$, where σ is the scale parameter for the intermolecular potential (r_0 in eqn 18.31).

The typical behaviour of a solid under stress is illustrated in Fig. 20.49. For small strains, the stress–strain relation is a Hooke’s law of force, with the strain directly proportional to the stress. For larger strains, though, dislocations begin to play a major role and the strain becomes plastic in the sense that the sample does not recover its original shape when the stress is removed.

The differing rheological characteristics of metals can be traced to the presence of **slip planes**, which are planes of atoms that under stress may slip or slide relative to one another. The slip planes of a ccp structure are the close-packed planes, and careful inspection of a unit cell shows that there are eight sets of slip planes in different directions. As a result, metals with cubic close-packed structures, like copper, are malleable: they can easily be bent, flattened, or pounded into shape. In contrast, a hexagonal close-packed structure has only one set of slip planes; and metals with hexagonal close packing, like zinc or cadmium, tend to be brittle.

20.9 Electrical properties

We shall confine attention to electronic conductivity, but note that some ionic solids display ionic conductivity. Two types of solid are distinguished by the temperature dependence of their electrical conductivity (Fig. 20.50):

A **metallic conductor** is a substance with a conductivity that decreases as the temperature is raised.

A **semiconductor** is a substance with a conductivity that increases as the temperature is raised.

A semiconductor generally has a lower conductivity than that typical of metals, but the magnitude of the conductivity is not the criterion of the distinction. It is conventional to classify semiconductors with very low electrical conductivities, such as most synthetic polymers, as **insulators**. We shall use this term, but it should be appreciated that it is one of convenience rather than one of fundamental significance. A **superconductor** is a solid that conducts electricity without resistance.

(a) The formation of bands

The central aspect of solids that determines their electrical properties is the distribution of their electrons. There are two models of this distribution. In one, the **nearby**

Fig. 20.49 At small strains, a body obeys Hooke’s law (stress proportional to strain) and is elastic (recovers its shape when the stress is removed). At high strains, the body is no longer elastic, may yield and become plastic. At even higher strains, the solid fails (at its limiting tensile strength) and finally fractures.

Fig. 20.50 The variation of the electrical conductivity of a substance with temperature is the basis of its classification as a metallic conductor, a semiconductor, or a superconductor. We shall see in Chapter 21 that conductivity is expressed in siemens per metre (S m^{-1} or, as here, S cm^{-1}), where $1 \text{ S} = 1 \Omega^{-1}$ (the resistance is expressed in ohms, Ω).

Fig. 20.51 The formation of a band of N molecular orbitals by successive addition of N atoms to a line. Note that the band remains of finite width as N becomes infinite and, although it looks continuous, it consists of N different orbitals.

free-electron approximation, the valence electrons are assumed to be trapped in a box with a periodic potential, with low energy corresponding to the locations of cations. In the **tight-binding approximation**, the valence electrons are assumed to occupy molecular orbitals delocalized throughout the solid. The latter model is more in accord with the discussion in the foregoing chapters, and we confine our attention to it.

We shall consider a one-dimensional solid, which consists of a single, infinitely long line of atoms. At first sight, this model may seem too restrictive and unrealistic. However, not only does it give us the concepts we need to understand conductivity in three-dimensional, macroscopic samples of metals and semiconductors, it is also the starting point for the description of long and thin structures, such as the carbon nanotubes discussed earlier in the chapter.

Suppose that each atom has one s orbital available for forming molecular orbitals. We can construct the LCAO-MOs of the solid by adding N atoms in succession to a line, and then infer the electronic structure using the building-up principle. One atom contributes one s orbital at a certain energy (Fig. 20.51). When a second atom is brought up it overlaps the first and forms bonding and antibonding orbitals. The third atom overlaps its nearest neighbour (and only slightly the next-nearest), and from these three atomic orbitals, three molecular orbitals are formed: one is fully bonding, one fully antibonding, and the intermediate orbital is nonbonding between neighbours. The fourth atom leads to the formation of a fourth molecular orbital. At this stage, we can begin to see that the general effect of bringing up successive atoms is to spread the range of energies covered by the molecular orbitals, and also to fill in the range of energies with more and more orbitals (one more for each atom). When N atoms have been added to the line, there are N molecular orbitals covering a band of energies of finite width, and the Hückel secular determinant (Section 11.6) is

$$\begin{vmatrix} \alpha - E & \beta & 0 & 0 & 0 & \cdots & 0 \\ \beta & \alpha - E & \beta & 0 & 0 & \cdots & 0 \\ 0 & \beta & \alpha - E & \beta & 0 & \cdots & 0 \\ 0 & 0 & \beta & \alpha - E & \beta & \cdots & 0 \\ 0 & 0 & 0 & \beta & \alpha - E & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \cdots & \vdots \\ 0 & 0 & 0 & 0 & 0 & \cdots & \alpha - E \end{vmatrix} = 0$$

where β is now the (s,s) resonance integral. The theory of determinants applied to such a symmetrical example as this (technically a ‘tridiagonal determinant’) leads to the following expression for the roots:

$$E_R = \alpha + 2\beta \cos \frac{k\pi}{N+1} \quad k = 1, 2, \dots, N \quad (20.21)$$

When N is infinitely large, the difference between neighbouring energy levels (the energies corresponding to k and $k+1$) is infinitely small, but, as we show in the following *Justification*, the band still has finite width overall:

$$E_N - E_1 \rightarrow 4\beta \quad \text{as } N \rightarrow \infty \quad (20.22)$$

We can think of this band as consisting of N different molecular orbitals, the lowest-energy orbital ($k=1$) being fully bonding, and the highest-energy orbital ($k=N$) being fully antibonding between adjacent atoms (Fig. 20.52). Similar bands form in three-dimensional solids.

Fig. 20.52 The overlap of s orbitals gives rise to an s band and the overlap of p orbitals gives rise to a p band. In this case, the s and p orbitals of the atoms are so widely spaced that there is a band gap. In many cases the separation is less and the bands overlap.

Justification 20.5 *The width of a band*

The energy of the level with $k = 1$ is

$$E_1 = \alpha + 2\beta \cos \frac{\pi}{N+1}$$

As N becomes infinite, the cosine term becomes $\cos 0 = 1$. Therefore, in this limit

$$E_1 = \alpha + 2\beta$$

When k has its maximum value of N ,

$$E_N = \alpha + 2\beta \cos \frac{N\pi}{N+1}$$

As N approaches infinity, we can ignore the 1 in the denominator, and the cosine term becomes $\cos \pi = -1$. Therefore, in this limit

$$E_N = \alpha - 2\beta$$

The difference between the upper and lower energies of the band is therefore 4β .

The band formed from overlap of s orbitals is called the **s band**. If the atoms have p orbitals available, the same procedure leads to a **p band** (as shown in the upper half of Fig. 20.52). If the atomic p orbitals lie higher in energy than the s orbitals, then the p band lies higher than the s band, and there may be a **band gap**, a range of energies to which no orbital corresponds. However, the s and p bands may also be contiguous or even overlap (as is the case for the $3s$ and $3p$ bands in magnesium).

(b) The occupation of orbitals

Now consider the electronic structure of a solid formed from atoms each able to contribute one electron (for example, the alkali metals). There are N atomic orbitals and therefore N molecular orbitals packed into an apparently continuous band. There are N electrons to accommodate.

At $T = 0$, only the lowest $\frac{1}{2}N$ molecular orbitals are occupied (Fig. 20.53), and the HOMO is called the **Fermi level**. However, unlike in molecules, there are empty orbitals very close in energy to the Fermi level, so it requires hardly any energy to excite the uppermost electrons. Some of the electrons are therefore very mobile and give rise to electrical conductivity.

Fig. 20.53 When N electrons occupy a band of N orbitals, it is only half full and the electrons near the Fermi level (the top of the filled levels) are mobile.

Fig. 20.54 The Fermi–Dirac distribution, which gives the population of the levels at a temperature T . The high-energy tail decays exponentially towards zero. The curves are labelled with the value of μ/kT . The pale green region shows the occupation of levels at $T = 0$.

 **Exploration** Express the population P as a function of the variables $(E - \mu)/\mu$ and μ/kT and then display the set of curves shown in Fig. 20.54 as a single surface.

At temperatures above absolute zero, electrons can be excited by the thermal motion of the atoms. The population, P , of the orbitals is given by the **Fermi–Dirac distribution**, a version of the Boltzmann distribution that takes into account the effect of the Pauli principle:

$$P = \frac{1}{e^{(E-\mu)/kT} + 1} \quad (20.23)$$

The quantity μ is the **chemical potential**, which in this context is the energy of the level for which $P = \frac{1}{2}$ (note that the chemical potential decreases as the temperature increases). The chemical potential in eqn 20.23 has the dimensions of energy, not energy per mole.

The shape of the Fermi–Dirac distribution is shown in Fig. 20.54. For energies well above μ , the 1 in the denominator can be neglected, and then

$$P \approx e^{-(E-\mu)/kT} \quad (20.24)$$

The population now resembles a Boltzmann distribution, decaying exponentially with increasing energy. The higher the temperature, the longer the exponential tail.

The electrical conductivity of a metallic solid decreases with increasing temperature even though more electrons are excited into empty orbitals. This apparent paradox is resolved by noting that the increase in temperature causes more vigorous thermal motion of the atoms, so collisions between the moving electrons and an atom are more likely. That is, the electrons are scattered out of their paths through the solid, and are less efficient at transporting charge.

(c) Insulators and semiconductors

When each atom provides two electrons, the $2N$ electrons fill the N orbitals of the s band. The Fermi level now lies at the top of the band (at $T = 0$), and there is a gap before the next band begins (Fig. 20.55). As the temperature is increased, the tail of the Fermi–Dirac distribution extends across the gap, and electrons leave the lower band, which is called the **valence band**, and populate the empty orbitals of the upper band, which is called the **conduction band**. As a consequence of electron promotion, positively charged ‘holes’ are left in the valence band. The holes and promoted electrons are now mobile, and the solid is an electrical conductor. In fact, it is a semiconductor, because the electrical conductivity depends on the number of electrons that are promoted across the gap, and that number increases as the temperature is raised. If the gap is large, though, very few electrons will be promoted at ordinary temperatures and the conductivity will remain close to zero, resulting in an insulator. Thus, the conventional distinction between an insulator and a semiconductor is related to the size of the band gap and is not an absolute distinction like that between a metal (incomplete bands at $T = 0$) and a semiconductor (full bands at $T = 0$).

Figure 20.55 depicts conduction in an **intrinsic semiconductor**, in which semiconduction is a property of the band structure of the pure material. Examples of intrinsic semiconductors include silicon and germanium. A **compound semiconductor** is an intrinsic semiconductor that is a combination of different elements, such as GaN, CdS, and many d -metal oxides. An **extrinsic semiconductor** is one in which charge carriers are present as a result of the replacement of some atoms (to the extent of about 1 in 10^9) by **dopant** atoms, the atoms of another element. If the dopants can trap electrons, they withdraw electrons from the filled band, leaving holes which allow the remaining electrons to move (Fig. 20.56a). This procedure gives rise to **p-type semiconductivity**, the p indicating that the holes are positive relative to the electrons in the band. An example is silicon doped with indium. We can picture the

Fig. 20.55 (a) When $2N$ electrons are present, the band is full and the material is an insulator at $T = 0$. (b) At temperatures above $T = 0$, electrons populate the levels of the upper *conduction band* and the solid is a semiconductor.

Fig. 20.56 (a) A dopant with fewer electrons than its host can form a narrow band that accepts electrons from the valence band. The holes in the band are mobile and the substance is a p-type semiconductor. (b) A dopant with more electrons than its host forms a narrow band that can supply electrons to the conduction band. The electrons it supplies are mobile and the substance is an n-type semiconductor.

semiconduction as arising from the transfer of an electron from a Si atom to a neighbouring In atom. The electrons at the top of the silicon valence band are now mobile, and carry current through the solid. Alternatively, a dopant might carry excess electrons (for example, phosphorus atoms introduced into germanium), and these additional electrons occupy otherwise empty bands, giving **n-type semiconductivity**, where n denotes the negative charge of the carriers (Fig. 20.56b). The preparation of doped but otherwise ultrapure materials was described in *Impact* I6.2.

Now we consider the properties of a **p–n junction**, the interface of a p-type and n-type semiconductor. Consider the application of a ‘reverse bias’ to the junction, in the sense that a negative electrode is attached to the p-type semiconductor and a positive electrode is attached to the n-type semiconductor (Fig. 20.57a). Under these conditions, the positively charged holes in p-type semiconductor are attracted to the negative electrode and the negatively charged electrons in the n-type semiconductor are attracted to the positive electrode. As a consequence, charge does not flow across the junction. Now consider the application of a ‘forward bias’ to the junction, in the sense that the positive electrode is attached to the p-type semiconductor and the negative electrode is attached to the n-type semiconductor (Fig. 20.57b). Now charge flows across the junction, with electrons in the n-type semiconductor moving toward the positive electrode and holes moving in the opposite direction. It follows that a p–n junction affords a great deal of control over the magnitude and direction of current

Fig. 20.57 A p–n junction under (a) reverse bias, (b) forward bias.

through a material. This control is essential for the operation of transistors and diodes, which are key components of modern electronic devices.

As electrons and holes move across a p–n junction under forward bias, they recombine and release energy. However, as long as the forward bias continues to be applied, the flow of charge from the electrodes to the semiconductors will replenish them with electrons and holes, so the junction will sustain a current. In some solids, the energy of electron–hole recombination is released as heat and the device becomes warm. This is the case for silicon semiconductors, and is one reason why computers need efficient cooling systems.

IMPACT ON NANOSCIENCE

20.2 Nanowires

We have already remarked (*Impacts* I9.1, I9.2, and I19.3) that research on nanometre-sized materials is motivated by the possibility that they will form the basis for cheaper and smaller electronic devices. The synthesis of *nanowires*, nanometre-sized atomic assemblies that conduct electricity, is a major step in the fabrication of nanodevices. An important type of nanowire is based on carbon nanotubes, which, like graphite, can conduct electrons through delocalized π molecular orbitals that form from unhybridized $2p$ orbitals on carbon. Recent studies have shown a correlation between structure and conductivity in single-walled nanotubes (SWNTs) that does not occur in graphite. The SWNT in Fig. 20.45 is a semiconductor. If the hexagons are rotated by 90° about their sixfold axis, the resulting SWNT is a metallic conductor.

Carbon nanotubes are promising building blocks not only because they have useful electrical properties but also because they have unusual mechanical properties. For example, an SWNT has a Young's modulus that is approximately five times larger and a tensile strength that is approximately 375 times larger than that of steel.

Silicon nanowires can be made by focusing a pulsed laser beam on to a solid target composed of silicon and iron. The laser ejects Fe and Si atoms from the surface of the target, forming a vapour that can condense into liquid FeSi_n nanoclusters at sufficiently low temperatures. The phase diagram for this complex mixture shows that solid silicon and liquid FeSi_n coexist at temperatures higher than 1473 K. Hence, it is possible to precipitate solid silicon from the mixture if the experimental conditions are controlled to maintain the FeSi_n nanoclusters in a liquid state that is supersaturated with silicon. It is observed that the silicon precipitate consists of nanowires with diameters of about 10 nm and lengths greater than 1 μm .

Nanowires are also fabricated by *molecular beam epitaxy* (MBE), in which gaseous atoms or molecules are sprayed onto a crystalline surface in an ultra-high vacuum chamber. The result is formation of highly ordered structures. Through careful control of the chamber temperature and of the spraying process, it is possible to deposit thin films on to a surface or to create nanometre-sized assemblies with specific shapes. For example, Fig. 20.58 shows an AFM image of germanium nanowires on a silicon surface. The wires are about 2 nm high, 10–32 nm wide, and 10–600 nm long.

Direct manipulation of atoms on a surface also leads to the formation of nanowires. The Coulomb attraction between an atom and the tip of an STM can be exploited to move atoms along a surface, arranging them into patterns, such as wires.

20.10 Optical properties

In this section, we explore the consequences of interactions between electromagnetic radiation and solids. Our focus will be on the origins of phenomena that inform the design of useful devices, such as lasers and light-emitting diodes.

(a) Light absorption by molecular solids, metallic conductors, and semiconductors

From the discussion in earlier chapters, we are already familiar with the factors that determine the energy and intensity of light absorbed by atoms and molecules in the gas phase and in solution. Now we consider the effects on the electronic absorption spectrum of bringing atoms or molecules together into a solid.

Consider an electronic excitation of a molecule (or an ion) in a crystal. If the excitation corresponds to the removal of an electron from one orbital of a molecule and its elevation to an orbital of higher energy, then the excited state of the molecule can be envisaged as the coexistence of an electron and a hole. This electron–hole pair, the particle-like **exciton**, migrates from molecule to molecule in the crystal (Fig. 20.59). Exciton formation causes spectral lines to shift, split, and change intensity.

The electron and the hole jump together from molecule to molecule as they migrate. A migrating excitation of this kind is called a **Frenkel exciton**. The electron and hole can also be on different molecules, but in each other's vicinity. A migrating excitation of this kind, which is now spread over several molecules (more usually ions), is a **Wannier exciton**.

Frenkel excitons are more common in molecular solids. Their migration implies that there is an interaction between the species that constitute the crystal, for otherwise the excitation on one unit could not move to another. This interaction affects the energy levels of the system. The strength of the interaction governs the rate at which an exciton moves through the crystal: a strong interaction results in fast migration, and a vanishingly small interaction leaves the exciton localized on its original molecule. The specific mechanism of interaction that leads to exciton migration is the interaction between the transition dipole moments of the excitation. Thus, an electric dipole transition in a molecule is accompanied by a shift of charge, and the transient dipole exerts a force on an adjacent molecule. The latter responds by shifting its charge. This process continues and the excitation migrates through the crystal.

The energy shift arising from the interaction between transition dipoles can be understood in terms of their electrostatic interaction. An all-parallel arrangement of the dipoles (Fig. 20.60a) is energetically unfavourable, so the absorption occurs at a higher frequency than in the isolated molecule. Conversely, a head-to-tail alignment of transient dipoles (Fig. 20.60b) is energetically favourable, and the transition occurs at a lower frequency than in the isolated molecules.

Fig. 20.59 The electron–hole pair shown on the left can migrate through a solid lattice as the excitation hops from molecule to molecule. The mobile excitation is called an exciton.

Fig. 20.60 (a) The alignment of transition dipoles (the yellow arrows) is energetically unfavourable, and the exciton absorption is shifted to higher energy (higher frequency). (b) The alignment is energetically favourable for a transition in this orientation, and the exciton band occurs at lower frequency than in the isolated molecules.

Illustration 20.1 Predicting the frequency of exciton absorption in a molecular solid

Recall from Section 18.4 that the potential energy of interaction between two parallel dipoles μ_1 and μ_2 separated by a distance r is $V = \mu_1\mu_2(1 - 3\cos^2\theta)/4\pi\epsilon_0r^3$, where the angle θ is defined in (1). We see that $\theta = 0^\circ$ for a head-to-tail alignment and $\theta = 90^\circ$ for a parallel alignment. It follows that $V < 0$ (an attractive interaction) for $0^\circ \leq \theta < 54.74^\circ$, $V = 0$ when $\theta = 54.74^\circ$ (for then $1 - 3\cos^2\theta = 0$), and $V > 0$ (a repulsive interaction) for $54.74^\circ < \theta \leq 90^\circ$. This result is expected on the basis of qualitative arguments. In a head-to-tail arrangement, the interaction between the region of partial positive charge in one molecule with the region of partial negative charge in the other molecule is attractive. By contrast, in a parallel arrangement, the molecular interaction is repulsive because of the close approach of regions of partial charge with the same sign.

It follows from this discussion that, when $0^\circ \leq \theta < 54.74^\circ$, the frequency of exciton absorption is lower than the corresponding absorption frequency for the isolated molecule (a *red shift* in the spectrum of the solid with respect to that of the isolated

Fig. 20.61 When the transition moments within a unit cell may lie in different relative directions, as depicted in (a) and (b), the energies of the transitions are shifted and give rise to the two bands labelled (a) and (b) in the spectrum. The separation of the bands is the Davydov splitting.

molecule). Conversely, when $54.74^\circ < \theta \leq 90^\circ$, the frequency of exciton absorption is higher than the corresponding absorption frequency for the isolated molecule (a *blue shift* in the spectrum of the solid with respect to that of the isolated molecule). In the special case $\theta = 54.74^\circ$ the solid and the isolated molecule have absorption lines at the same frequency.

If there are N molecules per unit cell, there are N **exciton bands** in the spectrum (if all of them are allowed). The splitting between the bands is the **Davydov splitting**. To understand the origin of the splitting, consider the case $N = 2$ with the molecules arranged as in Fig. 20.61. Let the transition dipoles be along the length of the molecules. The radiation stimulates the collective excitation of the transition dipoles that are in-phase between neighbouring unit cells. *Within* each unit cell the transition dipoles may be arrayed in the two different ways shown in the illustration. Since the two orientations correspond to different interaction energies, with interaction being repulsive in one and attractive in the other, the two transitions appear in the spectrum at two bands of different frequencies. The Davydov splitting is determined by the energy of interaction between the transition dipoles within the unit cell.

Now we turn our attention to metallic conductors and semiconductors. Again we need to consider the consequences of interactions between particles, in this case atoms, which are now so strong that we need to abandon arguments based primarily on van der Waals interactions in favour of a full molecular orbital treatment, the band model of Section 20.9.

Consider Fig. 20.53, which shows bands in an idealized metallic conductor. The absorption of light can excite electrons from the occupied levels to the unoccupied levels. There is a near continuum of unoccupied energy levels above the Fermi level, so we expect to observe absorption over a wide range of frequencies. In metals, the bands are sufficiently wide that radiation from the radiofrequency to the middle of the ultraviolet region of the electromagnetic spectrum is absorbed (metals are transparent to very high-frequency radiation, such as X-rays and γ -rays). Because this range of absorbed frequencies includes the entire visible spectrum, we expect that all metals should appear black. However, we know that metals are shiny (that is, they reflect light) and some are coloured (that is, they absorb light of only certain wavelengths), so we need to extend our model.

To explain the shiny appearance of a smooth metal surface, we need to realize that the absorbed energy can be re-emitted very efficiently as light, with only a small fraction of the energy being released to the surroundings as heat. Because the atoms near the surface of the material absorb most of the radiation, emission also occurs primarily from the surface. In essence, if the sample is excited with visible light, then visible light will be reflected from the surface, accounting for the lustre of the material.

The perceived colour of a metal depends on the frequency range of reflected light which, in turn, depends on the frequency range of light that can be absorbed and, by extension, on the band structure. Silver reflects light with nearly equal efficiency across the visible spectrum because its band structure has many unoccupied energy levels that can be populated by absorption of, and depopulated by emission of, visible light. On the other hand, copper has its characteristic colour because it has relatively fewer unoccupied energy levels that can be excited with violet, blue, and green light. The material reflects at all wavelengths, but more light is emitted at lower frequencies (corresponding to yellow, orange, and red) Similar arguments account for the colours of other metals, such as the yellow of gold.

Finally, consider semiconductors. We have already seen that promotion of electrons from the valence to the conduction band of a semiconductor can be the result of

thermal excitation, if the band gap E_g is comparable to the energy that can be supplied by heating. In some materials, the band gap is very large and electron promotion can occur only by excitation with electromagnetic radiation. However, we see from Fig. 20.55 that there is a frequency $\nu_{\min} = E_g/h$ below which light absorption cannot occur. Above this frequency threshold, a wide range of frequencies can be absorbed by the material, as in a metal.

Illustration 20.2 Predicting the colour of a semiconductor

The semiconductor cadmium sulfide (CdS) has a band gap energy of 2.4 eV (equivalent to 3.8×10^{-19} J). It follows that the minimum electronic absorption frequency is

$$\nu_{\min} = \frac{3.8 \times 10^{-19} \text{ J}}{6.626 \times 10^{-34} \text{ J}} = 5.8 \times 10^{14} \text{ s}^{-1}$$

This frequency, of 5.8×10^{14} Hz, corresponds to a wavelength of 517 nm (green light; see Table 14.1). Lower frequencies, corresponding to yellow, orange, and red, are not absorbed and consequently CdS appears yellow-orange.

Self-test 20.7 Predict the colours of the following materials, given their band-gap energies (in parentheses): GaAs (1.43 eV), HgS (2.1 eV), and ZnS (3.6 eV).
[Black, red, and colourless]

(b) Light emission by solid-state lasers and light-emitting diodes

Here we explore the further consequences of light emission in solids, focusing our attention on ionic crystals and semiconductors used in the design of lasers and light-emitting diodes. In Chapter 14 we discussed the conditions under which a material can become a laser and it would be helpful to review those concepts.

The **neodymium laser** is an example of a four-level laser, in which the laser transition terminates in a state other than the ground state of the laser material (Fig. 20.62). In one form it consists of Nd^{3+} ions at low concentration in yttrium aluminium garnet (YAG, specifically $\text{Y}_3\text{Al}_5\text{O}_{12}$), and is then known as a **Nd–YAG laser**. The population inversion results from pumping a majority of the Nd^{3+} ions into an excited state by using an intense flash from another source, followed by a radiationless transition to another excited state. The pumping flash need not be monochromatic because the upper level actually consists of several states spanning a band of frequencies. A neodymium laser operates at a number of wavelengths in the infrared, the band at 1064 nm being most common. The transition at 1064 nm is very efficient and the laser is capable of substantial power output, either in continuous or pulsed (by Q-switching or mode-locking as discussed in Section 14.5) modes of operation.

The **titanium sapphire laser** consists of Ti^{3+} ions at low concentration in a crystal of sapphire (Al_2O_3). The electronic absorption spectrum of Ti^{3+} ion in sapphire is very similar to that shown in Fig. 14.13, with a broad absorption band centred at around 500 nm that arises from vibronically allowed $d-d$ transitions of the Ti^{3+} ion in an octahedral environment provided by oxygen atoms of the host lattice. As a result, the emission spectrum of Ti^{3+} in sapphire is also broad and laser action occurs over a wide range of wavelengths (Fig. 20.63). Therefore, the titanium sapphire laser is an example of a **vibronic laser**, in which the laser transitions originate from vibronic transitions in the laser medium. The titanium sapphire laser is usually pumped by another laser, such as a Nd–YAG laser or an argon-ion laser (*Further information 14.1*),

Fig. 20.62 The transitions involved in a neodymium laser. The laser action takes place between the ^4F and ^4I excited states.

Fig. 20.63 The transitions involved in a titanium sapphire laser. The laser medium consists of sapphire (Al_2O_3) doped with Ti^{3+} ions. Monochromatic light from a pump laser induces a $^2\text{E} \leftarrow ^2\text{T}_2$ transition in a Ti^{3+} ion that resides in a site with octahedral symmetry. After radiationless vibrational excitation in the ^2E state, laser emission occurs from a very large number of closely spaced vibronic states of the medium. As a result, the titanium sapphire laser emits radiation over a broad spectrum that spans from about 700 nm to about 1000 nm.

and can be operated in either a continuous or pulsed fashion. Mode-locked titanium sapphire lasers produce energetic (20 mJ to 1 J) and very short (20–100 fs, $1 \text{ fs} = 10^{-15} \text{ s}$) pulses. When considered together with broad wavelength tunability (700–1000 nm), these features of the titanium sapphire laser justify its wide use in modern spectroscopy and photochemistry.

The unique electrical properties of p–n junctions between semiconductors can be put to good use in optical devices. In some materials, most notably gallium arsenide, GaAs, energy from electron–hole recombination is released not as heat but is carried away by photons as electrons move across the junction under forward bias. Practical **light-emitting diodes** of this kind are widely used in electronic displays. The wavelength of emitted light depends on the band gap of the semiconductor. Gallium arsenide itself emits infrared light, but the band gap is widened by incorporating phosphorus, and a material of composition approximately $\text{GaAs}_{0.6}\text{P}_{0.4}$ emits light in the red region of the spectrum.

A light-emitting diode is not a laser, because no resonance cavity and stimulated emission are involved. In **diode lasers**, light emission due to electron–hole recombination is employed as the basis of laser action. The population inversion can be sustained by sweeping away the electrons that fall into the holes of the p-type semiconductor, and a resonant cavity can be formed by using the high refractive index of the semiconducting material and cleaving single crystals so that the light is trapped by the abrupt variation of refractive index. One widely used material is $\text{Ga}_{1-x}\text{Al}_x\text{As}$, which produces infrared laser radiation and is widely used in compact-disc (CD) players.

High-power diode lasers are also used to pump other lasers. One example is the pumping of Nd:YAG lasers by $\text{Ga}_{0.91}\text{Al}_{0.09}\text{As}/\text{Ga}_{0.7}\text{Al}_{0.3}\text{As}$ diode lasers. The Nd:YAG laser is often used to pump yet another laser, such as a Ti:sapphire laser. As a result, it is now possible to construct a laser system for steady-state or time-resolved spectroscopy entirely out of solid-state components.

Comment 20.7

The refractive index, n_r , of the medium, the ratio of the speed of light in a vacuum, c , to its speed c' in the medium: $n_r = c/c'$. A beam of light changes direction ('bends') when it passes from a region of one refractive index to a region with a different refractive index. See Appendix 3 for details.

(c) Nonlinear optical phenomena

Nonlinear optical phenomena arise from changes in the optical properties of a material in the presence of an intense electric field from electromagnetic radiation. Here we explore two phenomena that not only can be studied conveniently with intense laser beams but are commonly used in the laboratory to modify the output of lasers for specific experiments, such as those described in Section 14.6.

In **frequency doubling**, or **second harmonic generation**, an intense laser beam is converted to radiation with twice (and in general a multiple) of its initial frequency as it passes through a suitable material. It follows that frequency doubling and tripling of a Nd–YAG laser, which emits radiation at 1064 nm, produce green light at 532 nm and ultraviolet radiation at 355 nm, respectively.

We can account for frequency doubling by examining how a substance responds nonlinearly to incident radiation of frequency $\omega = 2\pi\nu$. Radiation of a particular frequency arises from oscillations of an electric dipole at that frequency and the incident electric field $\mathcal{E}$ induces an electric dipole of magnitude μ , in the substance. At low light intensity, most materials respond linearly, in the sense that $\mu = \alpha\mathcal{E}$, where α is the polarizability (see Section 18.2). To allow for nonlinear response by some materials at high light intensity, we can write

$$\mu = \alpha\mathcal{E} + \frac{1}{2}\beta\mathcal{E}^2 + \dots \quad (20.25)$$

where the coefficient β is the **hyperpolarizability** of the material. The nonlinear term $\beta\mathcal{E}^2$ can be expanded as follows if we suppose that the incident electric field is $\mathcal{E}_0 \cos \omega t$:

$$\beta\mathcal{E}^2 = \beta\mathcal{E}_0^2 \cos^2 \omega t = \frac{1}{2}\beta\mathcal{E}_0^2 (1 + \cos 2\omega t) \quad (20.26)$$

Hence, the nonlinear term contributes an induced electric dipole that oscillates at the frequency 2ω and that can act as a source of radiation of that frequency. Common materials that can be used for frequency doubling in laser systems include crystals of potassium dihydrogenphosphate (KH_2PO_4), lithium niobate (LiNbO_3), and β -barium borate ($\beta\text{-BaB}_2\text{O}_4$).

Another important nonlinear optical phenomenon is the **optical Kerr effect**, which arises from a change in refractive index of a well chosen medium, the **Kerr medium**, when it is exposed to intense laser pulses. Because a beam of light changes direction when it passes from a region of one refractive index to a region with a different refractive index, changes in refractive index result in the self-focusing of an intense laser pulse as it travels through the Kerr medium (Fig. 20.64).

The optical Kerr effect is used as a mechanism of mode-locking lasers (Section 14.5). A Kerr medium is included in the cavity and next to it is a small aperture. The procedure makes use of the fact that the **gain**, the growth in intensity, of a frequency component of the radiation in the cavity is very sensitive to amplification and, once a particular frequency begins to grow, it can quickly dominate. When the power inside the cavity is low, a portion of the photons will be blocked by the aperture, creating a significant loss. A spontaneous fluctuation in intensity—a bunching of photons—may begin to turn on the optical Kerr effect and the changes in the refractive index of the Kerr medium will result in a **Kerr lens**, which is the self-focusing of the laser beam. The bunch of photons can pass through and travel to the far end of the cavity, amplifying as it goes. The Kerr lens immediately disappears (if the medium is well chosen), but is re-created when the intense pulse returns from the mirror at the far end. In this way, that particular bunch of photons may grow to considerable intensity because it alone is stimulating emission in the cavity. Sapphire is an example of a Kerr medium that facilitates the mode locking of titanium sapphire lasers, resulting in very short laser pulses of duration in the femtosecond range.

In addition to being useful laboratory tools, nonlinear optical materials are also finding many applications in the telecommunications industry, which is becoming ever more reliant on optical signals transmitted through optical fibres to carry voice and data. Judicious use of nonlinear phenomena leads to more ways in which the properties of optical signals, and hence the information they carry, can be manipulated.

20.11 Magnetic properties

The magnetic properties of metallic solids and semiconductors depend strongly on the band structures of the material (see *Further reading*). Here we confine our attention largely to magnetic properties that stem from collections of individual molecules or ions such as *d*-metal complexes. Much of the discussion applies to liquid and gas phase samples as well as to solids.

(a) Magnetic susceptibility

The magnetic and electric properties of molecules and solids are analogous. For instance, some molecules possess permanent magnetic dipole moments, and an applied magnetic field can induce a magnetic moment, with the result that the entire solid sample becomes magnetized. The analogue of the electric polarization, P , is the **magnetization**, $\mathcal{M}$, the average molecular magnetic dipole moment multiplied by the number density of molecules in the sample. The magnetization induced by a field of strength H is proportional to H , and we write

$$\mathcal{M} = \chi H \quad [20.27]$$

Fig. 20.64 An illustration of the Kerr effect. An intense laser beam is focused inside a Kerr medium and passes through a small aperture in the laser cavity. This effect may be used to mode-lock a laser, as explained in the text.

where χ is the dimensionless **volume magnetic susceptibility**. A closely related quantity is the **molar magnetic susceptibility**, χ_m :

$$\chi_m = \chi V_m \quad [20.28]$$

where V_m is the molar volume of the substance (we shall soon see why it is sensible to introduce this quantity). The **magnetic flux density**, $\mathcal{B}$, is related to the applied field strength and the magnetization by

$$\mathcal{B} = \mu_0(H + \mathcal{M}) = \mu_0(1 + \chi)H \quad [20.29]$$

where μ_0 is the vacuum permeability, $\mu_0 = 4\pi \times 10^{-7} \text{ J C}^{-2} \text{ m}^{-1} \text{ s}^2$. The magnetic flux density can be thought of as the density of magnetic lines of force permeating the medium. This density is increased if $\mathcal{M}$ adds to H (when $\chi > 0$), but the density is decreased if $\mathcal{M}$ opposes H (when $\chi < 0$). Materials for which χ is positive are called **paramagnetic**. Those for which χ is negative are called **diamagnetic**.

Just as polar molecules in fluid phases contribute a term proportional to $\mu^2/3kT$ to the electric polarization of a medium (eqn 18.15), so molecules with a permanent magnetic dipole moment of magnitude m contribute to the magnetization an amount proportional to $m^2/3kT$. However, unlike for polar molecules, this contribution to the magnetization is obtained even for paramagnetic species trapped in solids, because the direction of the spin of the electrons is typically not coupled to the orientation of the molecular framework and so contributes even when the nuclei are stationary. An applied field can also induce a magnetic moment by stirring up currents in the electron distribution like those responsible for the chemical shift in NMR (Section 15.5). The constant of proportionality between the induced moment and the applied field is called the **magnetizability**, ξ (xi), and the magnetic analogue of eqn 18.15 is

$$\chi = \mathcal{N}\mu_0 \left(\xi + \frac{m^2}{3kT} \right) \quad (20.30)$$

We can now see why it is convenient to introduce χ_m , because the product of the number density $\mathcal{N}$ and the molar volume is Avogadro's constant, N_A :

$$\mathcal{N}V_m = \frac{NV_m}{V} = \frac{nN_A V_m}{nV_m} = N_A \quad (20.31)$$

Hence

$$\chi_m = N_A \mu_0 \left(\xi + \frac{m^2}{3kT} \right) \quad (20.32)$$

and the density dependence of the susceptibility (which occurs in eqn 20.30 via $\mathcal{N} = N_A \rho/M$) has been eliminated. The expression for χ_m is in agreement with the empirical **Curie law**:

$$\chi_m = A + \frac{C}{T} \quad (20.33)$$

with $A = N_A \mu_0 \xi$ and $C = N_A \mu_0 m^2/3k$. As indicated above, and in contrast to electric moments, this expression applies to solids as well as fluid phases.

The magnetic susceptibility is traditionally measured with a **Gouy balance**. This instrument consists of a sensitive balance from which the sample hangs in the form of a narrow cylinder and lies between the poles of a magnet. If the sample is paramagnetic, it is drawn into the field, and its apparent weight is greater than when the field is off. A diamagnetic sample tends to be expelled from the field and appears to weigh less when the field is turned on. The balance is normally calibrated against a sample of

Synoptic table 20.6* Magnetic susceptibilities at 298 K

* More values are given in the Data section.

known susceptibility. The modern version of the determination makes use of a **superconducting quantum interference device** (SQUID, Fig. 20.65). A SQUID takes advantage of the quantization of magnetic flux and the property of current loops in superconductors that, as part of the circuit, include a weakly conducting link through which electrons must tunnel. The current that flows in the loop in a magnetic field depends on the value of the magnetic flux, and a SQUID can be exploited as a very sensitive magnetometer.

Table 20.6 lists some experimental values. A typical paramagnetic volume susceptibility is about 10^{-3} , and a typical diamagnetic volume susceptibility is about $(-)10^{-5}$. The permanent magnetic moment can be extracted from susceptibility measurements by plotting χ against $1/T$.

(b) The permanent magnetic moment

The permanent magnetic moment of a molecule arises from any unpaired electron spins in the molecule. We saw in Section 10.8 that the magnitude of the magnetic moment of an electron is proportional to the magnitude of the spin angular momentum, $\{s(s+1)\}^{1/2}\hbar$.

$$\mu = g_e \{s(s+1)\}^{1/2} \mu_B \quad \mu_B = \frac{e\hbar}{2m_e} \quad (20.34)$$

where $g_e = 2.0023$ (see Section 15.1). If there are several electron spins in each molecule, they combine to a total spin S , and then $s(s+1)$ should be replaced by $S(S+1)$. It follows that the spin contribution to the molar magnetic susceptibility is

$$\chi_m = \frac{N_A g_e^2 \mu_0 \mu_B^2 S(S+1)}{3kT} \quad (20.35)$$

This expression shows that the susceptibility is positive, so the spin magnetic moments contribute to the paramagnetic susceptibilities of materials. The contribution decreases with increasing temperature because the thermal motion randomizes the spin orientations. In practice, a contribution to the paramagnetism also arises from the orbital angular momenta of electrons: we have discussed the spin-only contribution.

Fig. 20.65 The arrangement used to magnetic susceptibility with a SQUID. The sample is moved upwards in small increments and the potential difference across the SQUID is measured.

Illustration 20.3 Calculating a magnetic susceptibility

Consider a complex salt with three unpaired electrons per complex cation at 298 K, of mass density 3.24 g cm^{-3} , and molar mass 200 g mol^{-1} . First note that

$$\frac{N_A g_e^2 \mu_0 \mu_B^2}{3k} = 6.3001 \times 10^{-6} \text{ m}^3 \text{ K}^{-1} \text{ mol}^{-1}$$

Fig. 20.66 (a) In a paramagnetic material, the electron spins are aligned at random in the absence of an applied magnetic field. (b) In a ferromagnetic material, the electron spins are locked into a parallel alignment over large domains. (c) In an antiferromagnetic material, the electron spins are locked into an antiparallel arrangement. The latter two arrangements survive even in the absence of an applied field.

Consequently,

$$\chi_m = 6.3001 \times 10^{-6} \times \frac{S(S+1)}{T/K} \text{ m}^3 \text{ mol}^{-1}$$

Substitution of the data with $S = \frac{3}{2}$ gives $\chi_m = 7.9 \times 10^{-8} \text{ m}^3 \text{ mol}^{-1}$. Note that the density is not needed at this stage. To obtain the volume magnetic susceptibility, the molar susceptibility is divided by the molar volume $V_m = M/\rho$, where ρ is the mass density. In this illustration, $V_m = 61.7 \text{ cm}^3 \text{ mol}^{-1}$, so $\chi = 1.3 \times 10^{-3}$.

At low temperatures, some paramagnetic solids make a phase transition to a state in which large domains of spins align with parallel orientations. This cooperative alignment gives rise to a very strong magnetization and is called **ferromagnetism** (Fig. 20.66). In other cases, the cooperative effect leads to alternating spin orientations: the spins are locked into a low-magnetization arrangement to give an **antiferromagnetic phase**. The ferromagnetic phase has a nonzero magnetization in the absence of an applied field, but the antiferromagnetic phase has a zero magnetization because the spin magnetic moments cancel. The ferromagnetic transition occurs at the **Curie temperature**, and the antiferromagnetic transition occurs at the **Néel temperature**.

(c) Induced magnetic moments

An applied magnetic field induces the circulation of electronic currents. These currents give rise to a magnetic field that usually opposes the applied field, so the substance is diamagnetic. In a few cases the induced field augments the applied field, and the substance is then paramagnetic.

The great majority of molecules with no unpaired electron spins are diamagnetic. In these cases, the induced electron currents occur within the orbitals of the molecule that are occupied in its ground state. In the few cases in which molecules are paramagnetic despite having no unpaired electrons, the induced electron currents flow in the opposite direction because they can make use of unoccupied orbitals that lie close to the HOMO in energy. This orbital paramagnetism can be distinguished from spin paramagnetism by the fact that it is temperature independent: this is why it is called **temperature-independent paramagnetism** (TIP).

We can summarize these remarks as follows. All molecules have a diamagnetic component to their susceptibility, but it is dominated by spin paramagnetism if the molecules have unpaired electrons. In a few cases (where there are low-lying excited states) TIP is strong enough to make the molecules paramagnetic even though their electrons are paired.

20.12 Superconductors

The resistance to flow of electrical current of a normal metallic conductor decreases smoothly with temperature but never vanishes. However, certain solids known as **superconductors** conduct electricity without resistance below a critical temperature, T_c . Following the discovery in 1911 that mercury is a superconductor below 4.2 K, the boiling point of liquid helium, physicists and chemists made slow but steady progress in the discovery of superconductors with higher values of T_c . Metals, such as tungsten, mercury, and lead, tend to have T_c values below about 10 K. Intermetallic compounds, such as Nb_3X ($\text{X} = \text{Sn}, \text{Al}, \text{or Ge}$), and alloys, such as Nb/Ti and Nb/Zr , have intermediate T_c values ranging between 10 K and 23 K. In 1986, **high-temperature superconductors** (HTSC) were discovered. Several **ceramics**, inorganic powders that have

Fig. 20.67 Structure of the $\text{YBa}_2\text{Cu}_3\text{O}_7$ superconductor. (a) Metal atom positions. (b) The polyhedra show the positions of oxygen atoms and indicate that the metal ions are in square-planar and square-pyramidal coordination environments.

been fused and hardened by heating to a high temperature, containing oxocuprate motifs, Cu_mO_n , are now known with T_c values well above 77 K, the boiling point of the inexpensive refrigerant liquid nitrogen. For example, $\text{HgBa}_2\text{Ca}_2\text{Cu}_2\text{O}_8$ has $T_c = 153$ K.

Superconductors have unique magnetic properties as well. Some superconductors, classed as **Type I**, show abrupt loss of superconductivity when an applied magnetic field exceeds a critical value H_c characteristic of the material. It is observed that the value of H_c depends on temperature and T_c as

$$H_c(T) = H_c(0) \left(1 - \frac{T^2}{T_c^2} \right) \quad (20.36)$$

where $H_c(0)$ is the value of H_c as $T \rightarrow 0$. Type I superconductors are also completely diamagnetic below H_c , meaning that no magnetic field lines penetrate into the material. This complete exclusion of a magnetic field in a material is known as the **Meissner effect**, which can be visualized by the levitation of a superconductor above a magnet. **Type II** superconductors, which include the HTSCs, show a gradual loss of superconductivity and diamagnetism with increasing magnetic field.

There is a degree of periodicity in the elements that exhibit superconductivity. The metals iron, cobalt, nickel, copper, silver, and gold do not display superconductivity, nor do the alkali metals. It is observed that, for simple metals, ferromagnetism and superconductivity never coexist, but in some of the oxocuprate superconductors ferromagnetism and superconductivity can coexist. One of the most widely studied oxocuprate superconductors $\text{YBa}_2\text{Cu}_3\text{O}_7$ (informally known as ‘123’ on account of the proportions of the metal atoms in the compound) has the structure shown in Fig. 20.67. The square-pyramidal CuO_5 units arranged as two-dimensional layers and the square planar CuO_4 units arranged in sheets are common structural features of oxocuprate HTSCs.

The mechanism of superconduction is well-understood for low-temperature materials but there is as yet no settled explanation of high-temperature superconductivity. The central concept of low-temperature superconduction is the existence of a **Cooper pair**, a pair of electrons that exists on account of the indirect electron–electron interactions fostered by the nuclei of the atoms in the lattice. Thus, if one electron is in a particular region of a solid, the nuclei there move toward it to give a distorted local structure (Fig. 20.68). Because that local distortion is rich in positive charge, it is favourable for a second electron to join the first. Hence, there is a virtual attraction between the two electrons, and they move together as a pair. The local distortion can be easily disrupted by thermal motion of the ions in the solid, so the virtual attraction

Fig. 20.68 The formation of a Cooper pair. One electron distorts the crystal lattice and the second electron has a lower energy if it goes to that region. These electron–lattice interactions effectively bind the two electrons into a pair.

occurs only at very low temperatures. A Cooper pair undergoes less scattering than an individual electron as it travels through the solid because the distortion caused by one electron can attract back the other electron should it be scattered out of its path in a collision. Because the Cooper pair is stable against scattering, it can carry charge freely through the solid, and hence give rise to superconduction.

The Cooper pairs responsible for low-temperature superconductivity are likely to be important in HTSCs, but the mechanism for pairing is hotly debated. There is evidence implicating the arrangement of CuO_5 layers and CuO_4 sheets in the mechanism of high-temperature superconduction. It is believed that movement of electrons along the linked CuO_4 units accounts for superconductivity, whereas the linked CuO_5 units act as ‘charge reservoirs’ that maintain an appropriate number of electrons in the superconducting layers.

Superconductors can sustain large currents and, consequently, are excellent materials for the high-field magnets used in modern NMR spectroscopy (Chapter 15). However, the potential uses of superconducting materials are not limited to the field to chemical instrumentation. For example, HTSCs with T_c values near ambient temperature would be very efficient components of an electrical power transmission system, in which energy loss due to electrical resistance would be minimized. The appropriate technology is not yet available, but research in this area of materials science is active.

Checklist of key ideas

-
- ☐ 1. Solids are classified as metallic, ionic, covalent, and molecular.
 - ☐ 2. A space lattice is the pattern formed by points representing the locations of structural motifs (atoms, molecules, or groups of atoms, molecules, or ions). The Bravais lattices are the 14 distinct space lattices in three dimensions (Fig. 20.8).
 - ☐ 3. A unit cell is an imaginary parallelepiped that contains one unit of a translationally repeating pattern. Unit cells are classified into seven crystal systems according to their rotational symmetries.
 - ☐ 4. Crystal planes are specified by a set of Miller indices (hkl) and the separation of neighbouring planes in a rectangular lattice is given by $1/d_{hkl}^2 = h^2/a^2 + k^2/b^2 + l^2/c^2$.
 - ☐ 5. Bragg’s law relating the glancing angle θ to the separation of lattice planes is $\lambda = 2d \sin \theta$, where λ is the wavelength of the radiation.
 - ☐ 6. The scattering factor is a measure of the ability of an atom to diffract radiation (eqn 20.6).
 - ☐ 7. The structure factor is the overall amplitude of a wave diffracted by the $\{hkl\}$ planes (eqn 20.7). Fourier synthesis is the construction of the electron density distribution from structure factors (eqn 20.8).
 - ☐ 8. A Patterson synthesis is a map of interatomic vectors obtained by Fourier analysis of diffraction intensities (eqn 20.9).
 - ☐ 9. Structure refinement is the adjustment of structural parameters to give the best fit between the observed intensities and those calculated from the model of the structure deduced from the diffraction pattern.
 - ☐ 10. Many elemental metals have close-packed structures with coordination number 12; close-packed structures may be either cubic (ccp) or hexagonal (hcp).
 - ☐ 11. Representative ionic structures include the caesium-chloride, rock-salt, and zinc-blende structures.
 - ☐ 12. The radius-ratio rule may be used cautiously to predict which of these three structures is likely (eqn 20.12).
 - ☐ 13. The lattice enthalpy is the change in enthalpy (per mole of formula units) accompanying the complete separation of the components of the solid. The electrostatic contribution to the lattice enthalpy is expressed by the Born–Mayer equation (eqn 20.15).
 - ☐ 14. A covalent network solid is a solid in which covalent bonds in a definite spatial orientation link the atoms in a network extending through the crystal. A molecular solid is a solid consisting of discrete molecules held together by van der Waals interactions.
 - ☐ 15. The mechanical properties of a solid are discussed in terms of the relationship between stress, the applied force divided by the area to which it is applied, and strain, the distortion of a sample resulting from an applied stress.
 - ☐ 16. The response of a solid to an applied stress is summarized by the Young’s modulus (eqn 20.16a), the bulk modulus (eqn 20.16b), the shear modulus (eqn 20.16c), and Poisson’s ratio (eqn 20.17).
 - ☐ 17. Electronic conductors are classified as metallic conductors or semiconductors according to the temperature dependence of their conductivities. An insulator is a semiconductor with a very low electrical conductivity.

18. According to the band theory, electrons occupy molecular orbitals formed from the overlap of atomic orbitals: full bands are called valence bands and empty bands are called conduction bands. The occupation of the orbitals in a solid is given by the Fermi–Dirac distribution (eqn 20.23).
19. Semiconductors are classified as p-type or n-type according to whether conduction is due to holes in the valence band or electrons in the conduction band.
20. The spectroscopic properties of molecular solids can be understood in terms of the formation and migration of excitons, electron–hole pairs, from molecule to molecule.
21. The spectroscopic properties of metallic conductors and semiconductors can be understood in terms of the light-induced promotion of electrons from valence bands to conduction bands.
22. Examples of solid state lasers include the neodymium laser, the titanium sapphire laser, and diode lasers.
23. Nonlinear optical phenomena arise from changes in the optical properties of a material in the presence of an intense field from electromagnetic radiation. Examples include second harmonic generation, and the optical Kerr effect.
24. A bulk sample exposed to a magnetic field of strength H acquires a magnetization, $M = \chi H$, where χ is the dimensionless volume magnetic susceptibility. When $\chi < 0$, the material is diamagnetic and moves out of a magnetic field. When $\chi > 0$, the material is paramagnetic and moves into a magnetic field.
25. The temperature dependence of χ_m is given by the Curie law $\chi_m = A + C/T$, where $A = N_A \mu_0 \xi$, $C = N_A \mu_0 m^2 / 3k$, and ξ is the magnetizability, a measure of the extent to which a magnetic dipole moment may be induced in a molecule.
26. Ferromagnetism is the cooperative alignment of electron spins in a material and gives rise to strong magnetization. Antiferromagnetism results from alternating spin orientations in a material and leads to weak magnetization.
27. Temperature-independent paramagnetism arises from induced electron currents within the orbitals of a molecule that are occupied in its ground state.
28. Superconductors conduct electricity without resistance below a critical temperature T_c . Type I superconductors show abrupt loss of superconductivity when an applied magnetic field exceeds a critical value H_c characteristic of the material. They are also completely diamagnetic below H_c . Type II superconductors show a gradual loss of superconductivity and diamagnetism with increasing magnetic field.

Discussion questions

- 20.1 Explain how planes of lattice points are labelled.
- 20.2 Describe the procedure for identifying the type and size of a cubic unit cell.
- 20.3 What is meant by a systematic absence? How do they arise?
- 20.4 Describe the phase problem and explain how it may be overcome.
- 20.5 Describe the structures of elemental metallic solids in terms of the packing of hard spheres. To what extent is the hard-sphere model inaccurate?
- 20.6 Describe the caesium-chloride and rock-salt structures in terms of the occupation of holes in expanded close-packed lattices.
- 20.7 Explain how X-ray diffraction can be used to determine the absolute configuration of molecules.
- 20.8 Explain how metallic conductors and semiconductors are identified and explain their electrical and optical properties in terms of band theory.
- 20.9 Describe the characteristics of the Fermi–Dirac distribution. Why is it appropriate to call the parameter μ a chemical potential?
- 20.10 To what extent are the electric and magnetic properties of molecules analogous? How do they differ?

Exercises

20.1a Equivalent lattice points within the unit cell of a Bravais lattice have identical surroundings. What points within a face-centred cubic unit cell are equivalent to the point $(\frac{1}{2}, 0, 0)$?

20.1b Equivalent lattice points within the unit cell of a Bravais lattice have identical surroundings. What points within a body-centred cubic unit cell are equivalent to the point $(\frac{1}{2}, 0, \frac{1}{2})$?

20.2a Find the Miller indices of the planes that intersect the crystallographic axes at the distances $(2a, 3b, 2c)$ and $(2a, 2b, \infty c)$.

20.2b Find the Miller indices of the planes that intersect the crystallographic axes at the distances $(1a, 3b, -c)$ and $(2a, 3b, 4c)$.

20.3a Calculate the separations of the planes $\{111\}$, $\{211\}$, and $\{100\}$ in a crystal in which the cubic unit cell has side 432 pm.

20.3b Calculate the separations of the planes $\{121\}$, $\{221\}$, and $\{244\}$ in a crystal in which the cubic unit cell has side 523 pm.

20.4a The glancing angle of a Bragg reflection from a set of crystal planes separated by 99.3 pm is 20.85° . Calculate the wavelength of the X-rays.

20.4b The glancing angle of a Bragg reflection from a set of crystal planes separated by 128.2 pm is 19.76° . Calculate the wavelength of the X-rays.

20.5a What are the values of 2θ of the first three diffraction lines of bcc iron (atomic radius 126 pm) when the X-ray wavelength is 58 pm?

20.5b What are the values of 2θ of the first three diffraction lines of fcc gold (atomic radius 144 pm) when the X-ray wavelength is 154 pm?

20.6a Copper K_α radiation consists of two components of wavelengths 154.433 pm and 154.051 pm. Calculate the separation of the diffraction lines arising from the two components in a powder diffraction pattern recorded in a circular camera of radius 5.74 cm (with the sample at the centre) from planes of separation 77.8 pm.

20.6b A synchrotron source produces X-radiation at a range of wavelengths. Consider two components of wavelengths 95.401 and 96.035 pm. Calculate the separation of the diffraction lines arising from the two components in a powder diffraction pattern recorded in a circular camera of radius 5.74 cm (with the sample at the centre) from planes of separation 82.3 pm.

20.7a The compound Rb_3TlF_6 has a tetragonal unit cell with dimensions $a = 651$ pm and $c = 934$ pm. Calculate the volume of the unit cell.

20.7b Calculate the volume of the hexagonal unit cell of sodium nitrate, for which the dimensions are $a = 1692.9$ pm and $c = 506.96$ pm.

20.8a The orthorhombic unit cell of NiSO_4 has the dimensions $a = 634$ pm, $b = 784$ pm, and $c = 516$ pm, and the density of the solid is estimated as 3.9 g cm^{-3} . Determine the number of formula units per unit cell and calculate a more precise value of the density.

20.8b An orthorhombic unit cell of a compound of molar mass $135.01 \text{ g mol}^{-1}$ has the dimensions $a = 589$ pm, $b = 822$ pm, and $c = 798$ pm. The density of the solid is estimated as 2.9 g cm^{-3} . Determine the number of formula units per unit cell and calculate a more precise value of the density.

20.9a The unit cells of SbCl_3 are orthorhombic with dimensions $a = 812$ pm, $b = 947$ pm, and $c = 637$ pm. Calculate the spacing, d , of the $\{411\}$ planes.

20.9b An orthorhombic unit cell has dimensions $a = 679$ pm, $b = 879$ pm, and $c = 860$ pm. Calculate the spacing, d , of the $\{322\}$ planes.

20.10a A substance known to have a cubic unit cell gives reflections with $\text{Cu } K_\alpha$ radiation (wavelength 154 pm) at glancing angles 19.4° , 22.5° , 32.6° , and

39.4° . The reflection at 32.6° is known to be due to the $\{220\}$ planes. Index the other reflections.

20.10b A substance known to have a cubic unit cell gives reflections with radiation of wavelength 137 pm at the glancing angles 10.7° , 13.6° , 17.7° , and 21.9° . The reflection at 17.7° is known to be due to the $\{111\}$ planes. Index the other reflections.

20.11a Potassium nitrate crystals have orthorhombic unit cells of dimensions $a = 542$ pm, $b = 917$ pm, and $c = 645$ pm. Calculate the glancing angles for the $\{100\}$, $\{010\}$, and $\{111\}$ reflections using $\text{Cu } K_\alpha$ radiation (154 pm).

20.11b Calcium carbonate crystals in the form of aragonite have orthorhombic unit cells of dimensions $a = 574.1$ pm, $b = 796.8$ pm, and $c = 495.9$ pm. Calculate the glancing angles for the $\{100\}$, $\{010\}$, and $\{111\}$ reflections using radiation of wavelength 83.42 pm (from aluminium).

20.12a Copper(I) chloride forms cubic crystals with four formula units per unit cell. The only reflections present in a powder photograph are those with either all even indices or all odd indices. What is the (Bravais) lattice type of the unit cell?

20.12b A powder diffraction photograph from tungsten shows lines that index as $\{110\}$, $\{200\}$, $\{211\}$, $\{220\}$, $\{310\}$, $\{222\}$, $\{321\}$, $\{400\}$, . . . Identify the (Bravais) lattice type of the unit cell.

20.13a The coordinates, in units of a , of the atoms in a body-centred cubic lattice are $(0,0,0)$, $(0,1,0)$, $(0,0,1)$, $(0,1,1)$, $(1,0,0)$, $(1,1,0)$, $(1,0,1)$, and $(1,1,1)$. Calculate the structure factors F_{hkl} when all the atoms are identical.

20.13b The coordinates, in units of a , of the atoms in a body-centred cubic lattice are $(0,0,0)$, $(0,1,0)$, $(0,0,1)$, $(0,1,1)$, $(1,0,0)$, $(1,1,0)$, $(1,0,1)$, $(1,1,1)$, and $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$. Calculate the structure factors F_{hkl} when all the atoms are identical.

20.14a Calculate the packing fraction for close-packed cylinders.

20.14b Calculate the packing fraction for equilateral triangular rods stacked as shown in 2.

20.15a Verify that the radius ratios for sixfold coordination is 0.414.

20.15b Verify that the radius ratios for eightfold coordination is 0.732.

20.16a From the data in Table 20.3 determine the radius of the smallest cation that can have (a) sixfold and (b) eightfold coordination with the O^{2-} ion.

20.16b From the data in Table 20.3 determine the radius of the smallest cation that can have (a) sixfold and (b) eightfold coordination with the K^+ ion.

20.17a Calculate the atomic packing factor for diamond.

20.17b Calculate the atomic packing factor for a side-centred (C) cubic unit cell.

20.18a Is there an expansion or a contraction as titanium transforms from hcp to body-centred cubic? The atomic radius of titanium is 145.8 pm in hcp but 142.5 pm in bcc.

20.18b Is there an expansion or a contraction as iron transforms from hcp to bcc? The atomic radius of iron is 126 pm in hcp but 122 pm in bcc.

20.19a In a Patterson synthesis, the spots correspond to the lengths and directions of the vectors joining the atoms in a unit cell. Sketch the pattern that would be obtained for a planar, triangular isolated BF_3 molecule.

20.19b In a Patterson synthesis, the spots correspond to the lengths and directions of the vectors joining the atoms in a unit cell. Sketch the pattern that would be obtained from the C atoms in an isolated benzene molecule.

20.20a What velocity should neutrons have if they are to have wavelength 50 pm?

20.20b Calculate the wavelength of neutrons that have reached thermal equilibrium by collision with a moderator at 300 K.

20.21a Derive the Born–Mayer equation (eqn 20.15) by calculating the energy at which $d(E_p + E_p^*)/dd = 0$, with E_p and E_p^* given by eqns 20.13 and 20.14, respectively.

20.21b Calculate the lattice enthalpy of MgBr_2 from the following data:

	$\Delta H/(\text{kJ mol}^{-1})$
Sublimation of $\text{Mg}(\text{s})$	+148
Ionization of $\text{Mg}(\text{g})$ to $\text{Mg}^{2+}(\text{g})$	+2187
Vaporization of $\text{Br}_2(\text{l})$	+31
Dissociation of $\text{Br}_2(\text{g})$	+193
Electron attachment to $\text{Br}(\text{g})$	−331
Formation of $\text{MgBr}_2(\text{s})$ from $\text{Mg}(\text{s})$ and $\text{Br}_2(\text{l})$	−524

20.22a Cotton consists of the polymer cellulose, which is a linear chain of glucose molecules. The chains are held together by hydrogen bonding. When a cotton shirt is ironed, it is first moistened, then heated under pressure. Explain this process.

20.22b Sections of the solid fuel rocket boosters of the space shuttle *Challenger* were sealed together with O-ring rubber seals of circumference 11 m. These seals failed at 0°C, a temperature well above the crystallization temperature of the rubber. Speculate on why the failure occurred.

20.23a Young's modulus for polyethylene at room temperature is 1.2 GPa. What strain will be produced when a mass of 1.0 kg is suspended from a polyethylene thread of diameter 1.0 mm?

20.23b Young's modulus for iron at room temperature is 215 GPa. What strain will be produced when a mass of 10.0 kg is suspended from an iron wire of diameter 0.10 mm?

20.24a Poisson's ratio for polyethylene is 0.45. What change in volume takes place when a cube of polyethylene of volume 1.0 cm^3 is subjected to a uniaxial stress that produces a strain of 1.0 per cent?

20.24b Poisson's ratio for lead is 0.41. What change in volume takes place when a cube of lead of volume 1.0 dm^3 is subjected to a uniaxial stress that produces a strain of 2.0 per cent?

20.25a Is arsenic-doped germanium a p-type or n-type semiconductor?

20.25b Is gallium-doped germanium a p-type or n-type semiconductor?

20.26a The promotion of an electron from the valence band into the conduction band in pure TiO_2 by light absorption requires a wavelength of less than 350 nm. Calculate the energy gap in electronvolts between the valence and conduction bands.

20.26b The band gap in silicon is 1.12 eV. Calculate the minimum frequency of electromagnetic radiation that results in promotion of electrons from the valence to the conduction band.

20.27a The magnetic moment of CrCl_3 is $3.81\mu_B$. How many unpaired electrons does the Cr possess?

20.27b The magnetic moment of Mn^{2+} in its complexes is typically $5.3\mu_B$. How many unpaired electrons does the ion possess?

20.28a Calculate the molar susceptibility of benzene given that its volume susceptibility is -7.2×10^{-7} and its density 0.879 g cm^{-3} at 25°C.

20.28b Calculate the molar susceptibility of cyclohexane given that its volume susceptibility is -7.9×10^{-7} and its density 811 kg m^{-3} at 25°C.

20.29a According to Lewis theory, an O_2 molecule should be diamagnetic. However, experimentally it is found that $\chi_m/(\text{m}^3 \text{ mol}^{-1}) = (1.22 \times 10^{-5} \text{ K})/T$. Determine the number of unpaired spins in O_2 . How is the problem of the Lewis structure resolved?

20.29b Predict the molar susceptibility of nitrogen dioxide at 298 K. Why does the molar susceptibility of a sample of nitrogen dioxide gas decrease as it is compressed?

20.30a Data on a single crystal of MnF_2 give $\chi_m = 0.1463 \text{ cm}^3 \text{ mol}^{-1}$ at 294.53 K. Determine the effective number of unpaired electrons in this compound and compare your result with the theoretical value.

20.30b Data on a single crystal of $\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$ give $\chi_m = 6.00 \times 10^{-8} \text{ m}^3 \text{ mol}^{-1}$ at 298 K. Determine the effective number of unpaired electrons in this compound and compare your result with the theoretical value.

20.31a Estimate the spin-only molar susceptibility of $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ at 25°C.

20.31b Estimate the spin-only molar susceptibility of $\text{MnSO}_4 \cdot 4\text{H}_2\text{O}$ at 298 K.

20.32a Approximately how large must the magnetic induction, B , be for the orientational energy of an $S = 1$ system to be comparable to kT at 298 K?

20.32b Estimate the ratio of populations of the M_S states of a system with $S = 1$ in 15.0 T at 298 K.

Problems*

Numerical problems

20.1 In the early days of X-ray crystallography there was an urgent need to know the wavelengths of X-rays. One technique was to measure the diffraction angle from a mechanically ruled grating. Another method was to estimate the separation of lattice planes from the measured density of a crystal. The density

of NaCl is 2.17 g cm^{-3} and the (100) reflection using PdK_α radiation occurred at 6.0° . Calculate the wavelength of the X-rays.

20.2 The element polonium crystallizes in a cubic system. Bragg reflections, with X-rays of wavelength 154 pm, occur at $\sin \theta = 0.225, 0.316$, and 0.388 from the (100), (110), and (111) sets of planes. The separation between the

* Problems denoted with the symbol ‡ were supplied by Charles Trapp and Carmen Giunta.

sixth and seventh lines observed in the powder diffraction pattern is larger than between the fifth and sixth lines. Is the unit cell simple, body-centred, or face-centred? Calculate the unit cell dimension.

20.3 The unit cell dimensions of NaCl, KCl, NaBr, and KBr, all of which crystallize in face-centred cubic lattices, are 562.8 pm, 627.7 pm, 596.2 pm, and 658.6 pm, respectively. In each case, anion and cation are in contact along an edge of the unit cell. Do the data support the contention that ionic radii are constants independent of the counter-ion?

20.4 The powder diffraction patterns of (a) tungsten, (b) copper obtained in a camera of radius 28.7 mm are shown in Fig. 20.69. Both were obtained with 154 pm X-rays and the scales are marked. Identify the unit cell in each case, and calculate the lattice spacing. Estimate the metallic radii of W and Cu.

Fig. 20.69

20.5 Elemental silver reflects X-rays of wavelength 154.18 pm at angles of 19.076° , 22.171° , and 32.256° . However, there are no other reflections at angles of less than 33° . Assuming a cubic unit cell, determine its type and dimension. Calculate the density of silver.

20.6 Genuine pearls consist of concentric layers of calcite crystals (CaCO_3) in which the trigonal axes are oriented along the radii. The nucleus of a cultured pearl is a piece of mother-of-pearl that has been worked into a sphere on a lathe. The oyster then deposits concentric layers of calcite on the central seed. Suggest an X-ray method for distinguishing between real and cultured pearls.

20.7 In their book *X-rays and crystal structures* (which begins 'It is now two years since Dr. Laue conceived the idea . . .') the Braggs give a number of simple examples of X-ray analysis. For instance, they report that the reflection from (100) planes in KCl occurs at $5^\circ 23'$, but for NaCl it occurs at $6^\circ 0'$ for X-rays of the same wavelength. If the side of the NaCl unit cell is 564 pm, what is the side of the KCl unit cell? The densities of KCl and NaCl are 1.99 g cm^{-3} and 2.17 g cm^{-3} respectively. Do these values support the X-ray analysis?

20.8 Calculate the coefficient of thermal expansion of diamond given that the (111) reflection shifts from $22^\circ 2' 25''$ to $21^\circ 57' 59''$ on heating a crystal from 100 K to 300 K and 154.0562 pm X-rays are used.

20.9 The carbon-carbon bond length in diamond is 154.45 pm. If diamond were considered to be a close-packed structure of hard spheres with radii equal to half the bond length, what would be its expected density? The diamond lattice is face-centred cubic and its actual density is 3.516 g cm^{-3} . Can you explain the discrepancy?

20.10 The volume of a monoclinic unit cell is $abc \sin \beta$. Naphthalene has a monoclinic unit cell with two molecules per cell and sides in the ratio 1.377:1:1.436. The angle β is $122^\circ 49'$ and the density of the solid is 1.152 g cm^{-3} . Calculate the dimensions of the cell.

20.11 The structures of crystalline macromolecules may be determined by X-ray diffraction techniques by methods similar to those for smaller molecules. Fully crystalline polyethylene has its chains aligned in an orthorhombic unit cell of dimensions $740 \text{ pm} \times 493 \text{ pm} \times 253 \text{ pm}$. There are two repeating

CH_2CH_2 units per unit cell. Calculate the theoretical density of fully crystalline polyethylene. The actual density ranges from 0.92 to 0.95 g cm^{-3} .

20.12 Construct the electron density along the x -axis of a crystal given the following structure factors:

h	0	1	2	3	4	5	6	7	8	9
F_h	+30.0	+8.2	+6.5	+4.1	+5.5	-2.4	+5.4	+3.2	-1.0	+1.1
h	10	11	12	13	14	15				
F_h	+6.5	+5.2	-4.3	-1.2	+0.1	+2.1				

20.13 The scattering of electrons or neutrons from a pair of nuclei separated by a distance R_{ij} and orientated at a definite angle to the incident beam can be calculated. When the molecule consists of a number of atoms, we sum over the contribution from all pairs, and find that the total intensity has an angular variation given by the Wierl equation:

$$I(\theta) = \sum_{ij} f_i f_j \frac{\sin s R_{ij}}{s R_{ij}} \quad s = \frac{4\pi}{\lambda} \sin \frac{1}{2} \theta$$

where λ is the wavelength of the electrons in the beam and θ is the scattering angle. The electron scattering factor, f_i is a measure of the intensity of the electron scattering powers of the atoms. (a) Predict from the Wierl equation the positions of the first maximum and first minimum in the neutron and electron diffraction patterns of a Br_2 molecule obtained with neutrons of wavelength 78 pm wavelength and electrons of wavelength 4.0 pm.

(b) Use the Wierl equation to predict the appearance of the 10.0 keV electron diffraction pattern of CCl_4 with an (as yet) undetermined C-Cl bond length but of known tetrahedral symmetry. Take $f_{\text{Cl}} = 17f$ and $f_{\text{C}} = 6f$ and note that $R(\text{Cl}, \text{Cl}) = (8/3)^{1/2} R(\text{C}, \text{Cl})$. Plot I/f^2 against positions of the maxima, which occurred at $3^\circ 0'$, $5^\circ 22'$, and $7^\circ 54'$, and minima, which occurred at $1^\circ 46'$, $4^\circ 6'$, $6^\circ 40'$, and $9^\circ 10'$. What is the C-Cl bond length in CCl_4 ?

20.14† B.A. Bovenzi and G.A. Pearce, Jr. (*J. Chem. Soc. Dalton Trans.* 2793 (1997)) synthesized coordination compounds of the tridentate ligand pyridine-2,6-diamidoxime ($\text{C}_7\text{H}_9\text{N}_5\text{O}_2$). The compound, which they isolated from the reaction of the ligand with CuSO_4 (aq), did not contain a $[\text{Cu}(\text{C}_7\text{H}_9\text{N}_5\text{O}_2)_2]^{2+}$ complex cation as expected. Instead, X-ray diffraction analysis revealed a linear polymer of formula $[\text{Cu}(\text{C}_7\text{H}_9\text{N}_5\text{O}_2)(\text{SO}_4) \cdot 2\text{H}_2\text{O}]_n$, which features bridging sulfate groups. The unit cell was primitive monoclinic with $a = 1.0427 \text{ nm}$, $b = 0.8876 \text{ nm}$, $c = 1.3777 \text{ nm}$, and $\beta = 93.254^\circ$. The mass density of the crystals is 2.024 g cm^{-3} . How many monomer units are there per unit cell?

20.15† D. Sellmann, M.W. Wemple, W. Donaubauer, and F.W. Heinemann (*Inorg. Chem.* 36, 1397 (1997)) describe the synthesis and reactivity of the ruthenium nitrido compound $[\text{N}(\text{C}_4\text{H}_9)_4][\text{Ru}(\text{N})(\text{S}_2\text{C}_6\text{H}_4)_2]$. The ruthenium complex anion has the two 1,2-benzenedithiolate ligands (**3**) at the base of a rectangular pyramid and the nitrido ligand at the apex. Compute the mass density of the compound given that it crystallizes into an orthorhombic unit cell with $a = 3.6881 \text{ nm}$, $b = 0.9402 \text{ nm}$, and $c = 1.7652 \text{ nm}$ and eight formula units per cell. Replacing the ruthenium with an osmium results in a compound with the same crystal structure and a unit cell with a volume less than 1 per cent larger. Estimate the mass density of the osmium analogue.

20.16 Aided by the Born-Mayer equation for the lattice enthalpy and a Born-Haber cycle, show that formation of CaCl is an exothermic process (the sublimation enthalpy of $\text{Ca}(\text{s})$ is 176 kJ mol^{-1}). Show that an explanation

for the nonexistence of CaCl can be found in the reaction enthalpy for the reaction $2\text{CaCl(s)} \rightarrow \text{Ca(s)} + \text{CaCl}_2$.

20.17 In an intrinsic semiconductor, the band gap is so small that the Fermi–Dirac distribution results in some electrons populating the conduction band. It follows from the exponential form of the Fermi–Dirac distribution that the conductance G , the inverse of the resistance (with units of siemens, $1 \text{ S} = 1 \Omega^{-1}$), of an intrinsic semiconductor should have an Arrhenius-like temperature dependence, shown in practice to have the form $G = G_0 e^{-E_g/2kT}$, where E_g is the band gap. The conductance of a sample of germanium varied with temperature as indicated below. Estimate the value of E_g .

T/K	312	354	420
G/S	0.0847	0.429	2.86

20.18 Here we investigate quantitatively the spectra of molecular solids. We begin by considering a dimer, with each monomer having a single transition with transition dipole moment μ_{mon} and wavenumber $\tilde{\nu}_{\text{mon}}$. We assume that the ground state wavefunctions are not perturbed as a result of dimerization and then write the dimer excited state wavefunctions Ψ_i as linear combinations of the excited state wavefunctions ψ_1 and ψ_2 of the monomer: $\Psi_i = c_j \psi_1 + c_k \psi_2$. Now we write the hamiltonian matrix with diagonal elements set to the energy between the excited and ground state of the monomer (which, expressed as a wavenumber, is simply $\tilde{\nu}_{\text{mon}}$), and off-diagonal elements correspond to the energy of interaction between the transition dipoles. Using the arrangement discussed in *Illustration 20.1*, we write this interaction energy (as a wavenumber) as:

$$\beta = \frac{\mu_{\text{mon}}^2}{4\pi\epsilon_0 h c r^3} (1 - 3 \cos^2 \theta)$$

It follows that the hamiltonian matrix is

$$\hat{H} = \begin{pmatrix} \tilde{\nu}_{\text{mon}} & \beta \\ \beta & \tilde{\nu}_{\text{mon}} \end{pmatrix}$$

The eigenvalues of the matrix are the dimer transition wavenumbers $\tilde{\nu}_1$ and $\tilde{\nu}_2$. The eigenvectors are the wavefunctions for the excited states of the dimer

and have the form $\begin{pmatrix} c_j \\ c_k \end{pmatrix}$. (a) The intensity of absorption of incident

radiation is proportional to the square of the transition dipole moment (Section 9.10). The monomer transition dipole moment is $\mu_{\text{mon}} = \int \psi_1^* \hat{\mu} \psi_0 d\tau = \int \psi_2^* \hat{\mu} \psi_0 d\tau$, where ψ_0 is the wavefunction of the monomer ground state. Assume that the dimer ground state may also be described by ψ_0 and show that the transition dipole moment μ_i of each dimer transition is given by $\mu_i = \mu_{\text{mon}}(c_j + c_k)$. (b) Consider a dimer of monomers with $\mu_{\text{mon}} = 4.00 \text{ D}$, $\tilde{\nu}_{\text{mon}} = 25\,000 \text{ cm}^{-1}$, and $r = 0.5 \text{ nm}$. How do the transition wavenumbers $\tilde{\nu}_1$ and $\tilde{\nu}_2$ vary with the angle θ ? The relative intensities of the dimer transitions may be estimated by calculating the ratio μ_2^2/μ_1^2 . How does this ratio vary with the angle θ ? (c) Now expand the treatment given above to a chain of N monomers ($N = 5, 10, 15$, and 20), with $\mu_{\text{mon}} = 4.00 \text{ D}$, $\tilde{\nu}_{\text{mon}} = 25\,000 \text{ cm}^{-1}$, and $r = 0.5 \text{ nm}$. For simplicity, assume that $\theta = 0$ and that only nearest neighbours interact with interaction energy V . For example the hamiltonian matrix for the case $N = 4$ is

$$\hat{H} = \begin{pmatrix} \tilde{\nu}_{\text{mon}} & V & 0 & 0 \\ V & \tilde{\nu}_{\text{mon}} & V & 0 \\ 0 & V & \tilde{\nu}_{\text{mon}} & V \\ 0 & 0 & V & \tilde{\nu}_{\text{mon}} \end{pmatrix}$$

How does the wavenumber of the lowest energy transition vary with size of the chain? How does the transition dipole moment of the lowest energy transition vary with the size of the chain?

20.19† J.J. Dannenberg, D. Liotard, P. Halvick, and J.C. Rayez (*J. Phys. Chem.* **100**, 9631 (1996)) carried out theoretical studies of organic molecules consisting of chains of unsaturated four-membered rings. The calculations

suggest that such compounds have large numbers of unpaired spins, and that they should therefore have unusual magnetic properties. For example, the lowest-energy state of the five-ring compound $\text{C}_{22}\text{H}_{14}$ (**4**) is computed to have $S = 3$, but the energies of $S = 2$ and $S = 4$ structures are each predicted to be 50 kJ mol^{-1} higher in energy. Compute the molar magnetic susceptibility of these three low-lying levels at 298 K . Estimate the molar susceptibility at 298 K if each level is present in proportion to its Boltzmann factor (effectively assuming that the degeneracy is the same for all three of these levels).

20.20 Lead has $T_c = 7.19 \text{ K}$ and $H_c = 63\,901 \text{ A m}^{-1}$. At what temperature does lead become superconducting in a magnetic field of 20 kA m^{-1} ?

20.21† P.G. Radaelli, M. Marezio, M. Perroux, S. de Brion, J.L. Tholence, Q. Huang, and A. Santoro (*Science* **265**, 380 (1994)) report the synthesis and structure of a material that becomes superconducting at temperatures below 45 K . The compound is based on a layered compound $\text{Hg}_2\text{Ba}_2\text{YCu}_2\text{O}_{8-\delta}$, which has a tetragonal unit cell with $a = 0.38606 \text{ nm}$ and $c = 2.8915 \text{ nm}$; each unit cell contains two formula units. The compound is made superconducting by partially replacing Y by Ca, accompanied by a change in unit cell volume by less than 1 per cent. Estimate the Ca content x in superconducting $\text{Hg}_2\text{Ba}_2\text{Y}_{1-x}\text{Ca}_x\text{Cu}_2\text{O}_{7.55}$ given that the mass density of the compound is 7.651 g cm^{-3} .

Theoretical problems

20.22 Show that the separation of the (hkl) planes in an orthorhombic crystal with sides a , b , and c is given by eqn 20.3.

20.23 Show that the volume of a triclinic unit cell of sides a , b , and c and angles α , β , and γ is

$$V = abc(1 - \cos^2 \alpha - \cos^2 \beta - \cos^2 \gamma + 2 \cos \alpha \cos \beta \cos \gamma)^{1/2}$$

Use this expression to derive expressions for monoclinic and orthorhombic unit cells. For the derivation, it may be helpful to use the result from vector analysis that $V = \mathbf{a} \cdot \mathbf{b} \times \mathbf{c}$ and to calculate V^2 initially.

20.24 Calculate the packing fractions of (a) a primitive cubic lattice, (b) a bcc unit cell, (c) an fcc unit cell.

20.25 The coordinates of the four I atoms in the unit cell of KIO_4 are $(0,0,0)$, $(0, \frac{1}{2}, \frac{1}{2})$, $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$, $(\frac{1}{2}, 0, \frac{3}{4})$. By calculating the phase of the I reflection in the structure factor, show that the I atoms contribute no net intensity to the (114) reflection.

20.26 The coordinates, in units of a , of the A atoms, with scattering factor f_A , in a cubic lattice are $(0,0,0)$, $(0,1,0)$, $(0,0,1)$, $(0,1,1)$, $(1,0,0)$, $(1,1,0)$, $(1,0,1)$, and $(1,1,1)$. There is also a B atom, with scattering factor f_B , at $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$. Calculate the structure factors F_{hkl} and predict the form of the powder diffraction pattern when (a) $f_A = f$, $f_B = 0$, (b) $f_B = \frac{1}{2}f_A$, and (c) $f_A = f_B = f$.

20.27 For an isotropic substance, the moduli and Poisson's ratio may be expressed in terms of two parameters λ and μ called the *Lamé constants*:

$$E = \frac{\mu(3\lambda + 2\mu)}{\lambda + \mu} \quad K = \frac{3\lambda + 2\mu}{3} \quad G = \mu \quad \nu_P = \frac{\lambda}{3(\lambda + \mu)}$$

Use the Lamé constants to confirm the relations between G , K , and E given in eqn 20.18.

20.28 When energy levels in a band form a continuum, the density of states $\rho(E)$, the number of levels in an energy range divided by the width of the range, may be written as $\rho(E) = dk/dE$, where dk is the change in the quantum number k and dE is the energy change. (a) Use eqn 20.21 to show that

$$\rho(E) = -\frac{(N+1)/2\pi\beta}{\left\{1 - \left(\frac{E-\alpha}{2\beta}\right)^2\right\}^{1/2}}$$

where k , N , α , and β have the meanings described in Section 20.9. (b) Use the expression above to show that $\rho(E)$ becomes infinite as E approaches $\alpha \pm 2\beta$. That is, show that the density of states increases towards the edges of the bands in a one-dimensional metallic conductor.

20.29 The treatment in Problem 20.28 applies only to one-dimensional solids. In three dimensions, the variation of density of states is more like that shown in Fig. 20.70. Account for the fact that in a three-dimensional solid the greatest density of states lies near the centre of the band and the lowest density at the edges.

Fig. 20.70

20.30 Show that, if a substance responds nonlinearly to two sources of radiation, one of frequency ω_1 and the other of frequency ω_2 , then it may give rise to radiation of the sum and difference of the two frequencies. This nonlinear optical phenomenon is known as *frequency mixing* and is used to expand the wavelength range of lasers in laboratory applications, such as spectroscopy and photochemistry.

20.31 The magnetizability, ξ , and the volume and molar magnetic susceptibilities can be calculated from the wavefunctions of molecules. For instance, the magnetizability of a hydrogenic atom is given by the expression $\xi = -(e^2/6m_e)\langle r^2 \rangle$, where $\langle r^2 \rangle$ is the (expectation) mean value of r^2 in the atom. Calculate ξ and χ_m for the ground state of a hydrogenic atom.

20.32 Nitrogen dioxide, a paramagnetic compound, is in equilibrium with its dimer, dinitrogen tetroxide, a diamagnetic compound. Derive an expression in terms of the equilibrium constant, K , for the dimerization to show how the molar susceptibility varies with the pressure of the sample. Suggest how the susceptibility might be expected to vary as the temperature is changed at constant pressure.

20.33 An NO molecule has thermally accessible electronically excited states. It also has an unpaired electron, and so may be expected to be paramagnetic. However, its ground state is not paramagnetic because the magnetic moment of the orbital motion of the unpaired electron almost exactly cancels the spin magnetic moment. The first excited state (at 121 cm^{-1}) is paramagnetic because the orbital magnetic moment adds to, rather than cancels, the spin magnetic moment. The upper state has a magnetic moment of $2\mu_B$. Because the upper state is thermally accessible, the paramagnetic susceptibility of NO shows a pronounced temperature dependence even near room temperature. Calculate the molar paramagnetic susceptibility of NO and plot it as a function of temperature.

Applications: to biochemistry and nanoscience

20.34 Although the crystallization of large biological molecules may not be as readily accomplished as that of small molecules, their crystal lattices are no different. Tobacco seed globulin forms face-centred cubic crystals with unit cell dimension of 12.3 nm and a density of 1.287 g cm^{-3} . Determine its molar mass.

20.35 What features in an X-ray diffraction pattern suggest a helical conformation for a biological macromolecule? Use Fig. 20.26 to deduce as much quantitative information as you can about the shape and size of a DNA molecule.

20.36 A transistor is a semiconducting device that is commonly used either as a switch or an amplifier of electrical signals. Prepare a brief report on the design of a nanometre-sized transistor that uses a carbon nanotube as a component. A useful starting point is the work summarized by Tans *et al.* *Nature* **393**, 49 (1998).

20.37 The tip of a scanning tunnelling microscope can be used to move atoms on a surface. The movement of atoms and ions depends on their ability to leave one position and stick to another, and therefore on the energy changes that occur. As an illustration, consider a two-dimensional square lattice of univalent positive and negative ions separated by 200 pm , and consider a cation on top of this array. Calculate, by direct summation, its Coulombic interaction when it is in an empty lattice point directly above an anion.

PART 3 Change

Part 3 considers the processes by which change occurs. We prepare the ground for a discussion of the rates of reactions by considering the motion of molecules in gases and in liquids. Then we establish the precise meaning of reaction rate, and see how the overall rate, and the complex behaviour of some reactions, may be expressed in terms of elementary steps and the atomic events that take place when molecules meet. Characteristic physical and chemical events take place at surfaces, including catalysis, and we see how to describe them. A special type of surface is that of an electrode, and we shall see how to describe and understand the rate at which electrons are transferred between an electrode and species in solution.

Molecules in motion

21

One of the simplest types of molecular motion to describe is the random motion of molecules of a perfect gas. We see that a simple theory accounts for the pressure of a gas and the rates at which molecules and energy migrate through gases. Molecular mobility is particularly important in liquids. Another simple kind of motion is the largely uniform motion of ions in solution in the presence of an electric field. Molecular and ionic motion have common features and, by considering them from a more general viewpoint, we derive expressions that govern the migration of properties through matter. One of the most useful consequences of this general approach is the formulation of the diffusion equation, which is an equation that shows how matter and energy spread through media of various kinds. Finally, we build a simple model for all types of molecular motion, in which the molecules migrate in a series of small steps, and see that it accounts for many of the properties of migrating molecules in both gases and condensed phases.

The general approach we describe in this chapter provides techniques for discussing the motion of all kinds of particles in all kinds of fluids. We set the scene by considering a simple type of motion, that of molecules in a perfect gas, and go on to see that molecular motion in liquids shows a number of similarities. We shall concentrate on the **transport properties** of a substance, its ability to transfer matter, energy, or some other property from one place to another. Four examples of transport properties are

Diffusion, the migration of matter down a concentration gradient.

Thermal conduction, the migration of energy down a temperature gradient.

Electric conduction, the migration of electric charge along an electrical potential gradient.

Viscosity, the migration of linear momentum down a velocity gradient.

It is convenient to include in the discussion **effusion**, the emergence of a gas from a container through a small hole.

Molecular motion in gases

Here we present the kinetic model of a perfect gas as a starting point for the discussion of its transport properties. In the **kinetic model** of gases we assume that the only contribution to the energy of the gas is from the kinetic energies of the molecules. The kinetic model is one of the most remarkable—and arguably most beautiful—models in physical chemistry for, from a set of very slender assumptions, powerful quantitative conclusions can be deduced.

Problems

21.1 The kinetic model of gases

The kinetic model is based on three assumptions:

- 1 The gas consists of molecules of mass m in ceaseless random motion.
- 2 The size of the molecules is negligible, in the sense that their diameters are much smaller than the average distance travelled between collisions.
- 3 The molecules interact only through brief, infrequent, and elastic collisions.

An **elastic collision** is a collision in which the total translational kinetic energy of the molecules is conserved.

(a) Pressure and molecular speeds

From the very economical assumptions of the kinetic model, we show in the following *Justification* that the pressure and volume of the gas are related by

$$pV = \frac{1}{3}nMc^2 \quad (21.1)^\circ$$

where $M = mN_A$, the molar mass of the molecules, and c is the **root mean square speed** of the molecules, the square root of the mean of the squares of the speeds, v , of the molecules:

$$c = \langle v^2 \rangle^{1/2} \quad [21.2]$$

Fig. 21.1 The pressure of a gas arises from the impact of its molecules on the walls. In an elastic collision of a molecule with a wall perpendicular to the x -axis, the x -component of velocity is reversed but the y - and z -components are unchanged.

Fig. 21.2 A molecule will reach the wall on the right within an interval Δt if it is within a distance $v_x \Delta t$ of the wall and travelling to the right.

Justification 21.1 The pressure of a gas according to the kinetic model

Consider the arrangement in Fig. 21.1. When a particle of mass m that is travelling with a component of velocity v_x parallel to the x -axis collides with the wall on the right and is reflected, its linear momentum (the product of its mass and its velocity) changes from mv_x before the collision to $-mv_x$ after the collision (when it is travelling in the opposite direction). The x -component of momentum therefore changes by $2mv_x$ on each collision (the y - and z -components are unchanged). Many molecules collide with the wall in an interval Δt , and the total change of momentum is the product of the change in momentum of each molecule multiplied by the number of molecules that reach the wall during the interval.

Because a molecule with velocity component v_x can travel a distance $v_x \Delta t$ along the x -axis in an interval Δt , all the molecules within a distance $v_x \Delta t$ of the wall will strike it if they are travelling towards it (Fig. 21.2). It follows that, if the wall has area A , then all the particles in a volume $A \times v_x \Delta t$ will reach the wall (if they are travelling towards it). The number density of particles is nN_A/V , where n is the total amount of molecules in the container of volume V and N_A is Avogadro's constant, so the number of molecules in the volume $Av_x \Delta t$ is $(nN_A/V) \times Av_x \Delta t$.

At any instant, half the particles are moving to the right and half are moving to the left. Therefore, the average number of collisions with the wall during the interval Δt is $\frac{1}{2}nN_A Av_x \Delta t/V$. The total momentum change in that interval is the product of this number and the change $2mv_x$:

$$\text{Momentum change} = \frac{nN_A Av_x \Delta t}{2V} \times 2mv_x = \frac{nmN_A v_x^2 \Delta t}{V} = \frac{nMAv_x^2 \Delta t}{V}$$

where $M = mN_A$.

Next, to find the force, we calculate the rate of change of momentum, which is this change of momentum divided by the interval Δt during which it occurs:

$$\text{Rate of change of momentum} = \frac{nMAv_x^2}{V}$$

This rate of change of momentum is equal to the force (by Newton's second law of motion). It follows that the pressure, the force divided by the area, is

$$\text{Pressure} = \frac{nMv_x^2}{V}$$

Not all the molecules travel with the same velocity, so the detected pressure, p , is the average (denoted $\langle \dots \rangle$) of the quantity just calculated:

$$p = \frac{nM\langle v_x^2 \rangle}{V}$$

This expression already resembles the perfect gas equation of state.

To write an expression of the pressure in terms of the root mean square speed, c , we begin by writing the speed of a single molecule, v , as $v^2 = v_x^2 + v_y^2 + v_z^2$. Because the root-mean-square speed, c , is defined as $c = \langle v^2 \rangle^{1/2}$ (eqn 21.2), it follows that

$$c^2 = \langle v^2 \rangle = \langle v_x^2 \rangle + \langle v_y^2 \rangle + \langle v_z^2 \rangle$$

However, because the molecules are moving randomly, all three averages are the same. It follows that $c^2 = 3\langle v_x^2 \rangle$. Equation 21.1 follows immediately by substituting $\langle v_x^2 \rangle = \frac{1}{3}c^2$ into $p = nM\langle v_x^2 \rangle/V$.

Equation 21.1 is one of the key results of the kinetic model. We see that if the root mean square speed of the molecules depends only on the temperature, then at constant temperature

$$pV = \text{constant}$$

which is the content of Boyle's law (Section 1.2). Moreover, for eqn 21.1 to be the equation of state of a perfect gas, its right-hand side must be equal to nRT . It follows that the root mean square speed of the molecules in a gas at a temperature T must be

$$c = \left(\frac{3RT}{M} \right)^{1/2} \quad (21.3)^\circ$$

We can conclude that *the root mean square speed of the molecules of a gas is proportional to the square root of the temperature and inversely proportional to the square root of the molar mass*. That is, the higher the temperature, the higher the root mean square speed of the molecules, and, at a given temperature, heavy molecules travel more slowly than light molecules. Sound waves are pressure waves, and for them to propagate the molecules of the gas must move to form regions of high and low pressure. Therefore, we should expect the root mean square speeds of molecules to be comparable to the speed of sound in air (340 m s^{-1}). The root mean square speed of N_2 molecules, for instance, is found from eqn 21.3 to be 515 m s^{-1} .

Equation 21.3 is an expression for the mean square speed of molecules. However, in an actual gas the speeds of individual molecules span a wide range, and the collisions in the gas continually redistribute the speeds among the molecules. Before a collision, a molecule may be travelling rapidly, but after a collision it may be accelerated to a very high speed, only to be slowed again by the next collision. The fraction of molecules that have speeds in the range v to $v + dv$ is proportional to the width of the range, and is written $f(v)dv$, where $f(v)$ is called the **distribution of speeds**.

The precise form of f for molecules of a gas at a temperature T was derived by J.C. Maxwell, and is

$$f(v) = 4\pi \left(\frac{M}{2\pi RT} \right)^{3/2} v^2 e^{-Mv^2/2RT} \quad (21.4)$$

Fig. 21.3 The distribution of molecular speeds with temperature and molar mass. Note that the most probable speed (corresponding to the peak of the distribution) increases with temperature and with decreasing molar mass, and simultaneously the distribution becomes broader.

Exploration (a) Plot different distributions by keeping the molar mass constant at 100 g mol^{-1} and varying the temperature of the sample between 200 K and 2000 K. (b) Use mathematical software or the *Living graph* applet from the text's web site to evaluate numerically the fraction of molecules with speeds in the range 100 m s^{-1} to 200 m s^{-1} at 300 K and 1000 K. (c) Based on your observations, provide a molecular interpretation of temperature.

This expression is called the **Maxwell distribution of speeds** and is derived in the following *Justification*. Let's consider its features, which are also shown pictorially in Fig. 21.3:

1 Equation 21.4 includes a decaying exponential function, the term $e^{-Mv^2/2RT}$. Its presence implies that the fraction of molecules with very high speeds will be very small because e^{-x^2} becomes very small when x^2 is large.

2 The factor $M/2RT$ multiplying v^2 in the exponent is large when the molar mass, M , is large, so the exponential factor goes most rapidly towards zero when M is large. That is, heavy molecules are unlikely to be found with very high speeds.

3 The opposite is true when the temperature, T , is high: then the factor $M/2RT$ in the exponent is small, so the exponential factor falls towards zero relatively slowly as v increases. In other words, a greater fraction of the molecules can be expected to have high speeds at high temperatures than at low temperatures.

4 A factor v^2 (the term before the e) multiplies the exponential. This factor goes to zero as v goes to zero, so the fraction of molecules with very low speeds will also be very small.

5 The remaining factors (the term in parentheses in eqn 21.4 and the 4π) simply ensure that, when we add together the fractions over the entire range of speeds from zero to infinity, then we get 1.

To use eqn 21.4 to calculate the fraction of molecules in a given narrow range of speeds, Δv , we evaluate $f(v)$ at the speed of interest, then multiply it by the width of the range of speeds of interest; that is, we form $f(v)\Delta v$. To use the distribution to calculate the fraction in a range of speeds that is too wide to be treated as infinitesimal, we evaluate the integral:

$$\text{Fraction in the range } v_1 \text{ to } v_2 = \int_{v_1}^{v_2} f(v) dv \quad (21.5)$$

This integral is the area under the graph of f as a function of v and, except in special cases, has to be evaluated numerically by using mathematical software (Fig. 21.4).

Justification 21.2 The Maxwell distribution of speeds

The Boltzmann distribution is a key result of physical chemistry and is treated fully in Section 16.1. It implies that the fraction of molecules with velocity components v_x , v_y , v_z is proportional to an exponential function of their kinetic energy, which is

$$E = \frac{1}{2}mv_x^2 + \frac{1}{2}mv_y^2 + \frac{1}{2}mv_z^2$$

Therefore, we can use the relation $a^{x+y+z+\dots} = a^x a^y a^z \dots$ to write

$$f = K e^{-E/kT} = K e^{-(\frac{1}{2}mv_x^2 + \frac{1}{2}mv_y^2 + \frac{1}{2}mv_z^2)/kT} = K e^{-mv_x^2/2kT} e^{-mv_y^2/2kT} e^{-mv_z^2/2kT}$$

where K is a constant of proportionality (at constant temperature) and $f dv_x dv_y dv_z$ is the fraction of molecules in the velocity range v_x to $v_x + dv_x$, v_y to $v_y + dv_y$, and v_z to $v_z + dv_z$. We see that the fraction factorizes into three factors, one for each axis, and we can write $f = f(v_x)f(v_y)f(v_z)$ with

$$f(v_x) = K^{1/3} e^{-mv_x^2/2kT}$$

and likewise for the two other directions.

To determine the constant K , we note that a molecule must have a velocity somewhere in the range $-\infty < v_x < \infty$, so

$$\int_{-\infty}^{\infty} f(v_x) dv_x = 1$$

Substitution of the expression for $f(v_x)$ then gives

$$1 = K^{1/3} \int_{-\infty}^{\infty} e^{-mv_x^2/2kT} dv_x = K^{1/3} \left(\frac{2\pi kT}{m} \right)^{1/2}$$

where we have used the standard integral

$$\int_{-\infty}^{\infty} e^{-ax^2} dx = \frac{\pi}{a}$$

Therefore, $K = (m/2\pi kT)^{3/2} = (M/2\pi RT)^{3/2}$, where M is the molar mass of the molecules. At this stage we know that

$$f(v_x) = \left(\frac{M}{2\pi RT} \right)^{1/2} e^{-Mv_x^2/2RT} \quad (21.6)$$

The probability that a molecule has a velocity in the range v_x to $v_x + dv_x$, v_y to $v_y + dv_y$, v_z to $v_z + dv_z$ is

$$f(v_x)f(v_y)f(v_z)dv_xdv_ydv_z = \left(\frac{M}{2\pi RT} \right)^{3/2} e^{-Mv^2/2RT} dv_xdv_ydv_z$$

where $v^2 = v_x^2 + v_y^2 + v_z^2$. The probability $f(v)dv$ that the molecules have a speed in the range v to $v + dv$ regardless of direction is the sum of the probabilities that the velocity lies in any of the volume elements $dv_xdv_ydv_z$ forming a spherical shell of radius v and thickness dv (Fig. 21.5). The sum of the volume elements on the right-hand side of the last equation is the volume of this shell, $4\pi v^2 dv$. Therefore,

$$f(v) = 4\pi \left(\frac{M}{2\pi RT} \right)^{3/2} v^2 e^{-Mv^2/2RT}$$

as given in eqn 21.4.

Fig. 21.4 To calculate the probability that a molecule will have a speed in the range v_1 to v_2 , we integrate the distribution between those two limits; the integral is equal to the area of the curve between the limits, as shown shaded here.

Fig. 21.5 To evaluate the probability that a molecule has a speed in the range v to $v + dv$, we evaluate the total probability that the molecule will have a speed that is anywhere on the surface of a sphere of radius $v = (v_x^2 + v_y^2 + v_z^2)^{1/2}$ by summing the probabilities that it is in a volume element $dv_x dv_y dv_z$ at a distance v from the origin.

Example 21.1 Calculating the mean speed of molecules in a gas

What is the mean speed, $\bar{c}$, of N_2 molecules in air at 25°C?

Method We need to use the results of probability theory summarized in *Appendix 2*. In this case, we are asked to calculate the mean speed, not the root mean square speed. A mean speed is calculated by multiplying each speed by the fraction of molecules that have that speed, and then adding all the products together. When the speed varies over a continuous range, the sum is replaced by an integral. To employ this approach here, we note that the fraction of molecules with a speed in the range v to $v + dv$ is $f(v)dv$, so the product of this fraction and the speed is $vf(v)dv$. The mean speed, $\bar{c}$, is obtained by evaluating the integral

$$\bar{c} = \int_0^{\infty} vf(v)dv$$

with f given in eqn 21.4.

Answer The integral required is

$$\begin{aligned} \bar{c} &= 4\pi \left(\frac{M}{2\pi RT} \right)^{3/2} \int_0^{\infty} v^3 e^{-Mv^2/2RT} dv \\ &= 4\pi \left(\frac{M}{2\pi RT} \right)^{3/2} \times \frac{1}{2} \left(\frac{2RT}{M} \right)^2 = \left(\frac{8RT}{\pi M} \right)^{1/2} \end{aligned}$$

Fig. 21.6 A summary of the conclusions that can be deduced from the Maxwell distribution for molecules of molar mass M at a temperature T : c^* is the most probable speed, $\bar{c}$ is the mean speed, and c is the root mean square speed.

Comment 21.1

To find the location of the peak of the distribution, differentiate f with respect to v and look for the value of v at which the derivative is zero (other than at $v = 0$ and $v = \infty$).

where we have used the standard result from tables of integrals (or software) that

$$\int_0^\infty x^3 e^{-ax^2} dx = \frac{1}{2a^2}$$

Substitution of the data then gives

$$\bar{c} = \left(\frac{8 \times (8.3141 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})}{\pi \times (28.02 \times 10^{-3} \text{ kg mol}^{-1})} \right)^{1/2} = 475 \text{ m s}^{-1}$$

where we have used $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$.

Self-test 21.1 Evaluate the root mean square speed of the molecules by integration. You will need the integral

$$\int_0^\infty x^4 e^{-ax^2} dx = \frac{3}{8} \left(\frac{\pi}{a^5} \right)^{1/2} \quad [c = (3RT/M)^{1/2}, 515 \text{ m s}^{-1}]$$

As shown in Example 21.1, we can use the Maxwell distribution to evaluate the **mean speed**, $\bar{c}$, of the molecules in a gas:

$$\bar{c} = \left(\frac{8RT}{\pi M} \right)^{1/2} \quad (21.7)$$

We can identify the **most probable speed**, c^* , from the location of the peak of the distribution:

$$c^* = \left(\frac{2RT}{M} \right)^{1/2} \quad (21.8)$$

Figure 21.6 summarizes these results.

The **relative mean speed**, $\bar{c}_{\text{rel}}$, the mean speed with which one molecule approaches another, can also be calculated from the distribution:

$$\bar{c}_{\text{rel}} = 2^{1/2} \bar{c} \quad (21.9)$$

This result is much harder to derive, but the diagram in Fig. 21.7 should help to show that it is plausible. The last result can also be generalized to the relative mean speed of two dissimilar molecules of masses m_A and m_B :

$$\bar{c}_{\text{rel}} = \left(\frac{8kT}{\pi\mu} \right)^{1/2} \quad \mu = \frac{m_A m_B}{m_A + m_B} \quad (21.10)$$

Note that the molecular masses (not the molar masses) and Boltzmann's constant, $k = R/N_A$, appear in this expression; the quantity μ is called the **reduced mass** of the molecules. Equation 21.10 turns into eqn 21.7 when the molecules are identical (that is, $m_A = m_B = m$, so $\mu = \frac{1}{2}m$).

The Maxwell distribution has been verified experimentally. For example, molecular speeds can be measured directly with a velocity selector (Fig. 21.8). The spinning cylinder has channels that permit the passage of only those molecules moving through them at the appropriate speed, and the number of molecules can be determined by collecting them at a detector.

(b) The collision frequency

A qualitative picture of the events taking place in a gas was first described in Section 1.2. The kinetic model enables us to make that picture more quantitative. In particular,

Fig. 21.7 A simplified version of the argument to show that the mean relative speed of molecules in a gas is related to the mean speed. When the molecules are moving in the same direction, the mean relative speed is zero; it is $2v$ when the molecules are approaching each other. A typical mean direction of approach is from the side, and the mean speed of approach is then $2^{1/2}v$. The last direction of approach is the most characteristic, so the mean speed of approach can be expected to be about $2^{1/2}v$. This value is confirmed by more detailed calculation.

Fig. 21.8 A velocity selector. The molecules are produced in the source (which may be an oven with a small hole in one wall), and travel in a beam towards the rotating channels. Only if the speed of a molecule is such as to carry it along the channel that rotates into its path will it reach the detector. Thus, the number of slow molecules can be counted by rotating the cylinder slowly, and the number of fast molecules counted by rotating the cylinder rapidly.

it enables us to calculate the frequency with which molecular collisions occur and the distance a molecule travels on average between collisions.

We count a 'hit' whenever the centres of two molecules come within a distance d of each other, where d , the **collision diameter**, is of the order of the actual diameters of the molecules (for impenetrable hard spheres d is the diameter). As we show in the following *Justification*, we can use kinetic model to deduce that the **collision frequency**, z , the number of collisions made by one molecule divided by the time interval during which the collisions are counted, when there are N molecules in a volume V is

$$z = \sigma \bar{c}_{\text{rel}} \mathcal{N} \quad (21.11a)^\circ$$

with $\mathcal{N} = N/V$ and $\bar{c}_{\text{rel}}$ given in eqn 21.10. The area $\sigma = \pi d^2$ is called the **collision cross-section** of the molecules. Some typical collision cross-sections are given in Table 21.1 (they are obtained by the techniques described in Section 18.6). In terms of the pressure,

$$z = \frac{\sigma \bar{c}_{\text{rel}} p}{kT} \quad (21.11b)^\circ$$

Justification 21.3 Using the kinetic model to calculate the collision frequency

We consider the positions of all the molecules except one to be frozen. Then we note what happens as one mobile molecule travels through the gas with a mean relative speed $\bar{c}_{\text{rel}}$ for a time Δt . In doing so it sweeps out a 'collision tube' of cross-sectional area $\sigma = \pi d^2$ and length $\bar{c}_{\text{rel}} \Delta t$, and therefore of volume $\sigma \bar{c}_{\text{rel}} \Delta t$ (Fig. 21.9). The number of stationary molecules with centres inside the collision tube is given by the

Synoptic table 21.1* Collision cross-sections

	σ/nm^2
C_6H_6	0.88
CO_2	0.52
He	0.21
N_2	0.43

* More values are given in the *Data section*.

Fig. 21.9 In an interval Δt , a molecule of diameter d sweeps out a tube of radius d and length $\bar{c}_{\text{rel}} \Delta t$. As it does so it encounters other molecules with centres that lie within the tube, and each such encounter counts as one collision. In reality, the tube is not straight, but changes direction at each collision. Nevertheless, the volume swept out is the same, and this straightened version of the tube can be used as a basis of the calculation.

volume of the tube multiplied by the number density $\mathcal{N} = N/V$, and is $\mathcal{N}\bar{\sigma}\bar{c}_{\text{rel}}\Delta t$. The number of hits scored in the interval Δt is equal to this number, so the number of collisions divided by the time interval, is $\mathcal{N}\bar{\sigma}\bar{c}_{\text{rel}}$. The expression in terms of the pressure of the gas is obtained by using the perfect gas equation to write

$$\mathcal{N} = \frac{N}{V} = \frac{nN_A}{V} = \frac{pN_A}{RT} = \frac{p}{kT}$$

Equation 21.11a shows that, at constant volume, the collision frequency increases with increasing temperature. The reason for this increase is that the relative mean speed increases with temperature (eqns 21.9 and 21.10). Equation 21.11b shows that, at constant temperature, the collision frequency is proportional to the pressure. Such a proportionality is plausible, for the greater the pressure, the greater the number density of molecules in the sample, and the rate at which they encounter one another is greater even though their average speed remains the same. For an N_2 molecule in a sample at 1 atm and 25°C , $z \approx 5 \times 10^9 \text{ s}^{-1}$, so a given molecule collides about 5×10^9 times each second. We are beginning to appreciate the timescale of events in gases.

(c) The mean free path

Once we have the collision frequency, we can calculate the **mean free path**, λ (lambda), the average distance a molecule travels between collisions. If a molecule collides with a frequency z , it spends a time $1/z$ in free flight between collisions, and therefore travels a distance $(1/z)\bar{c}$. It follows that the mean free path is

$$\lambda = \frac{\bar{c}}{z} \quad (21.12)$$

Substitution of the expression for z in eqn 21.11b gives

$$\lambda = \frac{kT}{2^{1/2}\sigma p} \quad (21.13)$$

Doubling the pressure reduces the mean free path by half. A typical mean free path in nitrogen gas at 1 atm is 70 nm, or about 10^3 molecular diameters. Although the temperature appears in eqn 21.13, in a sample of constant volume, the pressure is proportional to T , so T/p remains constant when the temperature is increased. Therefore, the mean free path is independent of the temperature in a sample of gas in a container of fixed volume. The distance between collisions is determined by the number of molecules present in the given volume, not by the speed at which they travel.

In summary, a typical gas (N_2 or O_2) at 1 atm and 25°C can be thought of as a collection of molecules travelling with a mean speed of about 500 m s^{-1} . Each molecule makes a collision within about 1 ns, and between collisions it travels about 10^3 molecular diameters. The kinetic model of gases is valid (and the gas behaves nearly perfectly) if the diameter of the molecules is much smaller than the mean free path ($d \ll \lambda$), for then the molecules spend most of their time far from one another.

IMPACT ON ASTROPHYSICS

121.1 The Sun as a ball of perfect gas

The kinetic model of gases is valid when the size of the particles is negligible compared with their mean free path. It may seem absurd, therefore, to expect the kinetic model and, as a consequence, the perfect gas law, to be applicable to the dense matter of stellar interiors. In the Sun, for instance, the density at its centre is 1.50 times that of liquid water and comparable to that of water about half way to its surface. However,

we have to realize that the state of matter is that of a *plasma*, in which the electrons have been stripped from the atoms of hydrogen and helium that make up the bulk of the matter of stars. As a result, the particles making up the plasma have diameters comparable to those of nuclei, or about 10 fm. Therefore, a mean free path of only 0.1 pm satisfies the criterion for the validity of the kinetic theory and the perfect gas law. We can therefore use $pV = nRT$ as the equation of state for the stellar interior.

As for any perfect gas, the pressure in the interior of the Sun is related to the mass density, $\rho = m/V$, by $p = \rho RT/M$. Atoms are stripped of their electrons in the interior of stars so, if we suppose that the interior consists of ionized hydrogen atoms, the mean molar mass is one-half the molar mass of hydrogen, or 0.5 g mol^{-1} (the mean of the molar mass of H^+ and e^- , the latter being virtually 0). Half way to the centre of the Sun, the temperature is 3.6 MK and the mass density is 1.20 g cm^{-3} (slightly denser than water); so the pressure there works out as $7.2 \times 10^{13} \text{ Pa}$, or about 720 million atmospheres.

We can combine this result with the expression for the pressure from the kinetic model (eqn 21.1). Because the total kinetic energy of the particles is $E_K = \frac{1}{2}Nmc^2$, we can write $p = \frac{2}{3}E_K/V$. That is, the pressure of the plasma is related to the *kinetic energy density*, $\rho_K = E_K/V$, the kinetic energy of the molecules in a region divided by the volume of the region, by $p = \frac{2}{3}\rho_K$. It follows that the kinetic energy density half way to the centre of the Sun is about 0.11 GJ cm^{-3} . In contrast, on a warm day (25°C) on Earth, the (translational) kinetic energy density of our atmosphere is only 0.15 J cm^{-3} .

21.2 Collisions with walls and surfaces

The key result for accounting for transport in the gas phase is the rate at which molecules strike an area (which may be an imaginary area embedded in the gas, or part of a real wall). The **collision flux**, Z_W , is the number of collisions with the area in a given time interval divided by the area and the duration of the interval. The **collision frequency**, the number of hits per second, is obtained by multiplication of the collision flux by the area of interest. We show in the *Justification* below that the collision flux is

$$Z_W = \frac{p}{(2\pi mkT)^{1/2}} \quad (21.14)^\circ$$

When $p = 100 \text{ kPa}$ (1.00 bar) and $T = 300 \text{ K}$, $Z_W \approx 3 \times 10^{23} \text{ cm}^{-2} \text{ s}^{-1}$.

Justification 21.4 The collision flux

Consider a wall of area A perpendicular to the x -axis (as in Fig. 21.2). If a molecule has $v_x > 0$ (that is, it is travelling in the direction of positive x), then it will strike the wall within an interval Δt if it lies within a distance $v_x \Delta t$ of the wall. Therefore, all molecules in the volume $Av_x \Delta t$, and with positive x -component of velocities, will strike the wall in the interval Δt . The total number of collisions in this interval is therefore the volume $Av_x \Delta t$ multiplied by the number density, $\mathcal{N}$, of molecules. However, to take account of the presence of a range of velocities in the sample, we must sum the result over all the positive values of v_x weighted by the probability distribution of velocities (eqn 21.6):

$$\text{Number of collisions} = \mathcal{N} A \Delta t \int_0^\infty v_x f(v_x) dx$$

The collision flux is the number of collisions divided by A and Δt , so

$$Z_W = \mathcal{N} \int_0^\infty v_x f(v_x) dx$$

Then, using the velocity distribution in eqn 21.6,

$$\int_0^\infty v_x f(v_x) dv_x = \left(\frac{m}{2\pi kT} \right)^{1/2} \int_0^\infty v_x e^{-mv_x^2/2kT} dv_x = \left(\frac{kT}{2\pi m} \right)^{1/2}$$

where we have used the standard integral

$$\int_0^\infty x e^{-ax^2} dx = \frac{1}{2a}$$

Therefore,

$$Z_W = \mathcal{N} \left(\frac{kT}{2\pi m} \right)^{1/2} = \frac{1}{4} \bar{c} \mathcal{N} \quad (21.15)^\circ$$

where we have used eqn 21.7 in the form $\bar{c} = (8kT/\pi m)^{1/2}$, which implies that $\frac{1}{4}\bar{c} = (kT/2\pi m)^{1/2}$. Substitution of $\mathcal{N} = nN_A/V = p/kT$ gives eqn 21.14.

21.3 The rate of effusion

The essential empirical observations on effusion are summarized by **Graham's law of effusion**, which states that the rate of effusion is inversely proportional to the square root of the molar mass. The basis of this result is that, as remarked above, the mean speed of molecules is inversely proportional to $M^{1/2}$, so the rate at which they strike the area of the hole is also inversely proportional to $M^{1/2}$. However, by using the expression for the rate of collisions, we can obtain a more detailed expression for the rate of effusion and hence use effusion data more effectively.

When a gas at a pressure p and temperature T is separated from a vacuum by a small hole, the rate of escape of its molecules is equal to the rate at which they strike the area of the hole (which is given by eqn 21.14). Therefore, for a hole of area A_0 ,

$$\text{Rate of effusion} = Z_W A = \frac{pA_0}{(2\pi mkT)^{1/2}} = \frac{pA_0 N_A}{(2\pi MRT)^{1/2}} \quad (21.16)^\circ$$

where, in the last step, we have used $R = N_A k$ and $M = mN_A$. This rate is inversely proportional to $M^{1/2}$, in accord with Graham's law.

Equation 21.16 is the basis of the **Knudsen method** for the determination of the vapour pressures of liquids and solids, particularly of substances with very low vapour pressures. Thus, if the vapour pressure of a sample is p , and it is enclosed in a cavity with a small hole, then the rate of loss of mass from the container is proportional to p .

Example 21.2 Calculating the vapour pressure from a mass loss

Caesium (m.p. 29°C, b.p. 686°C) was introduced into a container and heated to 500°C. When a hole of diameter 0.50 mm was opened in the container for 100 s, a mass loss of 385 mg was measured. Calculate the vapour pressure of liquid caesium at 500 K.

Method The pressure of vapour is constant inside the container despite the effusion of atoms because the hot liquid metal replenishes the vapour. The rate of effusion is therefore constant, and given by eqn 21.16. To express the rate in terms of mass, multiply the number of atoms that escape by the mass of each atom.

Answer The mass loss Δm in an interval Δt is related to the collision flux by

$$\Delta m = Z_W A_0 m \Delta t$$

where A_0 is the area of the hole and m is the mass of one atom. It follows that

$$Z_W = \frac{\Delta m}{A_0 m \Delta t}$$

Because Z_W is related to the pressure by eqn 21.14, we can write

$$p = \left(\frac{2\pi RT}{M} \right)^{1/2} \frac{\Delta m}{A_0 \Delta t}$$

Because $M = 132.9 \text{ g mol}^{-1}$, substitution of the data gives $p = 11 \text{ kPa}$ (using $1 \text{ Pa} = 1 \text{ N m}^{-2} = 1 \text{ J m}^{-1}$), or 83 Torr.

Self-test 21.2 How long would it take 1.0 g of Cs atoms to effuse out of the oven under the same conditions? [260 s]

21.4 Transport properties of a perfect gas

Transport properties are commonly expressed in terms of a number of ‘phenomenological’ equations, or equations that are empirical summaries of experimental observations. These phenomenological equations apply to all kinds of properties and media. In the following sections, we introduce the equations for the general case and then show how to calculate the parameters that appear in them.

(a) The phenomenological equations

The rate of migration of a property is measured by its **flux**, J , the quantity of that property passing through a given area in a given time interval divided by the area and the duration of the interval. If matter is flowing (as in diffusion), we speak of a **matter flux** of so many molecules per square metre per second; if the property is energy (as in thermal conduction), then we speak of the **energy flux** and express it in joules per square metre per second, and so on.

Experimental observations on transport properties show that the flux of a property is usually proportional to the first derivative of some other related property. For example, the flux of matter diffusing parallel to the z -axis of a container is found to be proportional to the first derivative of the concentration:

$$J(\text{matter}) \propto \frac{d\mathcal{N}}{dz} \quad (21.17)$$

where $\mathcal{N}$ is the number density of particles with units number per metre cubed (m^{-3}). The SI units of J are number per metre squared per second ($\text{m}^{-2} \text{s}^{-1}$). The proportionality of the flux of matter to the concentration gradient is sometimes called **Fick’s first law of diffusion**: the law implies that, if the concentration varies steeply with position, then diffusion will be fast. There is no net flux if the concentration is uniform ($d\mathcal{N}/dz = 0$). Similarly, the rate of thermal conduction (the flux of the energy associated with thermal motion) is found to be proportional to the temperature gradient:

$$J(\text{energy}) \propto \frac{dT}{dz} \quad (21.18)$$

The SI units of this flux are joules per metre squared per second ($\text{J m}^{-2} \text{s}^{-1}$).

A positive value of J signifies a flux towards positive z ; a negative value of J signifies a flux towards negative z . Because matter flows down a concentration gradient, from high concentration to low concentration, J is positive if $d\mathcal{N}/dz$ is negative (Fig. 21.10).

Fig. 21.10 The flux of particles down a concentration gradient. Fick’s first law states that the flux of matter (the number of particles passing through an imaginary window in a given interval divided by the area of the window and the duration of the interval) is proportional to the density gradient at that point.

Synoptic table 21.2* Transport properties of gases at 1 atm

	$\kappa/(\text{J K}^{-1} \text{m}^{-1} \text{s}^{-1})$	$\eta/(\mu\text{P})^\dagger$	
	273 K	273 K	293 K

CO ₂	0.0145	136	147
He	0.1442	187	196
N ₂	0.0240	166	176

* More values are given in the Data section.
† 1 $\mu\text{P} = 10^{-7} \text{ kg m}^{-1} \text{ s}^{-1}$.

Fig. 21.11 The viscosity of a fluid arises from the transport of linear momentum. In this illustration the fluid is undergoing laminar flow, and particles bring their initial momentum when they enter a new layer. If they arrive with high x -component of momentum they accelerate the layer; if with low x -component of momentum they retard the layer.

Therefore, the coefficient of proportionality in eqn 21.18 must be negative, and we write it $-D$:

$$J(\text{matter}) = -D \frac{d\mathcal{N}}{dz} \quad (21.19)$$

The constant D is called the **diffusion coefficient**; its SI units are metre squared per second ($\text{m}^2 \text{s}^{-1}$). Energy migrates down a temperature gradient, and the same reasoning leads to

$$J(\text{energy}) = -\kappa \frac{dT}{dz} \quad (21.20)$$

where κ is the **coefficient of thermal conductivity**. The SI units of κ are joules per kelvin per metre per second ($\text{J K}^{-1} \text{m}^{-1} \text{s}^{-1}$). Some experimental values are given in Table 21.2.

To see the connection between the flux of momentum and the viscosity, consider a fluid in a state of **Newtonian flow**, which can be imagined as occurring by a series of layers moving past one another (Fig. 21.11). The layer next to the wall of the vessel is stationary, and the velocity of successive layers varies linearly with distance, z , from the wall. Molecules ceaselessly move between the layers and bring with them the x -component of linear momentum they possessed in their original layer. A layer is retarded by molecules arriving from a more slowly moving layer because they have a low momentum in the x -direction. A layer is accelerated by molecules arriving from a more rapidly moving layer. We interpret the net retarding effect as the fluid's viscosity.

Because the retarding effect depends on the transfer of the x -component of linear momentum into the layer of interest, the viscosity depends on the flux of this x -component in the z -direction. The flux of the x -component of momentum is proportional to dv_x/dz because there is no net flux when all the layers move at the same velocity. We can therefore write

$$J(x\text{-component of momentum}) = -\eta \frac{dv_x}{dz} \quad (21.21)$$

The constant of proportionality, η , is the **coefficient of viscosity** (or simply 'the viscosity'). Its units are kilograms per metre per second ($\text{kg m}^{-1} \text{s}^{-1}$). Viscosities are often reported in poise (P), where 1 P = $10^{-1} \text{ kg m}^{-1} \text{s}^{-1}$. Some experimental values are given in Table 21.2.

(b) The transport parameters

As shown in *Further information* 21.1 and summarized in Table 21.3, the kinetic model leads to expressions for the diffusional parameters of a perfect gas.

Table 21.3 Transport properties of perfect gases

Property	Transported quantity	Simple kinetic theory	Units
Diffusion	Matter	$D = \frac{1}{3} \lambda \bar{c}$	$\text{m}^2 \text{s}^{-1}$
Thermal conductivity	Energy	$\kappa = \frac{1}{3} \lambda \bar{c} C_{V,m}[A]$ $= \frac{\bar{c} C_{V,m}}{3\sqrt{2}\sigma N_A}$	$\text{J K}^{-1} \text{m}^{-1} \text{s}^{-1}$
Viscosity	Linear momentum	$\eta = \frac{1}{3} \lambda \bar{c} m \mathcal{N}$ $= \frac{m \bar{c}}{3\sqrt{2}\sigma}$	$\text{kg m}^{-1} \text{s}^{-1}$

The diffusion coefficient is

$$D = \frac{1}{3} \lambda \bar{c} \quad (21.22)^\circ$$

As usual, we need to consider the significance of this expression:

1 The mean free path, λ , decreases as the pressure is increased (eqn 21.13), so D decreases with increasing pressure and, as a result, the gas molecules diffuse more slowly.

2 The mean speed, $\bar{c}$, increases with the temperature (eqn 21.7), so D also increases with temperature. As a result, molecules in a hot sample diffuse more quickly than those in a cool sample (for a given concentration gradient).

3 Because the mean free path increases when the collision cross-section of the molecules decreases (eqn 21.13), the diffusion coefficient is greater for small molecules than for large molecules.

Similarly, according to the kinetic model of gases, the thermal conductivity of a perfect gas A having molar concentration $[A]$ is given by the expression

$$\kappa = \frac{1}{3} \lambda \bar{c} C_{V,m}[A] \quad (21.23)^\circ$$

where $C_{V,m}$ is the molar heat capacity at constant volume. To interpret this expression, we note that:

1 Because λ is inversely proportional to the pressure, and hence inversely proportional to the molar concentration of the gas, the thermal conductivity is independent of the pressure.

2 The thermal conductivity is greater for gases with a high heat capacity because a given temperature gradient then corresponds to a greater energy gradient.

The physical reason for the pressure independence of κ is that the thermal conductivity can be expected to be large when many molecules are available to transport the energy, but the presence of so many molecules limits their mean free path and they cannot carry the energy over a great distance. These two effects balance. The thermal conductivity is indeed found experimentally to be independent of the pressure, except when the pressure is very low, when $\kappa \propto p$. At low pressures λ exceeds the dimensions of the apparatus, and the distance over which the energy is transported is determined by the size of the container and not by the other molecules present. The flux is still proportional to the number of carriers, but the length of the journey no longer depends on λ , so $\kappa \propto [A]$, which implies that $\kappa \propto p$.

Finally, the kinetic model leads to the following expression for the viscosity (see *Further information 21.1*):

$$\eta = \frac{1}{3} M \lambda \bar{c} [A] \quad (21.24)^\circ$$

where $[A]$ is the molar concentration of the gas molecules and M is their molar mass. We can interpret this expression as follows:

1 Because $\lambda \propto 1/p$ (eqn 21.13) and $[A] \propto p$, it follows that $\eta \propto \bar{c}$, independent of p . That is, the viscosity is independent of the pressure

2 Because $\bar{c} \propto T^{1/2}$ (eqn 21.7), $\eta \propto T^{1/2}$. That is, the viscosity of a gas *increases* with temperature.

The physical reason for the pressure-independence of the viscosity is the same as for the thermal conductivity: more molecules are available to transport the momentum, but they carry it less far on account of the decrease in mean free path. The increase of viscosity with temperature is explained when we remember that at high temperatures the molecules travel more quickly, so the flux of momentum is greater. By contrast, as

Fig. 21.12 The experimental results for (a) the pressure dependence of the viscosity of argon, and (b) its temperature dependence. The blue line in the latter is the calculated value. Fitting the observed and calculating curves is one way of determining the collision cross-section.

we shall see in Section 21.6, the viscosity of a liquid *decreases* with increase in temperature because intermolecular interactions must be overcome.

There are two main techniques for measuring viscosities of gases. One technique depends on the rate of damping of the torsional oscillations of a disc hanging in the gas. The half-life of the decay of the oscillation depends on the viscosity and the design of the apparatus, and the apparatus needs to be calibrated. The other method is based on **Poiseuille's formula** for the rate of flow of a fluid through a tube of radius r :

$$\frac{dV}{dt} = \frac{(p_1^2 - p_2^2)\pi r^4}{16l\eta p_0} \quad (21.25)$$

where V is the volume flowing, p_1 and p_2 are the pressures at each end of the tube of length l , and p_0 is the pressure at which the volume is measured.

Such measurements confirm that the viscosities of gases are independent of pressure over a wide range. For instance, the results for argon from 10^{-3} atm to 10^2 atm are shown in Fig. 21.12, and we see that η is constant from about 0.01 atm to 20 atm. The measurements also confirm (to a lesser extent) the $T^{1/2}$ dependence. The blue line in the illustration shows the calculated values using $\sigma = 22 \times 10^{-20} \text{ m}^2$, implying a collision diameter of 260 pm, in contrast to the van der Waals diameter of 335 pm obtained from the density of the solid. The agreement is not too bad, considering the simplicity of the model, especially the neglect of intermolecular forces.

Illustration 21.1 Using the Poiseuille formula

In a Poiseuille flow experiment to measure the viscosity of air at 298 K, the sample was allowed to flow through a tube of length 100 cm and internal diameter 1.00 mm. The high-pressure end was at 765 Torr and the low-pressure end was at 760 Torr. The volume was measured at the latter pressure. In 100 s, 90.2 cm³ of air passed through the tube. The viscosity of air at 298 K is found by reorganizing the Poiseuille formula, eqn 21.25, into

$$\eta = \frac{(p_1^2 - p_2^2)\pi r^4}{16lp_0(dV/dt)}$$

and substituting the data (after converting the pressures to pascals by using 1 Torr = 133.3 Pa):

$$\begin{aligned} \eta &= \frac{\{(765 \times 133.3 \text{ Pa})^2 - (760 \times 133.3 \text{ Pa})^2\} \times \pi \times (5.00 \times 10^{-4} \text{ m})^4}{16 \times (1.00 \times 10^{-1} \text{ m}) \times (760 \times 133.3 \text{ Pa}) \times \left(\frac{9.02 \times 10^{-5} \text{ m}^3}{100 \text{ s}} \right)} \\ &= 1.82 \times 10^{-4} \text{ kg m}^{-1} \text{ s}^{-1} \end{aligned}$$

where we have used $1 \text{ Pa} = 1 \text{ kg m}^{-1} \text{ s}^{-2}$. The kinetic model expression gives $\eta = 1.4 \times 10^{-5} \text{ kg m}^{-1} \text{ s}^{-1}$, so the agreement is reasonably good. Viscosities are commonly expressed in centipoise (cP) or (for gases) micropoise (μP), the conversion being $1 \text{ cP} = 10^{-3} \text{ kg m}^{-1} \text{ s}^{-1}$; the viscosity of air at 20°C is about 180 μP .

Self-test 21.3 What volume would be collected if the pressure gradient were doubled, other conditions remaining constant? [181 cm³]

Molecular motion in liquids

We outlined what is currently known about the structure of simple liquids in Section 17.6. Here we consider a particularly simple type of motion through a liquid, that of an ion, and see that the information that motion provides can be used to infer the behaviour of uncharged species too.

21.5 Experimental results

The motion of molecules in liquids can be studied experimentally by a variety of methods. Relaxation time measurements in NMR and EPR (Chapter 15) can be interpreted in terms of the mobilities of the molecules, and have been used to show that big molecules in viscous fluids typically rotate in a series of small (about 5°) steps, whereas small molecules in nonviscous fluids typically jump through about 1 radian (57°) in each step. Another important technique is **inelastic neutron scattering**, in which the energy neutrons collect or discard as they pass through a sample is interpreted in terms of the motion of its particles. The same technique is used to examine the internal dynamics of macromolecules.

More mundane than these experiments are viscosity measurements (Table 21.4). For a molecule to move in a liquid, it must acquire at least a minimum energy to escape from its neighbours. The probability that a molecule has at least an energy E_a is proportional to $e^{-E_a/RT}$, so the mobility of the molecules in the liquid should follow this type of temperature dependence. Because the coefficient of viscosity, η , is inversely proportional to the mobility of the particles, we should expect that

$$\eta \propto e^{E_a/RT} \quad (21.26)$$

(Note the positive sign of the exponent.) This expression implies that the viscosity should decrease sharply with increasing temperature. Such a variation is found experimentally, at least over reasonably small temperature ranges (Fig. 21.13). The activation energy typical of viscosity is comparable to the mean potential energy of intermolecular interactions.

One problem with the interpretation of viscosity measurements is that the change in density of the liquid as it is heated makes a pronounced contribution to the temperature variation of the viscosity. Thus, the temperature dependence of viscosity at constant volume, when the density is constant, is much less than that at constant pressure. The intermolecular interactions between the molecules of the liquid govern the magnitude of E_a , but the problem of calculating it is immensely difficult and still largely unsolved. At low temperatures, the viscosity of water decreases as the pressure is increased. This behaviour is consistent with the rupture of hydrogen bonds.

21.6 The conductivities of electrolyte solutions

Further insight into the nature of molecular motion can be obtained by studying the motion of ions in solution, for ions can be dragged through the solvent by the application of a potential difference between two electrodes immersed in the sample. By studying the transport of charge through electrolyte solutions it is possible to build up a picture of the events that occur in them and, in some cases, to extrapolate the conclusions to species that have zero charge, that is, to neutral molecules.

(a) Conductance and conductivity

The fundamental measurement used to study the motion of ions is that of the electrical resistance, R , of the solution. The **conductance**, G , of a solution is the inverse of its

Synoptic table 21.4* Viscosities of liquids at 298 K

	$\eta/(10^{-3} \text{ kg m}^{-1} \text{ s}^{-1})$

[†] The viscosity of water corresponds to 0.891 cP.

Fig. 21.13 The experimental temperature dependence of the viscosity of water. As the temperature is increased, more molecules are able to escape from the potential wells provided by their neighbours, and so the liquid becomes more fluid. A plot of $\ln \eta$ against $1/T$ is a straight line (over a small range) with positive slope.

resistance R : $G = 1/R$. As resistance is expressed in ohms, Ω , the conductance of a sample is expressed in Ω^{-1} . The reciprocal ohm used to be called the mho, but its official designation is now the siemens, S, and $1\text{ S} = 1\text{ }\Omega^{-1} = 1\text{ C V}^{-1}\text{ s}^{-1}$. The conductance of a sample decreases with its length l and increases with its cross-sectional area A . We therefore write

$$G = \frac{\kappa A}{l} \quad (21.27)$$

where κ is the **conductivity**. With the conductance in siemens and the dimensions in metres, it follows that the SI units of κ are siemens per metre (S m^{-1}).

The conductivity of a solution depends on the number of ions present, and it is normal to introduce the **molar conductivity**, Λ_m , which is defined as

$$\Lambda_m = \frac{\kappa}{c} \quad (21.28)$$

where c is the molar concentration of the added electrolyte. The SI unit of molar conductivity is siemens metre-squared per mole ($\text{S m}^2\text{ mol}^{-1}$), and typical values are about $10\text{ mS m}^2\text{ mol}^{-1}$ (where $1\text{ mS} = 10^{-3}\text{ S}$).

The molar conductivity is found to vary with the concentration. One reason for this variation is that the number of ions in the solution might not be proportional to the concentration of the electrolyte. For instance, the concentration of ions in a solution of a weak acid depends on the concentration of the acid in a complicated way, and doubling the concentration of the acid added does not double the number of ions. Secondly, because ions interact strongly with one another, the conductivity of a solution is not exactly proportional to the number of ions present.

The concentration dependence of molar conductivities indicates that there are two classes of electrolyte. The characteristic of a **strong electrolyte** is that its molar conductivity depends only slightly on the molar concentration (and in general decreases slightly as the concentration is increased, Fig. 21.14). The characteristic of a **weak electrolyte** is that its molar conductivity is normal at concentrations close to zero, but falls sharply to low values as the concentration increases. The classification depends on the solvent employed as well as the solute: lithium chloride, for example, is a strong electrolyte in water but a weak electrolyte in propanone.

Fig. 21.14 The concentration dependence of the molar conductivities of (a) a typical strong electrolyte (aqueous potassium chloride) and (b) a typical weak electrolyte (aqueous acetic acid).

(b) Strong electrolytes

Strong electrolytes are substances that are virtually fully ionized in solution, and include ionic solids and strong acids. As a result of their complete ionization, the concentration of ions in solution is proportional to the concentration of strong electrolyte added.

In an extensive series of measurements during the nineteenth century, Friedrich Kohlrausch showed that at low concentrations the molar conductivities of strong electrolytes vary linearly with the square root of the concentration:

$$\Lambda_m = \Lambda_m^\circ - \mathcal{K}c^{1/2} \quad (21.29)$$

This variation is called **Kohlrausch's law**. The constant Λ_m° is the **limiting molar conductivity**, the molar conductivity in the limit of zero concentration (when the ions are effectively infinitely far apart and do not interact with one another). The constant $\mathcal{K}$ is found to depend more on the stoichiometry of the electrolyte (that is, whether it is of the form MA, or M_2A , etc.) than on its specific identity. In due course we shall see that the $c^{1/2}$ dependence arises from interactions between ions: when charge is conducted ionically, ions of one charge are moving past the ions of interest and retard its progress.

Synoptic table 21.5* Limiting ionic conductivities in water at 298 K

	$\lambda/(\text{mS m}^2 \text{mol}^{-1})$		$\lambda/(\text{mS m}^2 \text{mol}^{-1})$
H^+	34.96	OH^-	19.91
Na^+	5.01	Cl^-	7.63
K^+	7.35	Br^-	7.81
Zn^{2+}	10.56	SO_4^{2-}	16.00

* More values are given in the *Data section*.

Kohlrausch was also able to establish experimentally that Λ_m° can be expressed as the sum of contributions from its individual ions. If the limiting molar conductivity of the cations is denoted λ_+ and that of the anions λ_- , then his **law of the independent migration of ions** states that

$$\Lambda_m^\circ = \nu_+ \lambda_+ + \nu_- \lambda_- \quad (21.30)^\circ$$

where ν_+ and ν_- are the numbers of cations and anions per formula unit of electrolyte (for example, $\nu_+ = \nu_- = 1$ for HCl, NaCl, and CuSO_4 , but $\nu_+ = 1$, $\nu_- = 2$ for MgCl_2). This simple result, which can be understood on the grounds that the ions migrate independently in the limit of zero concentration, lets us predict the limiting molar conductivity of any strong electrolyte from the data in Table 21.5.

Illustration 21.2 Calculating a limiting molar conductivity

The limiting molar conductivity of BaCl_2 in water at 298 K is

$$\Lambda_m^\circ = (12.72 + 2 \times 7.63) \text{ mS m}^2 \text{mol}^{-1} = 27.98 \text{ mS m}^2 \text{mol}^{-1}$$

(c) Weak electrolytes

Weak electrolytes are not fully ionized in solution. They include weak Brønsted acids and bases, such as CH_3COOH and NH_3 . The marked concentration dependence of their molar conductivities arises from the displacement of the equilibrium

towards products at low molar concentrations.

The conductivity depends on the number of ions in the solution, and therefore on the **degree of ionization**, α , of the electrolyte; when referring to weak acids, we speak instead of the **degree of deprotonation**. It is defined so that, for the acid HA at a molar concentration c , at equilibrium

$$[\text{H}_3\text{O}^+] = \alpha c \quad [\text{A}^-] = \alpha c \quad [\text{HA}] = (1 - \alpha)c \quad (21.32)$$

If we ignore activity coefficients, the acidity constant, K_a , is approximately

$$K_a = \frac{\alpha^2 c}{1 - \alpha} \quad (21.33)^\circ$$

from which it follows that

$$\alpha = \frac{K_a}{2c} \left\{ \left(1 + \frac{4c}{K_a} \right)^{1/2} - 1 \right\} \quad (21.34)^\circ$$

Comment 21.2

It will be familiar from introductory chemistry that a *Brønsted acid* is a proton donor and a *Brønsted base* is a proton acceptor. In eqn 21.31, $\text{HA}(\text{aq})$ is a Brønsted acid and $\text{H}_2\text{O}(\text{l})$ is a Brønsted base. The equilibrium constant for the reaction between $\text{HA}(\text{aq})$ and $\text{H}_2\text{O}(\text{l})$ is the *acidity constant* K_a of HA. Acids with $K_a < 1$, indicating only a small extent of deprotonation in water, are classified as *weak acids*.

The acid is fully deprotonated at infinite dilution, and its molar conductivity is then Λ_m° . Because only a fraction α is actually present as ions in the actual solution, the measured molar conductivity Λ_m is given by

$$\Lambda_m = \alpha \Lambda_m^\circ \quad (21.35)^\circ$$

with α given by eqn 21.34.

Illustration 21.3 Using molar conductivity data to calculate an acidity constant

The molar conductivity of 0.0100 M $\text{CH}_3\text{COOH}(\text{aq})$ at 298 K is $\Lambda_m = 1.65 \text{ mS m}^2 \text{ mol}^{-1}$. The degree of deprotonation, α , is calculated from eqn 21.35 with $\Lambda_m^\circ = 39.05 \text{ mS cm}^2 \text{ mol}^{-1}$ (Table 21.5). It follows that $\alpha = 0.0423$. The acidity constant, K_a , is calculated by substitution of α into eqn 21.33, which gives $K_a = 1.9 \times 10^{-5}$.

Self-test 21.4 The molar conductivity of 0.0250 M $\text{HCOOH}(\text{aq})$ is $4.61 \text{ mS m}^2 \text{ mol}^{-1}$. Determine the $\text{p}K_a = -\log K_a$ of the acid. [3.44]

Fig. 21.15 The graph used to determine the limiting value of the molar conductivity of a solution by extrapolation to zero concentration.

Once we know K_a , we can use eqns 21.34 and 21.35 to predict the concentration dependence of the molar conductivity. The result agrees quite well with the experimental curve in Fig. 21.14. More usefully, we can use the concentration dependence of Λ_m in measurements of the limiting molar conductance. First, we rearrange eqn 21.33 into

$$\frac{1}{\alpha} = 1 + \frac{\alpha c}{K_a} \quad (21.36)^\circ$$

Then, by using eqn 21.35, we obtain **Ostwald's dilution law**:

$$\frac{1}{\Lambda_m} = \frac{1}{\Lambda_m^\circ} + \frac{\Lambda_m c}{K_a (\Lambda_m^\circ)^2} \quad (21.37)^\circ$$

This equation implies that, if $1/\Lambda_m$ is plotted against $c\Lambda_m$, then the intercept at $c = 0$ will be $1/\Lambda_m^\circ$ (Fig. 21.15).

21.7 The mobilities of ions

To interpret conductivity measurements we need to know why ions move at different rates, why they have different molar conductivities, and why the molar conductivities of strong electrolytes decrease with the square root of the molar concentration. The central idea in this section is that, although the motion of an ion remains largely random, the presence of an electric field biases its motion, and the ion undergoes net migration through the solution.

(a) The drift speed

When the potential difference between two electrodes a distance l apart is $\Delta\phi$, the ions in the solution between them experience a uniform electric field of magnitude

$$\mathcal{E} = \frac{\Delta\phi}{l} \quad (21.38)$$

In such a field, an ion of charge ze experiences a force of magnitude

$$\mathcal{F} = ze\mathcal{E} = \frac{ze\Delta\phi}{l} \quad (21.39)$$

Synoptic table 21.6* Ionic mobilities in water at 298 K

	$u/(10^{-8} \text{ m}^2 \text{ s}^{-1} \text{ V}^{-1})$		$u/(10^{-8} \text{ m}^2 \text{ s}^{-1} \text{ V}^{-1})$
H^+	36.23	OH^-	20.64
Na^+	5.19	Cl^-	7.91
K^+	7.62	Br^-	8.09
Zn^{2+}	5.47	SO_4^{2-}	8.29

* More values are given in the *Data section*.

(In this chapter we disregard the sign of the charge number and so avoid notational complications.) A cation responds to the application of the field by accelerating towards the negative electrode and an anion responds by accelerating towards the positive electrode. However, this acceleration is short-lived. As the ion moves through the solvent it experiences a frictional retarding force, $\mathcal{F}_{\text{fric}}$, proportional to its speed. If we assume that the Stokes formula (eqn 19.12) for a sphere of radius a and speed s applies even on a microscopic scale (and independent evidence from magnetic resonance suggests that it often gives at least the right order of magnitude), then we can write this retarding force as

$$\mathcal{F}_{\text{fric}} = fs \quad f = 6\pi\eta a \quad (21.40)$$

The two forces act in opposite directions, and the ions quickly reach a terminal speed, the **drift speed**, when the accelerating force is balanced by the viscous drag. The net force is zero when

$$s = \frac{ze\mathcal{E}}{f} \quad (21.41)$$

It follows that the drift speed of an ion is proportional to the strength of the applied field. We write

$$s = u\mathcal{E} \quad [21.42]$$

where u is called the **mobility** of the ion (Table 21.6). Comparison of eqns 21.41 and 21.42 and use of eqn 21.40 shows that

$$u = \frac{ze}{f} = \frac{ze}{6\pi\eta a} \quad (21.43)$$

Illustration 21.4 Calculating an ionic mobility

For an order of magnitude estimate we can take $z = 1$ and a the radius of an ion such as Cs^+ (which might be typical of a smaller ion plus its hydration sphere), which is 170 pm. For the viscosity, we use $\eta = 1.0 \text{ cP}$ ($1.0 \times 10^{-3} \text{ kg m}^{-1} \text{ s}^{-1}$, Table 21.4). Then $u \approx 5 \times 10^{-8} \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$. This value means that, when there is a potential difference of 1 V across a solution of length 1 cm (so $\mathcal{E} = 100 \text{ V m}^{-1}$), the drift speed is typically about $5 \mu\text{m s}^{-1}$. That speed might seem slow, but not when expressed on a molecular scale, for it corresponds to an ion passing about 10^4 solvent molecules per second.

Fig. 21.16 The mechanism of conduction by hydrogen ions in water as proposed by N. Agmon (*Chem. Phys. Letts.* **244**, 456 (1995)). Proton transfer between neighbouring molecules occurs when one molecule rotates into such a position that an O—H...O hydrogen bond can flip into being an O...H—O hydrogen bond. See text for a description of the steps.

Because the drift speed governs the rate at which charge is transported, we might expect the conductivity to decrease with increasing solution viscosity and ion size. Experiments confirm these predictions for bulky ions (such as R_4N^+ and RCO_2^-) but not for small ions. For example, the molar conductivities of the alkali metal ions increase from Li^+ to Cs^+ (Table 21.6) even though the ionic radii increase. The paradox is resolved when we realize that the radius a in the Stokes formula is the **hydrodynamic radius** (or ‘Stokes radius’) of the ion, its effective radius in the solution taking into account all the H_2O molecules it carries in its hydration sphere. Small ions give rise to stronger electric fields than large ones (the electric field at the surface of a sphere of radius r is proportional to ze/r^2 and it follows that the smaller the radius the stronger the field), so small ions are more extensively solvated than big ions. Thus, an ion of small ionic radius may have a large hydrodynamic radius because it drags many solvent molecules through the solution as it migrates. The hydrating H_2O molecules are often very labile, however, and NMR and isotope studies have shown that the exchange between the coordination sphere of the ion and the bulk solvent is very rapid.

The proton, although it is very small, has a very high molar conductivity (Table 21.6)! Proton and ^{17}O -NMR show that the times characteristic of protons hopping from one molecule to the next are about 1.5 ps, which is comparable to the time that inelastic neutron scattering shows it takes a water molecule to reorientate through about 1 rad (1 to 2 ps). According to the **Grotthuss mechanism**, there is an effective motion of a proton that involves the rearrangement of bonds in a group of water molecules. However, the actual mechanism is still highly contentious. Attention now focuses on the $H_9O_4^+$ unit, in which the nearly trigonal planar H_3O^+ ion is linked to three strongly solvating H_2O molecules. This cluster of atoms is itself hydrated, but the hydrogen bonds in the secondary sphere are weaker than in the primary sphere. It is envisaged that the rate-determining step is the cleavage of one of the weaker hydrogen bonds of this secondary sphere (Fig. 21.16a). After this bond cleavage has taken place, and the released molecule has rotated through a few degrees (a process that takes about 1 ps), there is a rapid adjustment of bond lengths and angles in the remaining cluster, to form an $H_5O_2^+$ cation of structure $H_2O \cdots H^+ \cdots OH_2$ (Fig. 21.16b). Shortly after this reorganization has occurred, a new $H_9O_4^+$ cluster forms as other molecules rotate into a position where they can become members of a secondary hydration sphere, but now the positive charge is located one molecule to the right of its initial location (Fig. 21.16c). According to this model, there is no coordinated motion of a proton along a chain of molecules, simply a very rapid hopping between neighbouring sites, with a low activation energy. The model is consistent with the observation that the molar conductivity of protons increases as the pressure is raised, for increasing pressure ruptures the hydrogen bonds in water. The mobility of NH_4^+ is also anomalous and presumably occurs by an analogous mechanism.

Comment 21.3

The H_3O^+ ion is trigonal pyramidal in the gas phase but nearly planar in water.

(b) Mobility and conductivity

Ionic mobilities provide a link between measurable and theoretical quantities. As a first step we establish in the *Justification* below the following relation between an ion’s mobility and its molar conductivity:

$$\lambda = zuF \quad (21.44)^\circ$$

where F is Faraday’s constant ($F = N_A e$).

Justification 21.5 *The relation between ionic mobility and molar conductivity*

To keep the calculation simple, we ignore signs in the following, and concentrate on the magnitudes of quantities: the direction of ion flux can always be decided by common sense.

Consider a solution of a fully dissociated strong electrolyte at a molar concentration c . Let each formula unit give rise to v_+ cations of charge z_+e and v_- anions of charge z_-e . The molar concentration of each type of ion is therefore vc (with $v = v_+$ or v_-), and the number density of each type is vcN_A . The number of ions of one kind that pass through an imaginary window of area A during an interval Δt is equal to the number within the distance $s\Delta t$ (Fig. 21.17), and therefore to the number in the volume $s\Delta tA$. (The same sort of argument was used in Section 21.1 in the discussion of the pressure of a gas.) The number of ions of that kind in this volume is equal to $s\Delta tAvcN_A$. The flux through the window (the number of this type of ion passing through the window divided by the area of the window and the duration of the interval) is therefore

$$J(\text{ions}) = \frac{s\Delta tAvcN_A}{A\Delta t} = svcN_A$$

Each ion carries a charge ze , so the flux of charge is

$$J(\text{charge}) = zsvceN_A = zsvcF$$

Because $s = uE$, the flux is

$$J(\text{charge}) = zuvcFE$$

The current, I , through the window due to the ions we are considering is the charge flux times the area:

$$I = JA = zuvcFEA$$

Because the electric field is the potential gradient, $\Delta\phi/l$, we can write

$$I = \frac{zuvcFA\Delta\phi}{l} \quad (21.45)$$

Current and potential difference are related by Ohm's law, $\Delta\phi = IR$, so it follows that

$$I = \frac{\Delta\phi}{R} = G\Delta\phi = \frac{\kappa A\Delta\phi}{l}$$

where we have used eqn 21.27 in the form $\kappa = Gl/A$. Note that the proportionality of current to potential difference ($I \propto \Delta\phi$) is another example of a phenomenological flux equation like those introduced in Section 21.4. Comparison of the last two expressions gives $\kappa = zuvcF$. Division by the molar concentration of ions, vc , then results in eqn 21.44.

Fig. 21.17 In the calculation of the current, all the cations within a distance $s_+\Delta t$ (that is, those in the volume $s_+A\Delta t$) will pass through the area A . The anions in the corresponding volume the other side of the window will also contribute to the current similarly.

Equation 21.44 applies to the cations and to the anions. Therefore, for the solution itself in the limit of zero concentration (when there are no interionic interactions),

$$\Lambda_m^\circ = (z_+u_+v_+ + z_-u_-v_-)F \quad (21.46a)^\circ$$

For a symmetrical $z:z$ electrolyte (for example, CuSO_4 with $z = 2$), this equation simplifies to

$$\Lambda_m^\circ = z(u_+ + u_-)F \quad (21.46b)^\circ$$

Illustration 21.5 Estimating a limiting molar conductivity

Earlier, we estimated the typical ionic mobility as $5 \times 10^{-8} \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$; so, with $z = 1$ for both the cation and anion, we can estimate that a typical limiting molar conductivity should be about $10 \text{ mS m}^2 \text{ mol}^{-1}$, in accord with experiment. The experimental value for KCl, for instance, is $15 \text{ mS m}^2 \text{ mol}^{-1}$.

(c) Transport numbers

The **transport number**, $t_{\pm}$, is defined as the fraction of total current carried by the ions of a specified type. For a solution of two kinds of ion, the transport numbers of the cations (t_{+}) and anions (t_{-}) are

$$t_{\pm} = \frac{I_{\pm}}{I} \quad [21.47]$$

where $I_{\pm}$ is the current carried by the cation (I_{+}) or anion (I_{-}) and I is the total current through the solution. Because the total current is the sum of the cation and anion currents, it follows that

$$t_{+} + t_{-} = 1 \quad (21.48)$$

The **limiting transport number**, $t_{\pm}^{\circ}$, is defined in the same way but for the limit of zero concentration of the electrolyte solution. We shall consider only these limiting values from now on, for that avoids the problem of ionic interactions.

The current that can be ascribed to each type of ion is related to the mobility of the ion by eqn 21.45. Hence the relation between $t_{\pm}^{\circ}$ and $u_{\pm}$ is

$$t_{\pm}^{\circ} = \frac{z_{\pm} v_{\pm} u_{\pm}}{z_{+} v_{+} u_{+} + z_{-} v_{-} u_{-}} \quad (21.49a)^{\circ}$$

However, because $z_{+} v_{+} = z_{-} v_{-}$ for any electrolyte, eqn 21.49a simplifies to

$$t_{\pm}^{\circ} = \frac{u_{\pm}}{u_{+} + u_{-}} \quad (21.49b)^{\circ}$$

Moreover, because the ionic conductivities are related to the mobilities by eqn 21.44, it also follows from eqn 21.49b that

$$t_{\pm}^{\circ} = \frac{v_{\pm} \lambda_{\pm}}{v_{+} \lambda_{+} + v_{-} \lambda_{-}} = \frac{v_{\pm} \lambda_{\pm}}{\Lambda_m^{\circ}} \quad (21.50)^{\circ}$$

and hence, for each type of ion,

$$v_{\pm} \lambda_{\pm} = t_{\pm}^{\circ} \Lambda_m^{\circ} \quad (21.51)^{\circ}$$

Consequently, because there are independent ways of measuring transport numbers of ions, we can determine the individual ionic conductivities and (through eqn 21.44) the ionic mobilities.

There are several ways to measure transport numbers (see *Further reading*). One of the most accurate (and the only one we describe in detail) is the **moving boundary method**, in which the motion of a boundary between two ionic solutions having a common ion is observed as a current flows.

Let MX be the salt of interest and NX a salt giving a denser solution. The solution of NX is called the **indicator solution**; it occupies the lower part of a vertical tube of cross-sectional area A (Fig. 21.18). The MX solution, which is called the **leading**

Fig. 21.18 In the moving boundary method for the measurement of transport numbers the distance moved by the boundary is observed as a current is passed. All the M ions in the volume between AB and CD must have passed through CD if the boundary moves from AB to CD. One procedure is to add bromothymol blue indicator to a slightly alkaline solution of the ion of interest and to use a cadmium electrode at the lower end of the vertical tube. The electrode produces Cd^{2+} ions, which are slow moving and slightly acidic (the hydrated ion is a Brønsted acid), and the boundary is revealed by the colour change of the indicator.

solution, occupies the upper part of the tube. There is a sharp boundary between the two solutions. The indicator solution must be denser than the leading solution, and the mobility of the M ions must be greater than that of the N ions. Thus, if any M ions diffuse into the lower solution, they will be pulled upwards more rapidly than the N ions around them, and the boundary will reform. When a current I is passed for a time Δt , the boundary moves from AB to CD, so all the M ions in the volume between AB and CD must have passed through CD. That number is $c l A N_A$, so the charge that the M ions transfer through the plane is $z_+ c l A e N_A$. However, the *total* charge transferred when a current I flows for an interval Δt is $I \Delta t$. Therefore, the fraction due to the motion of the M ions, which is their transport number, is

$$t_+ = \frac{z_+ c l A F}{I \Delta t} \quad (21.52)$$

Hence, by measuring the distance moved, the transport number and hence the conductivity and mobility of the ions can be determined.

21.8 Conductivities and ion-ion interactions

The remaining problem is to account for the $c^{1/2}$ dependence of the Kohlrausch law (eqn 21.29). In Section 5.9 we saw something similar: the activity coefficients of ions at low concentrations also depend on $c^{1/2}$ and depend on their charge type rather than their specific identities. That $c^{1/2}$ dependence was explained in terms of the properties of the ionic atmosphere around each ion, and we can suspect that the same explanation applies here too.

To accommodate the effect of motion, we need to modify the picture of an ionic atmosphere as a spherical haze of charge. Because the ions forming the atmosphere do not adjust to the moving ion immediately, the atmosphere is incompletely formed in front of the moving ion and incompletely decayed behind the ion (Fig. 21.19). The overall effect is the displacement of the centre of charge of the atmosphere a short distance behind the moving ion. Because the two charges are opposite, the result is a retardation of the moving ion. This reduction of the ions' mobility is called the **relaxation effect**. A confirmation of the picture is obtained by observing the conductivities of ions at high frequencies, which are greater than at low frequencies: the atmosphere does not have time to follow the rapidly changing direction of motion of the ion, and the effect of the field averages to zero.

The ionic atmosphere has another effect on the motion of the ions. We have seen that the moving ion experiences a viscous drag. When the ionic atmosphere is present this drag is enhanced because the ionic atmosphere moves in an opposite direction to the central ion. The enhanced viscous drag, which is called the **electrophoretic effect**, reduces the mobility of the ions, and hence also reduces their conductivities.

The quantitative formulation of these effects is far from simple, but the **Debye-Hückel-Onsager theory** is an attempt to obtain quantitative expressions at about the same level of sophistication as the Debye-Hückel theory itself. The theory leads to a Kohlrausch-like expression in which

$$\mathcal{K} = A + B \Lambda_m^\circ \quad (21.53a)$$

with

$$A = \frac{z^2 e F^2}{3 \pi \eta} \left(\frac{2}{\epsilon R T} \right)^{1/2} \quad B = \frac{q z^3 e F}{24 \pi \epsilon R T} \left(\frac{2}{\epsilon R T} \right)^{1/2} \quad (21.53b)$$

where ϵ is the electric permittivity of the solvent (Section 18.3) and $q = 0.586$ for a 1,1-electrolyte (Table 21.7). The slopes of the conductivity curves are predicted to depend

Fig. 21.19 (a) In the absence of an applied field, the ionic atmosphere is spherically symmetric, but (b) when a field is present it is distorted and the centres of negative and positive charge no longer coincide. The attraction between the opposite charges retards the motion of the central ion.

Fig. 21.20 The dependence of molar conductivities on the square root of the ionic strength, and comparison (straight lines) with the dependence predicted by the Debye–Hückel–Onsager theory.

on the charge type of the electrolyte, in accord with the Kohlrausch law, and some comparisons between theory and experiment are shown in Fig. 21.20. The agreement is quite good at very low ionic strengths, corresponding to very low molar concentrations (less than about 10^{-3} M, depending on the charge type).

IMPACT ON BIOCHEMISTRY
I21.2 Ion channels and ion pumps

Controlled transport of molecules and ions across biological membranes is at the heart of a number of key cellular processes, such as the transmission of nerve impulses, the transfer of glucose into red blood cells, and the synthesis of ATP by oxidative phosphorylation (Impact I7.2). Here we examine in some detail the various ways in which ions cross the alien environment of the lipid bilayer.

Suppose that a membrane provides a barrier that slows down the transfer of molecules or ions into or out of the cell. We saw in Impact I7.2 that the thermodynamic tendency to transport an ion through the membrane is partially determined by a concentration gradient (more precisely, an activity gradient) across the membrane, which results in a difference in molar Gibbs energy between the inside and the outside of the cell, and a transmembrane potential gradient, which is due to the different potential energy of the ions on each side of the bilayer. There is a tendency, called **passive transport**, for a species to move down concentration and membrane potential gradients. It is also possible to move a species against these gradients, but now the flow must be driven by an exergonic process, such as the hydrolysis of ATP. This process is called **active transport**.

The transport of ions into or out of a cell needs to be mediated (that is, facilitated by other species) because the hydrophobic environment of the membrane is inhospitable to ions. There are two mechanisms for ion transport: mediation by a carrier molecule and transport through a **channel former**, a protein that creates a hydrophilic pore through which the ion can pass. An example of a channel former is the polypeptide gramicidin A, which increases the membrane permeability to cations such as H^+ , K^+ , and Na^+ .

Ion channels are proteins that effect the movement of specific ions down a membrane potential gradient. They are highly selective, so there is a channel protein for Ca^{2+} , another for Cl^- , and so on. The opening of the gate may be triggered by potential differences between the two sides of the membrane or by the binding of an *effector* molecule to a specific receptor site on the channel.

Ions such as H^+ , Na^+ , K^+ , and Ca^{2+} are often transported actively across membranes by integral proteins called **ion pumps**. Ion pumps are molecular machines that work by adopting conformations that are permeable to one ion but not others depending on the state of phosphorylation of the protein. Because protein phosphorylation requires dephosphorylation of ATP, the conformational change that opens or closes the pump is endergonic and requires the use of energy stored during metabolism.

Let's consider some of the experimental approaches used in the study of ion channels. The structures of a number of channel proteins have been obtained by the now traditional X-ray diffraction techniques described in Chapter 20. Information about the flow of ions across channels and pumps is supplied by the **patch clamp technique**. One of many possible experimental arrangements is shown in Fig. 21.21. With mild suction, a 'patch' of membrane from a whole cell or a small section of a broken cell can be attached tightly to the tip of a micropipette filled with an electrolyte solution and containing an electronic conductor, the so-called *patch electrode*. A potential difference (the 'clamp') is applied between the patch electrode and an intracellular electronic conductor in contact with the cytosol of the cell. If the membrane is permeable to ions at the applied potential difference, a current flows through the completed circuit. Using narrow micropipette tips with diameters of less than $1\ \mu\text{m}$, ion currents of a few picoamperes ($1\ \text{pA} = 10^{-12}\ \text{A}$) have been measured across sections of membranes containing only one ion channel protein.

A detailed picture of the mechanism of action of ion channels has emerged from analysis of patch clamp data and structural data. Here we focus on the K^+ ion channel protein, which, like all other mediators of ion transport, spans the membrane bilayer (Fig. 21.22). The pore through which ions move has a length of 3.4 nm and is divided into two regions: a wide region with a length of 2.2 nm and diameter of 1.0 nm and a narrow region with a length of 1.2 nm and diameter of 0.3 nm. The narrow region is called the *selectivity filter* of the K^+ ion channel because it allows only K^+ ions to pass.

Filtering is a subtle process that depends on ionic size and the thermodynamic tendency of an ion to lose its hydrating water molecules. Upon entering the selectivity filter, the K^+ ion is stripped of its hydrating shell and is then gripped by carbonyl groups of the protein. Dehydration of the K^+ ion is endergonic ($\Delta_{\text{dehyd}}G^\circ = +203\ \text{kJ mol}^{-1}$), but is driven by the energy of interaction between the ion and the protein. The Na^+ ion, though smaller than the K^+ ion, does not pass through the selectivity filter of the K^+ ion channel because interactions with the protein are not sufficient to compensate for the high Gibbs energy of dehydration of Na^+ ($\Delta_{\text{dehyd}}G^\circ = +301\ \text{kJ mol}^{-1}$). More specifically, a dehydrated Na^+ ion is too small and cannot be held tightly by the protein carbonyl groups, which are positioned for ideal interactions with the larger K^+ ion. In its hydrated form, the Na^+ ion is too large (larger than a dehydrated K^+ ion), does not fit in the selectivity filter, and does not cross the membrane.

Though very selective, a K^+ ion channel can still let other ions pass through. For example, K^+ and Tl^+ ions have similar radii and Gibbs energies of dehydration, so Tl^+ can cross the membrane. As a result, Tl^+ is a neurotoxin because it replaces K^+ in many neuronal functions.

The efficiency of transfer of K^+ ions through the channel can also be explained by structural features of the protein. For efficient transport to occur, a K^+ ion must enter the protein, but then must not be allowed to remain inside for very long so that, as one K^+ ion enters the channel from one side, another K^+ ion leaves from the opposite side. An ion is lured into the channel by water molecules about halfway through the length of the membrane. Consequently, the thermodynamic cost of moving an ion from an aqueous environment to the less hydrophilic interior of the protein is minimized. The ion is 'encouraged' to leave the protein by electrostatic interactions in the selectivity filter, which can bind two K^+ ions simultaneously, usually with a bridging water molecule. Electrostatic repulsion prevents the ions from binding too tightly, minimizing the residence time of an ion in the selectivity filter, and maximizing the transport rate.

Now we turn our attention to a very important ion pump, the H^+ -ATPase responsible for coupling of proton flow to synthesis of ATP from ADP and P_i (Impact I7.2). Structural studies show that the channel through which the protons flow is linked in

Fig. 21.21 A representation of the patch clamp technique for the measurement of ionic currents through membranes in intact cells. A section of membrane containing an ion channel (shown as a green rectangle) is in tight contact with the tip of a micropipette containing an electrolyte solution and the patch electrode. An intracellular electronic conductor is inserted into the cytosol of the cell and the two conductors are connected to a power supply and current measuring device.

Fig. 21.22 A schematic representation of the cross-section of a membrane-spanning K^+ ion channel protein. The bulk of the protein is shown in beige. The pore through which ions move is divided into two regions: a wide region with a length of 2.2 nm and diameter of 1.0 nm, and a narrow region, the *selectivity filter*, with a length of 1.2 nm and diameter of 0.3 nm. The selectivity filter has a number of carbonyl groups (shown in dark green) that grip K^+ ions. As explained in the text, electrostatic repulsions between two bound K^+ ions ‘encourage’ ionic movement through the selectivity filter and across the membrane.

Fig. 21.23 The mechanism of action of H^+ -ATPase, a molecular motor that transports protons across the mitochondrial membrane and catalyses either the formation or hydrolysis of ATP.

tandem to a unit composed of six protein molecules arranged in pairs of α and β subunits to form three interlocked $\alpha\beta$ segments (Fig. 21.23). The conformations of the three pairs may be loose (L), tight (T), or open (O), and one of each type is present at each stage. A protein at the centre of the interlocked structure, the γ subunit shown as a white arrow, rotates and induces structural changes that cycle each of the three segments between L, T, and O conformations. At the start of a cycle, a T unit holds an ATP molecule. Then ADP and a P_i group migrate into the L site and, as it closes into T, the earlier T site opens into O and releases its ATP. The ADP and P_i in the T site meanwhile condense into ATP, and the new L site is ready for the cycle to begin again. The proton flux drives the rotation of the γ subunit, and hence the conformational changes of the α/β segments, as well as providing the energy for the condensation reaction itself. Several key aspects of this mechanism have been confirmed experimentally. For example, the rotation of the γ subunit has been observed directly by using single-molecule spectroscopy (Section 14.6).

Diffusion

We are now in a position to extend the discussion of ionic motion to cover the migration of neutral molecules and of ions in the absence of an applied electric field. We shall do this by expressing ion motion in a more general way than hitherto, and will then discover that the same equations apply even when the charge on the particles is zero.

21.9 The thermodynamic view

We saw in Part 1 that, at constant temperature and pressure, the maximum non-expansion work that can be done per mole when a substance moves from a location where its chemical potential is μ to a location where its chemical potential is $\mu + d\mu$ is $dw = d\mu$. In a system in which the chemical potential depends on the position x ,

$$dw = d\mu = \left(\frac{\partial \mu}{\partial x} \right)_{p,T} dx \quad (21.54)$$

We also saw in Chapter 2 (Table 2.1) that in general work can always be expressed in terms of an opposing force (which here we write $\mathcal{F}$), and that

$$dw = -\mathcal{F} dx \quad (21.55)$$

By comparing these two expressions, we see that the slope of the chemical potential can be interpreted as an effective force per mole of molecules. We write this **thermodynamic force** as

$$\mathcal{F} = - \left(\frac{\partial \mu}{\partial x} \right)_{p,T} \quad [21.56]$$

There is not necessarily a real force pushing the particles down the slope of the chemical potential. As we shall see, the force may represent the spontaneous tendency of the molecules to disperse as a consequence of the Second Law and the hunt for maximum entropy.

(a) The thermodynamic force of a concentration gradient

In a solution in which the activity of the solute is a , the chemical potential is

$$\mu = \mu^\ominus + RT \ln a$$

If the solution is not uniform the activity depends on the position and we can write

$$\mathcal{F} = -RT \left(\frac{\partial \ln a}{\partial x} \right)_{p,T} \quad (21.57)$$

If the solution is ideal, a may be replaced by the molar concentration c , and then

$$\mathcal{F} = -\frac{RT}{c} \left(\frac{\partial c}{\partial x} \right)_{p,T} \quad (21.58)^\circ$$

where we have also used the relation $d \ln y/dx = (1/y)(dy/dx)$.

Example 21.3 Calculating the thermodynamic force

Suppose the concentration of a solute decays exponentially along the length of a container. Calculate the thermodynamic force on the solute at 25°C given that the concentration falls to half its value in 10 cm.

Method According to eqn 21.58, the thermodynamic force is calculated by differentiating the concentration with respect to distance. Therefore, write an expression for the variation of the concentration with distance, and then differentiate it.

Answer The concentration varies with position as

$$c = c_0 e^{-x/\lambda}$$

where λ is the decay constant. Therefore,

$$\frac{dc}{dx} = -\frac{c}{\lambda}$$

Equation 21.58 then implies that

$$\mathcal{F} = \frac{RT}{\lambda}$$

We know that the concentration falls to $\frac{1}{2}c_0$ at $x = 10$ cm, so we can find λ from $\frac{1}{2} = e^{-(10 \text{ cm})/\lambda}$. That is, $\lambda = (10 \text{ cm}/\ln 2)$. It follows that

$$\mathcal{F} = (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K}) \times \ln 2 / (1.0 \times 10^{-1} \text{ m}) = 17 \text{ kN mol}^{-1}$$

where we have used $1 \text{ J} = 1 \text{ N m}$.

Self-test 21.5 Calculate the thermodynamic force on the molecules of molar mass M in a vertical tube in a gravitational field on the surface of the Earth, and evaluate $\mathcal{F}$ for molecules of molar mass 100 g mol^{-1} . Comment on its magnitude relative to that just calculated.

[$\mathcal{F} = -Mg$, -0.98 N mol^{-1} ; the force arising from the concentration gradient greatly dominates that arising from the gravitational gradient.]

(b) Fick's first law of diffusion

In Section 21.4 we saw that Fick's first law of diffusion (that the particle flux is proportional to the concentration gradient) could be deduced from the kinetic model of gases. We shall now show that it can be deduced more generally and that it applies to the diffusion of species in condensed phases too.

We suppose that the flux of diffusing particles is motion in response to a thermodynamic force arising from a concentration gradient. The particles reach a steady drift speed, s , when the thermodynamic force, $\mathcal{F}$, is matched by the viscous drag. This drift speed is proportional to the thermodynamic force, and we write $s \propto \mathcal{F}$. However, the particle flux, J , is proportional to the drift speed, and the thermodynamic force is proportional to the concentration gradient, dc/dx . The chain of proportionalities ($J \propto s$, $s \propto \mathcal{F}$, and $\mathcal{F} \propto dc/dx$) implies that $J \propto dc/dx$, which is the content of Fick's law.

(c) The Einstein relation

If we divide both sides of eqn 21.19 by Avogadro's constant, thereby converting numbers into amounts (numbers of moles), then Fick's law becomes

$$J = -D \frac{dc}{dx} \quad (21.59)$$

In this expression, D is the diffusion coefficient and dc/dx is the slope of the molar concentration. The flux is related to the drift speed by

$$J = sc \quad (21.60)$$

This relation follows from the argument that we have used several times before. Thus, all particles within a distance $s\Delta t$, and therefore in a volume $s\Delta tA$, can pass through a window of area A in an interval Δt . Hence, the amount of substance that can pass through the window in that interval is $s\Delta tAc$. Therefore,

$$sc = -D \frac{dc}{dx}$$

If now we express dc/dx in terms of $\mathcal{F}$ by using eqn 21.58, we find

$$s = -\frac{D}{c} \frac{dc}{dx} = \frac{D\mathcal{F}}{RT} \quad (21.61)$$

Therefore, once we know the effective force and the diffusion coefficient, D , we can calculate the drift speed of the particles (and vice versa) whatever the origin of the force.

There is one case where we already know the drift speed and the effective force acting on a particle: an ion in solution has a drift speed $s = uE$ when it experiences a force ezE from an electric field of strength E (so $\mathcal{F} = N_A ezE = zFE$). Therefore, substituting these known values into eqn 21.61 gives

$$uE = \frac{zFED}{RT}$$

and hence

$$u = \frac{zFD}{RT} \quad (21.62)$$

This equation rearranges into the very important result known as the **Einstein relation** between the diffusion coefficient and the ionic mobility:

$$D = \frac{uRT}{zF} \quad (21.63)^\circ$$

On inserting the typical value $u = 5 \times 10^{-8} \text{ m}^2 \text{ s}^{-1} \text{ V}^{-1}$, we find $D \approx 1 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ at 25°C as a typical value of the diffusion coefficient of an ion in water.

(d) The Nernst–Einstein equation

The Einstein relation provides a link between the molar conductivity of an electrolyte and the diffusion coefficients of its ions. First, by using eqns 21.44 and 21.63 we write

$$\lambda = zuF = \frac{z^2 D F^2}{RT} \quad (21.64)^\circ$$

for each type of ion. Then, from $\Lambda_m^\circ = \nu_+ \lambda_+ + \nu_- \lambda_-$, the limiting molar conductivity is

$$\Lambda_m^\circ = (\nu_+ z_+^2 D_+ + \nu_- z_-^2 D_-) \frac{F^2}{RT} \quad (21.65)^\circ$$

which is the **Nernst–Einstein equation**. One application of this equation is to the determination of ionic diffusion coefficients from conductivity measurements; another is to the prediction of conductivities using models of ionic diffusion (see below).

(e) The Stokes–Einstein equation

Equations 21.43 ($u = ez/f$) and 21.63 relate the mobility of an ion to the frictional force and to the diffusion coefficient, respectively. We can combine the two expressions into the **Stokes–Einstein equation**:

$$D = \frac{kT}{f} \quad (21.66)$$

If the frictional force is described by Stokes's law, then we also obtain a relation between the diffusion coefficient and the viscosity of the medium:

$$D = \frac{kT}{6\pi\eta a} \quad (21.67)$$

An important feature of eqn 21.66 (and of its special case, eqn 21.67) is that it makes no reference to the charge of the diffusing species. Therefore, the equation also applies in the limit of vanishingly small charge, that is, it also applies to neutral molecules. Consequently, we may use viscosity measurements to estimate the diffusion coefficients for electrically neutral molecules in solution (Table 21.8). It must not be forgotten, however, that both equations depend on the assumption that the viscous drag is proportional to the speed.

Synoptic table 21.8* Diffusion coefficients at 298 K

	$D/(10^{-9} \text{ m}^2 \text{ s}^{-1})$

* More values are given in the *Data section*.

Example 21.4 Interpreting the mobility of an ion

Use the experimental value of the mobility to evaluate the diffusion coefficient, the limiting molar conductivity, and the hydrodynamic radius of a sulfate ion in aqueous solution.

Method The starting point is the mobility of the ion, which is given in Table 21.6. The diffusion coefficient can then be determined from the Einstein relation, eqn 21.63. The ionic conductivity is related to the mobility by eqn 21.44. To estimate the hydrodynamic radius, a , of the ion, use the Stokes–Einstein relation to find f and the Stokes law to relate f to a .

Answer From Table 21.6, the mobility of SO_4^{2-} is $8.29 \times 10^{-8} \text{ m}^2 \text{ s}^{-1} \text{ V}^{-1}$. It follows from eqn 21.63 that

$$D = \frac{uRT}{zF} = 1.1 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$$

From eqn 21.44 it follows that

$$\lambda = zuF = 16 \text{ mS m}^2 \text{ mol}^{-1}$$

Finally, from $f = 6\pi\eta a$ using 0.891 cP (or $8.91 \times 10^{-4} \text{ kg m}^{-1} \text{ s}^{-1}$) for the viscosity of water (Table 21.4):

$$a = \frac{kT}{6\pi\eta D} = 220 \text{ pm}$$

The bond length in SO_4^{2-} is 144 pm, so the radius calculated here is plausible and consistent with a small degree of solvation.

Self-test 21.6 Repeat the calculation for the NH_4^+ ion.

[$1.96 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$, $7.4 \text{ mS m}^2 \text{ mol}^{-1}$, 125 pm]

Experimental support for the relations derived above comes from conductivity measurements. In particular, **Walden's rule** is the empirical observation that the product $\eta\Lambda_m$ is very approximately constant for the same ions in different solvents (but there are numerous exceptions). Because $\Lambda_m \propto D$, and we have just seen that $D \propto 1/\eta$, we do indeed predict that $\Lambda_m \propto 1/\eta$, as Walden's rule implies. The usefulness of the rule, however, is muddled by the role of solvation: different solvents solvate the same ions to different extents, so both the hydrodynamic radius and the viscosity change with the solvent.

21.10 The diffusion equation

We now turn to the discussion of time-dependent diffusion processes, where we are interested in the spreading of inhomogeneities with time. One example is the temperature of a metal bar that has been heated at one end: if the source of heat is removed, then the bar gradually settles down into a state of uniform temperature. When the source of heat is maintained and the bar can radiate, it settles down into a steady state of nonuniform temperature. Another example (and one more relevant to chemistry) is the concentration distribution in a solvent to which a solute is added. We shall focus on the description of the diffusion of particles, but similar arguments apply to the diffusion of physical properties, such as temperature. Our aim is to obtain an equation for the rate of change of the concentration of particles in an inhomogeneous region.

The central equation of this section is the **diffusion equation**, also called 'Fick's second law of diffusion', which relates the rate of change of concentration at a point to the spatial variation of the concentration at that point:

$$\frac{\partial c}{\partial t} = D \frac{\partial^2 c}{\partial x^2} \quad (21.68)$$

We show in the following *Justification* that the diffusion equation follows from Fick's first law of diffusion.

Fig. 21.24 The net flux in a region is the difference between the flux entering from the region of high concentration (on the left) and the flux leaving to the region of low concentration (on the right).

Justification 21.6 The diffusion equation

Consider a thin slab of cross-sectional area A that extends from x to $x + l$ (Fig. 21.24). Let the concentration at x be c at the time t . The amount (number of moles) of particles that enter the slab in the infinitesimal interval dt is $JAdt$, so the rate of increase in molar concentration inside the slab (which has volume Al) on account of the flux from the left is

$$\frac{\partial c}{\partial t} = \frac{J A \Delta t}{A l \Delta t} = \frac{J}{l}$$

There is also an outflow through the right-hand window. The flux through that window is J' , and the rate of change of concentration that results is

$$\frac{\partial c}{\partial t} = -\frac{J' A \Delta t}{A l \Delta t} = -\frac{J'}{l}$$

The net rate of change of concentration is therefore

$$\frac{\partial c}{\partial t} = \frac{J - J'}{l}$$

Each flux is proportional to the concentration gradient at the window. So, by using Fick's first law, we can write

$$J - J' = -D \frac{\partial c}{\partial x} + D \frac{\partial c'}{\partial x} = -D \frac{\partial c}{\partial x} + D \frac{\partial}{\partial x} \left\{ c + \left(\frac{\partial c}{\partial x} \right) l \right\} = D l \frac{\partial^2 c}{\partial x^2}$$

When this relation is substituted into the expression for the rate of change of concentration in the slab, we get eqn 21.68.

The diffusion equation shows that the rate of change of concentration is proportional to the curvature (more precisely, to the second derivative) of the concentration with respect to distance. If the concentration changes sharply from point to point (if the distribution is highly wrinkled) then the concentration changes rapidly with time. Where the curvature is positive (a dip, Fig. 21.25), the change in concentration is positive; the dip tends to fill. Where the curvature is negative (a heap), the change in concentration is negative; the heap tends to spread. If the curvature is zero, then the concentration is constant in time. If the concentration decreases linearly with distance, then the concentration at any point is constant because the inflow of particles is exactly balanced by the outflow.

The diffusion equation can be regarded as a mathematical formulation of the intuitive notion that there is a natural tendency for the wrinkles in a distribution to disappear. More succinctly: Nature abhors a wrinkle.

(a) Diffusion with convection

The transport of particles arising from the motion of a streaming fluid is called **convection**. If for the moment we ignore diffusion, then the flux of particles through an area A in an interval Δt when the fluid is flowing at a velocity v can be calculated in the way we have used several times before (by counting the particles within a distance $v\Delta t$), and is

$$J = \frac{c A v \Delta t}{A \Delta t} = cv \quad (21.69)$$

This J is called the **convective flux**. The rate of change of concentration in a slab of thickness l and area A is, by the same argument as before and assuming that the velocity does not depend on the position,

$$\frac{\partial c}{\partial t} = \frac{J - J'}{l} = \left\{ c - \left[c + \left(\frac{\partial c}{\partial x} \right) l \right] \right\} \frac{v}{l} = -v \frac{\partial c}{\partial x} \quad (21.70)$$

When both diffusion and convection occur, the total change of concentration in a region is the sum of the two effects, and the **generalized diffusion equation** is

Fig. 21.25 Nature abhors a wrinkle. The diffusion equation tells us that peaks in distribution (regions of negative curvature) spread and troughs (regions of positive curvature) fill in.

$$\frac{\partial c}{\partial t} = D \frac{\partial^2 c}{\partial x^2} - v \frac{\partial c}{\partial x} \quad (21.71)$$

A further refinement, which is important in chemistry, is the possibility that the concentrations of particles may change as a result of reaction. When reactions are included in eqn 21.71 (Section 24.2), we get a powerful differential equation for discussing the properties of reacting, diffusing, convecting systems and which is the basis of reactor design in chemical industry and of the utilization of resources in living cells.

(b) Solutions of the diffusion equation

The diffusion equation, eqn 21.68, is a second-order differential equation with respect to space and a first-order differential equation with respect to time. Therefore, we must specify two boundary conditions for the spatial dependence and a single initial condition for the time-dependence.

As an illustration, consider a solvent in which the solute is initially coated on one surface of the container (for example, a layer of sugar on the bottom of a deep beaker of water). The single initial condition is that at $t = 0$ all N_0 particles are concentrated on the yz -plane (of area A) at $x = 0$. The two boundary conditions are derived from the requirements (1) that the concentration must everywhere be finite and (2) that the total amount (number of moles) of particles present is n_0 (with $n_0 = N_0/N_A$) at all times. These requirements imply that the flux of particles is zero at the top and bottom surfaces of the system. Under these conditions it is found that

$$c(x, t) = \frac{n_0}{A(\pi Dt)^{1/2}} e^{-x^2/4Dt} \quad (21.72)$$

as may be verified by direct substitution. Figure 21.26 shows the shape of the concentration distribution at various times, and it is clear that the concentration spreads and tends to uniformity.

Another useful result is for a localized concentration of solute in a three-dimensional solvent (a sugar lump suspended in a large flask of water). The concentration of diffused solute is spherically symmetrical and at a radius r is

$$c(r, t) = \frac{n_0}{8(\pi Dt)^{3/2}} e^{-r^2/4Dt} \quad (21.73)$$

Other chemically (and physically) interesting arrangements, such as transport of substances across biological membranes can be treated (*Impact I21.3*). In many cases the solutions are more cumbersome.

(c) The measurement of diffusion coefficients

The solutions of the diffusion equation are useful for experimental determinations of diffusion coefficients. In the **capillary technique**, a capillary tube, open at one end and containing a solution, is immersed in a well stirred larger quantity of solvent, and the change of concentration in the tube is monitored. The solute diffuses from the open end of the capillary at a rate that can be calculated by solving the diffusion equation with the appropriate boundary conditions, so D may be determined. In the **diaphragm technique**, the diffusion occurs through the capillary pores of a sintered glass diaphragm separating the well-stirred solution and solvent. The concentrations are monitored and then related to the solutions of the diffusion equation corresponding to this arrangement. Diffusion coefficients may also be measured by the dynamic light scattering technique described in Section 19.3 and by NMR.

Fig. 21.26 The concentration profiles above a plane from which a solute is diffusing. The curves are plots of eqn 21.72 and are labelled with different values of Dt . The units of Dt and x are arbitrary, but are related so that Dt/x^2 is dimensionless. For example, if x is in metres, Dt would be in metres²; so, for $D = 10^{-9} \text{ m}^2 \text{ s}^{-1}$, $Dt = 0.1 \text{ m}^2$ corresponds to $t = 10^8 \text{ s}$.

Exploration Generate a family of curves similar to that shown in Fig. 21.26 but by using eqn 21.73, which describes diffusion in three dimensions.

IMPACT ON BIOCHEMISTRY
21.3 Transport of non-electrolytes across biological membranes

We saw in *Impact I21.2* how electrolytes are transported across cell membranes. Here we use the diffusion equation to explore the way in which non-electrolytes cross the lipid bilayer.

Consider the passive transport of an uncharged species A across a lipid bilayer of thickness l . To simplify the problem, we will assume that the concentration of A is always maintained at $[A] = [A]_0$ on one surface of the membrane and at $[A] = 0$ on the other surface, perhaps by a perfect balance between the rate of the process that produces A on one side and the rate of another process that consumes A completely on the other side. This is one example of a steady-state assumption, which will be discussed in more detail in Section 22.7. Then $\partial[A]/\partial t = 0$ and the diffusion equation simplifies to

$$D \frac{d^2[A]}{dx^2} = 0 \quad (21.74)$$

where D is the diffusion coefficient and the steady-state assumption makes partial derivatives unnecessary. We use the boundary conditions $[A](0) = [A]_0$ and $[A](l) = 0$ to solve eqn 21.74 and the result, which may be verified by differentiation, is

$$[A](x) = [A]_0 \left(1 - \frac{x}{l} \right) \quad (21.75)$$

which implies that the $[A]$ decreases linearly inside the membrane. We now use Fick's first law to calculate the flux J of A through the membrane and the result is

$$J = D \frac{[A]_0}{l} \quad (21.76)$$

However, we need to modify this equation slightly to account for the fact that the concentration of A on the surface of a membrane is not always equal to the concentration of A measured in the bulk solution, which we assume to be aqueous. This difference arises from the significant difference in the solubility of A in an aqueous environment and in the solution–membrane interface. One way to deal with this problem is to define a **partition ratio**, K_D (D for distribution) as

$$K_D = \frac{[A]_0}{[A]_s} \quad [21.77]$$

where $[A]_s$ is the concentration of A in the bulk aqueous solution. It follows that

$$J = DK_D \frac{[A]_s}{l} \quad (21.78)$$

In spite of the assumptions that led to its final form, eqn 21.78 describes adequately the passive transport of many non-electrolytes through membranes of blood cells.

In many cases the flux is underestimated by eqn 21.78 and the implication is that the membrane is more permeable than expected. However, the permeability increases only for certain species and not others and this is evidence that transport can be mediated by carriers. One example is the transporter protein that carries glucose into cells.

A characteristic of a carrier C is that it binds to the transported species A and the dissociation of the AC complex is described by

Fig. 21.27 The flux of the species AC through a membrane varies with the concentration of the species A. The behaviour shown in the figure and explained in the text is characteristic of mediated transport of A, with C as a carrier molecule.

where we have used concentrations instead of activities. After writing $[C]_0 = [C] + [AC]$, where $[C]_0$ is the total concentration of carrier, it follows that

$$[AC] = \frac{[A][C]_0}{[A] + K} \quad (21.80)$$

We can now use eqns 21.80 and 21.78 to write an expression for the flux of the species AC through the membrane:

$$J = \frac{DK_D[C]_0}{l} \frac{[A]}{[A] + K} = J_{\max} \frac{[A]}{[A] + K} \quad (21.81)$$

where K_D and D are the partition ratio and diffusion coefficient of the species AC. We see from Fig. 21.27 that when $[A] \ll K$ the flux varies linearly with $[A]$ and that the flux reaches a maximum value of $J_{\max} = DK_D[C]_0/l$ when $[A] \gg K$. This behaviour is characteristic of mediated transport.

21.11 Diffusion probabilities

The solutions of the diffusion equation can be used to predict the concentration of particles (or the value of some other physical quantity, such as the temperature in a nonuniform system) at any location. We can also use them to calculate the net distance through which the particles diffuse in a given time.

Example 21.5 Calculating the net distance of diffusion

Calculate the net distance travelled on average by particles in a time t if they have a diffusion constant D .

Method We need to use the results of probability theory summarized in *Appendix 2*. In this case, we calculate the probability that a particle will be found at a certain distance from the origin, and then calculate the average by weighting each distance by that probability.

Answer The number of particles in a slab of thickness dx and area A at x , where the molar concentration is c , is $cAN_A dx$. The probability that any of the $N_0 = n_0 N_A$ particles is in the slab is therefore $cAN_A dx/N_0$. If the particle is in the slab, it has travelled a distance x from the origin. Therefore, the mean distance travelled by all the particles is the sum of each x weighted by the probability of its occurrence:

$$\langle x \rangle = \int_0^\infty \frac{xcAN_A}{N_0} dx = \frac{1}{(\pi Dt)^{1/2}} \int_0^\infty x e^{-x^2/4Dt} dx = 2 \left(\frac{Dt}{\pi} \right)^{1/2}$$

where we have used the same standard integral as that used in Justification 21.4.

The average distance of diffusion varies as the square root of the lapsed time. If we use the Stokes–Einstein relation for the diffusion coefficient, the mean distance travelled by particles of radius a in a solvent of viscosity η is

$$\langle x \rangle = \left(\frac{2kTt}{3\pi^2\eta a} \right)^{1/2}$$

Self-test 21.7 Derive an expression for the root mean square distance travelled by diffusing particles in a time t .
 $[\langle x^2 \rangle^{1/2} = (2Dt)^{1/2}]$

As shown in Example 21.5, the average distance travelled by diffusing particle in a time t is

$$\langle x \rangle = 2 \left(\frac{Dt}{\pi} \right)^{1/2} \quad (21.82)$$

and the root mean square distance travelled in the same time is

$$\langle x^2 \rangle^{1/2} = (2Dt)^{1/2} \quad (21.83)$$

The latter is a valuable measure of the spread of particles when they can diffuse in both directions from the origin (for then $\langle x \rangle = 0$ at all times). The root mean square distance travelled by particles with a typical diffusion coefficient ($D = 5 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$) is illustrated in Fig. 21.28, which shows how long it takes for diffusion to increase the net distance travelled on average to about 1 cm in an unstirred solution. The graph shows that diffusion is a very slow process (which is why solutions are stirred, to encourage mixing by convection).

Fig. 21.28 The root mean square distance covered by particles with $D = 5 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$. Note the great slowness of diffusion.

21.12 The statistical view

An intuitive picture of diffusion is of the particles moving in a series of small steps and gradually migrating from their original positions. We shall explore this idea using a model in which the particles can jump through a distance λ in a time τ . The total distance travelled by a particle in a time t is therefore $t\lambda/\tau$. However, the particle will not necessarily be found at that distance from the origin. The direction of each step may be different, and the net distance travelled must take the changing directions into account.

If we simplify the discussion by allowing the particles to travel only along a straight line (the x -axis), and for each step (to the left or the right) to be through the same distance λ , then we obtain the **one-dimensional random walk**. The same model was used in the discussion of a one-dimensional random coil in Section 19.8a.

We show in the *Justification* below that the probability of a particle being at a distance x from the origin after a time t is

$$P = \left(\frac{2\tau}{\pi t} \right)^{1/2} e^{-x^2 \tau / 2t \lambda^2} \quad (21.84)$$

Justification 21.7 The one-dimensional random walk

Consider a one-dimensional random walk in which each step is through a distance λ to the left or right. The net distance travelled after N steps is equal to the difference between the number of steps to the right (N_R) and to the left (N_L), and is $(N_R - N_L)\lambda$. We write $n = N_R - N_L$ and the total number of steps as $N = N_R + N_L$.

The number of ways of performing a walk with a given net distance of travel $n\lambda$ is the number of ways of making N_R steps to the right and N_L steps to the left, and is given by the binomial coefficient

$$W = \frac{N!}{N_L! N_R!} = \frac{N!}{\left\{ \frac{1}{2}(N+n) \right\}! \left\{ \frac{1}{2}(N-n) \right\}!}$$

The probability of the net distance walked being $n\lambda$ is

$$P = \frac{\text{number of paths with } N_R \text{ steps to the right}}{\text{total number of steps}} \\ = \frac{W}{2^N} = \frac{N!}{\left\{ \frac{1}{2}(N+n) \right\}! \left\{ \frac{1}{2}(N-n) \right\}! 2^N}$$

The use of Stirling's approximation (Section 16.1a) in the form

$$\ln x! \approx \ln(2\pi)^{1/2} + (x + \frac{1}{2}) \ln x - x$$

gives (after quite a lot of algebra; see Problem 21.33)

$$\ln P = \ln \left(\frac{2}{\pi N} \right)^{1/2} - \frac{1}{2}(N+n+1) \ln \left(1 + \frac{n}{N} \right) - \frac{1}{2}(N-n+1) \ln \left(1 - \frac{n}{N} \right)$$

For small net distances ($n \ll N$) we can use the approximation $\ln(1 \pm x) \approx \pm x - \frac{1}{2}x^2$, and so obtain

$$\ln P \approx \ln \left(\frac{2}{\pi N} \right)^{1/2} - \frac{n^2}{2N}$$

At this point, we note that the number of steps taken in a time t is $N = t/\tau$ and the net distance travelled from the origin is $x = n\lambda$. Substitution of these quantities into the expression for $\ln P$ gives

$$\ln P \approx \ln \left(\frac{2\tau}{\pi t} \right)^{1/2} - \frac{x^2 \tau}{2t\lambda^2}$$

which, upon using $e^{\ln x} = x$ and $e^{x+y} = e^x e^y$, rearranges into eqn 21.84.

The differences of detail between eqns 21.72 and 21.84 arise from the fact that in the present calculation the particles can migrate in either direction from the origin. Moreover, they can be found only at discrete points separated by λ instead of being anywhere on a continuous line. The fact that the two expressions are so similar suggests that diffusion can indeed be interpreted as the outcome of a large number of steps in random directions.

We can now relate the coefficient D to the step length λ and the rate at which the jumps occur. Thus, by comparing the two exponents in eqns 21.72 and 21.84 we can immediately write down the **Einstein–Smoluchowski equation**:

$$D = \frac{\lambda^2}{2\tau} \quad (21.85)$$

Illustration 21.6 Using the Einstein–Smoluchowski equation

Suppose that a SO_4^{2-} ion jumps through its own diameter each time it makes a move in an aqueous solution; then, because $D = 1.1 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ and $a = 210 \text{ pm}$ (as deduced from mobility measurements), it follows from $\lambda = 2a$ that $\tau = 80 \text{ ps}$. Because τ is the time for one jump, the ion makes 1×10^{10} jumps per second.

The Einstein–Smoluchowski equation is the central connection between the microscopic details of particle motion and the macroscopic parameters relating to diffusion (for example, the diffusion coefficient and, through the Stokes–Einstein relation, the viscosity). It also brings us back full circle to the properties of the perfect gas. For if we interpret λ/τ as $\bar{c}$, the mean speed of the molecules, and interpret λ as a mean free path, then we can recognize in the Einstein–Smoluchowski equation exactly the same expression as we obtained from the kinetic model of gases, eqn 21.22. That is, the diffusion of a perfect gas is a random walk with an average step size equal to the mean free path.

Checklist of key ideas

- ☐ 1. Diffusion is the migration of matter down a concentration gradient; thermal conduction is the migration of energy down a temperature gradient; electric conduction is the migration of electric charge along an electrical potential gradient; viscosity is the migration of linear momentum down a velocity gradient.
- ☐ 2. The kinetic model of a gas considers only the contribution to the energy from the kinetic energies of the molecules. Important results from the model include expressions for the pressure ($pV = \frac{1}{3}nMc^2$) and the root mean square speed ($c = \langle v^2 \rangle^{1/2} = (3RT/M)^{1/2}$).
- ☐ 3. The Maxwell distribution of speeds is the function which, through $f(v)dv$, gives the fraction of molecules that have speeds in the range v to $v + dv$.
- ☐ 4. The collision frequency is the number of collisions made by a molecule in an interval divided by the length of the interval: $z = \sigma \bar{c}_{rel} \mathcal{N}$, where the collision cross-section is $\sigma = \pi d^2$.
- ☐ 5. The mean free path is the average distance a molecule travels between collisions: $\lambda = \bar{c}/z$.
- ☐ 6. The collision flux, Z_w , is the number of collisions with an area in a given time interval divided by the area and the duration of the interval: $Z_w = p/(2\pi mkT)^{1/2}$.
- ☐ 7. Effusion is the emergence of a gas from a container through a small hole. Graham's law of effusion states that the rate of effusion is inversely proportional to the square root of the molar mass.
- ☐ 8. Flux J is the quantity of a property passing through a given area in a given time interval divided by the area and the duration of the interval.
- ☐ 9. Fick's first law of diffusion states that the flux of matter is proportional to the concentration gradient, $J(\text{matter}) = -Ddc/dz$, where D is the diffusion coefficient.
- ☐ 10. The conductance, G , is the inverse of resistance. The conductivity is the constant κ in $G = \kappa A/l$ and the molar conductivity is written as $\Lambda_m = \kappa/c$.
- ☐ 11. A strong electrolyte is an electrolyte with a molar conductivity that varies only slightly with concentration. A weak electrolyte is an electrolyte with a molar conductivity that is normal at concentrations close to zero, but falls sharply to low values as the concentration increases.
- ☐ 12. Kohlrausch's law for the concentration dependence of the molar conductivity of a strong electrolyte is written as $\Lambda_m = \Lambda_m^\circ - \mathcal{K}c^{1/2}$, where the limiting molar conductivity, Λ_m° , is the molar conductivity at zero concentration ($\Lambda_m^\circ = v_+ \lambda_+ + v_- \lambda_-$).
- ☐ 13. The drift speed s is the terminal speed when an accelerating force is balanced by the viscous drag: $s = uE$, where $u = ze/6\pi\eta a$ is the ionic mobility and a is the hydrodynamic radius (Stokes radius), the effective radius of a particle in solution.
- ☐ 14. The ionic conductivity is the contribution of ions of one type to the molar conductivity: $\lambda = zuF$.
- ☐ 15. The transport number is the fraction of total current I carried by the ions of a specified type: $t_{\pm} = I_{\pm}/I$.
- ☐ 16. The Debye–Hückel–Onsager theory explains the concentration dependence of the molar conductivity of a strong electrolyte in terms of ionic interactions.
- ☐ 17. The Einstein relation between the diffusion coefficient and the ionic mobility is $D = uRT/zF$.
- ☐ 18. The Nernst–Einstein relation between the molar conductivity of an electrolyte and the diffusion coefficients of its ions is $\Lambda_m = (v_+ z_+^2 D_+ + v_- z_-^2 D_-)(F^2/RT)$.
- ☐ 19. The Stokes–Einstein equation relates the diffusion coefficient to the frictional force: $D = kT/f$.
- ☐ 20. Walden's rule states that the product $\eta\Lambda_m$ is very approximately constant for the same ions in different solvents.
- ☐ 21. The diffusion equation is a relation between the rate of change of concentration at a point and the spatial variation of the concentration at that point: $\partial c/\partial t = D\partial^2 c/\partial x^2$.
- ☐ 22. In a one-dimensional random walk, the probability P that a molecule moves a distance x from the origin for a period t by taking small steps with size λ and time τ is: $P = (2\tau/\pi t)^{1/2} e^{-x^2\tau/2t\lambda^2}$.
- ☐ 23. The Einstein–Smoluchowski equation relates the diffusion coefficient to the parameters used in the formulation of the random walk model, $D = \lambda^2/2\tau$.

Further information

Further information 21.1 *The transport characteristics of a perfect gas*

In this Further information section, we derive expressions for the diffusion characteristics (specifically, the diffusion coefficient, the thermal conductivity, and the viscosity) of a perfect gas on the basis of the kinetic molecular theory.

The diffusion coefficient, D

Consider the arrangement depicted in Fig. 21.29. On average, the molecules passing through the area A at $z = 0$ have travelled about one mean free path λ since their last collision. Therefore, the number density where they originated is $\mathcal{N}(z)$ evaluated at $z = -\lambda$. This number density is approximately

$$\mathcal{N}(-\lambda) = \mathcal{N}(0) - \lambda \left(\frac{d\mathcal{N}}{dz} \right)_0 \quad (21.86)$$

where we have used a Taylor expansion of the form $f(x) = f(0) + (df/dx)_0 x + \dots$ truncated after the second term (see *Appendix 2*). The average number of impacts on the imaginary window of area A_0 during an interval Δt is $Z_W A_0 \Delta t$, with $Z_W = \frac{1}{4} \mathcal{N} \bar{c}$ (eqn 21.15). Therefore, the flux from left to right, $J(L \rightarrow R)$, arising from the supply of molecules on the left, is

$$J(L \rightarrow R) = \frac{\frac{1}{4} A_0 \mathcal{N}(-\lambda) \bar{c} \Delta t}{A_0 \Delta t} = \frac{1}{4} \mathcal{N}(-\lambda) \bar{c} \quad (21.87)$$

Fig. 21.29 The calculation of the rate of diffusion of a gas considers the net flux of molecules through a plane of area A as a result of arrivals from on average a distance λ away in each direction, where λ is the mean free path.

There is also a flux of molecules from right to left. On average, the molecules making the journey have originated from $z = +\lambda$ where the number density is $\mathcal{N}(\lambda)$. Therefore,

$$J(L \leftarrow R) = -\frac{1}{4} \mathcal{N}(\lambda) \bar{c} \quad (21.88)$$

The average number density at $z = +\lambda$ is approximately

$$\mathcal{N}(\lambda) = \mathcal{N}(0) + \lambda \left(\frac{d\mathcal{N}}{dz} \right)_0 \quad (21.89)$$

The net flux is

$$\begin{aligned} J_z &= J(L \rightarrow R) + J(L \leftarrow R) \\ &= \frac{1}{4} \bar{c} \left\{ \left[\mathcal{N}(0) - \lambda \left(\frac{d\mathcal{N}}{dz} \right)_0 \right] - \left[\mathcal{N}(0) + \lambda \left(\frac{d\mathcal{N}}{dz} \right)_0 \right] \right\} \\ &= -\frac{1}{2} \bar{c} \lambda \left(\frac{d\mathcal{N}}{dz} \right)_0 \end{aligned} \quad (21.90)$$

This equation shows that the flux is proportional to the first derivative of the concentration, in agreement with Fick's law.

At this stage it looks as though we can pick out a value of the diffusion coefficient by comparing eqns 21.19 and 21.90, so obtaining $D = \frac{1}{2} \lambda \bar{c}$. It must be remembered, however, that the calculation is quite crude, and is little more than an assessment of the order of magnitude of D . One aspect that has not been taken into account is illustrated in Fig. 21.30, which shows that, although a molecule may

Fig. 21.30 One approximation ignored in the simple treatment is that some particles might make a long flight to the plane even though they are only a short perpendicular distance away, and therefore they have a higher chance of colliding during their journey.

have begun its journey very close to the window, it could have a long flight before it gets there. Because the path is long, the molecule is likely to collide before reaching the window, so it ought to be added to the graveyard of other molecules that have collided. To take this effect into account involves a lot of work, but the end result is the appearance of a factor of $\frac{2}{3}$ representing the lower flux. The modification results in eqn 21.22.

Thermal conductivity

According to the equipartition theorem (Section 17.3), each molecule carries an average energy $\varepsilon = \nu kT$, where ν is a number of the order of 1. For monatomic particles, $\nu = \frac{3}{2}$. When one molecule passes through the imaginary window, it transports that energy on average. We suppose that the number density is uniform but that the temperature is not. On average, molecules arrive from the left after travelling a mean free path from their last collision in a hotter region, and therefore with a higher energy. Molecules also arrive from the right after travelling a mean free path from a cooler region. The two opposing energy fluxes are therefore

$$\begin{aligned} J(L \rightarrow R) &= \frac{1}{4} \bar{c} \mathcal{N} \varepsilon(-\lambda) & \varepsilon(-\lambda) &= \nu k \left\{ T - \lambda \left(\frac{dT}{dz} \right)_0 \right\} \\ J(L \leftarrow R) &= -\frac{1}{4} \bar{c} \mathcal{N} \varepsilon(\lambda) & \varepsilon(\lambda) &= \nu k \left\{ T + \lambda \left(\frac{dT}{dz} \right)_0 \right\} \end{aligned} \quad (21.91)$$

and the net flux is

$$J_z = J(L \rightarrow R) + J(L \leftarrow R) = -\frac{1}{2} \nu k \lambda \bar{c} \mathcal{N} \left(\frac{dT}{dz} \right)_0 \quad (21.92)$$

As before, we multiply by $\frac{2}{3}$ to take long flight paths into account, and so arrive at

$$J_z = -\frac{1}{3} \nu k \lambda \bar{c} \mathcal{N} \left(\frac{dT}{dz} \right)_0 \quad (21.93)$$

The energy flux is proportional to the temperature gradient, as we wanted to show. Comparison of this equation with eqn 21.20 shows that

$$\kappa = \frac{1}{3} \nu k \lambda \bar{c} \mathcal{N} \quad (21.94)$$

Equation 21.23 then follows from $C_{V,m} = \nu k N_A$ for a perfect gas, where $[A]$ is the molar concentration of A. For this step, we use $\mathcal{N} = N/V = n N_A/V = N_A [A]$.

Viscosity

Molecules travelling from the right in Fig. 21.31 (from a fast layer to a slower one) transport a momentum $mv_x(\lambda)$ to their new layer at $z = 0$;

Fig. 21.31 The calculation of the viscosity of a gas examines the net x -component of momentum brought to a plane from faster and slower layers on average a mean free path away in each direction.

those travelling from the left transport $mv_x(-\lambda)$ to it. If it is assumed that the density is uniform, the collision flux is $\frac{1}{4} \bar{c} \mathcal{N}$. Those arriving from the right on average carry a momentum

$$mv_x(\lambda) = mv_x(0) + m\lambda \left(\frac{dv_x}{dz} \right)_0 \quad (21.95a)$$

Those arriving from the left bring a momentum

$$mv_x(-\lambda) = mv_x(0) - m\lambda \left(\frac{dv_x}{dz} \right)_0 \quad (21.95b)$$

The net flux of x -momentum in the z -direction is therefore

$$\begin{aligned} J &= \frac{1}{4} \bar{c} \mathcal{N} \left\{ \left[mv_x(0) - m\lambda \left(\frac{dv_x}{dz} \right)_0 \right] - \left[mv_x(0) + m\lambda \left(\frac{dv_x}{dz} \right)_0 \right] \right\} \\ &= -\frac{1}{2} \bar{c} \mathcal{N} m \lambda \left(\frac{dv_x}{dz} \right)_0 \end{aligned} \quad (21.96)$$

The flux is proportional to the velocity gradient, as we wished to show. Comparison of this expression with eqn 21.21, and multiplication by $\frac{2}{3}$ in the normal way, leads to

$$\eta = \frac{1}{3} \bar{c} \mathcal{N} m \lambda \quad (21.97)$$

which can easily be converted into eqn 21.24 by using $Nm = nM$ and $[A] = n/V$.

Discussion questions

21.1 Use the kinetic theory to justify the following observations: (a) the rate of a reaction in the gas phase depends on the energy with which two molecules collide, which in turn depends on their speeds; (b) in the Earth's atmosphere, light gases, such as H_2 and He, are rare but heavier gases, such as O_2 , CO_2 , and N_2 , are abundant.

21.2 Provide a molecular interpretation for each of the following processes: diffusion, thermal conduction, electric conduction, and viscosity.

21.3 Provide a molecular interpretation for the observation that the viscosity of a gas increases with temperature, whereas the viscosity of a liquid decreases with increasing temperature.

21.4 Discuss the mechanism of proton conduction in liquid water.

21.5 Limit the generality of the following expressions: (a) $J = -D(dc/dx)$, (b) $D = kT/f$, and (c) $D = kT/6\pi\eta a$.

21.6 Provide a molecular interpretation for the observation that mediated transport across a biological membrane leads to a maximum flux $J_{\max}$ when the concentration of the transported species becomes very large.

21.7 Discuss how nuclear magnetic resonance spectroscopy, inelastic neutron scattering, and dynamic light scattering may be used to measure the mobility of molecules in liquids.

Exercises

21.1a Determine the ratios of (a) the mean speeds, (b) the mean kinetic energies of H_2 molecules and Hg atoms at 20°C .

21.1b Determine the ratios of (a) the mean speeds, (b) the mean kinetic energies of He atoms and Hg atoms at 25°C .

21.2a A 1.0 dm^3 glass bulb contains 1.0×10^{23} H_2 molecules. If the pressure exerted by the gas is 100 kPa, what are (a) the temperature of the gas, (b) the root mean square speeds of the molecules? (c) Would the temperature be different if they were O_2 molecules?

21.2b The best laboratory vacuum pump can generate a vacuum of about 1 nTorr. At 25°C and assuming that air consists of N_2 molecules with a collision diameter of 395 pm, calculate (a) the mean speed of the molecules, (b) the mean free path, (c) the collision frequency in the gas.

21.3a At what pressure does the mean free path of argon at 25°C become comparable to the size of a 1 dm^3 vessel that contains it? Take $\sigma = 0.36\text{ nm}^2$.

21.3b At what pressure does the mean free path of argon at 25°C become comparable to the diameters of the atoms themselves?

21.4a At an altitude of 20 km the temperature is 217 K and the pressure 0.050 atm. What is the mean free path of N_2 molecules? ($\sigma = 0.43\text{ nm}^2$.)

21.4b At an altitude of 15 km the temperature is 217 K and the pressure 12.1 kPa. What is the mean free path of N_2 molecules? ($\sigma = 0.43\text{ nm}^2$.)

21.5a How many collisions does a single Ar atom make in 1.0 s when the temperature is 25°C and the pressure is (a) 10 atm, (b) 1.0 atm, (c) 1.0 μatm ?

21.5b How many collisions per second does an N_2 molecule make at an altitude of 15 km? (See Exercise 21.4b for data.)

21.6a Calculate the mean free path of molecules in air using $\sigma = 0.43\text{ nm}^2$ at 25°C and (a) 10 atm, (b) 1.0 atm, (c) 1.0 μatm .

21.6b Calculate the mean free path of carbon dioxide molecules using $\sigma = 0.52\text{ nm}^2$ at 25°C and (a) 15 atm, (b) 1.0 bar, (c) 1.0 Torr.

21.7a Use the Maxwell distribution of speeds to estimate the fraction of N_2 molecules at 500 K that have speeds in the range 290 to 300 m s^{-1} .

21.7b Use the Maxwell distribution of speeds to estimate the fraction of CO_2 molecules at 300 K that have speeds in the range 200 to 250 m s^{-1} .

21.8a A solid surface with dimensions $2.5\text{ mm} \times 3.0\text{ mm}$ is exposed to argon gas at 90 Pa and 500 K. How many collisions do the Ar atoms make with this surface in 15 s?

21.8b A solid surface with dimensions $3.5\text{ mm} \times 4.0\text{ cm}$ is exposed to helium gas at 111 Pa and 1500 K. How many collisions do the He atoms make with this surface in 10 s?

21.9a An effusion cell has a circular hole of diameter 2.50 mm. If the molar mass of the solid in the cell is 260 g mol^{-1} and its vapour pressure is 0.835 Pa at 400 K, by how much will the mass of the solid decrease in a period of 2.00 h?

21.9b An effusion cell has a circular hole of diameter 3.00 mm. If the molar mass of the solid in the cell is 300 g mol^{-1} and its vapour pressure is 0.224 Pa at 450 K, by how much will the mass of the solid decrease in a period of 24.00 h?

21.10a A manometer was connected to a bulb containing carbon dioxide under slight pressure. The gas was allowed to escape through a small pinhole, and the time for the manometer reading to drop from 75 cm to 50 cm was 52 s. When the experiment was repeated using nitrogen (for which $M = 28.02\text{ g mol}^{-1}$) the same fall took place in 42 s. Calculate the molar mass of carbon dioxide.

21.10b A manometer was connected to a bulb containing nitrogen under slight pressure. The gas was allowed to escape through a small pinhole, and the time for the manometer reading to drop from 65.1 cm to 42.1 cm was 18.5 s. When the experiment was repeated using a fluorocarbon gas, the same fall took place in 82.3 s. Calculate the molar mass of the fluorocarbon.

21.11a A space vehicle of internal volume 3.0 m^3 is struck by a meteor and a hole of radius 0.10 mm is formed. If the oxygen pressure within the vehicle is initially 80 kPa and its temperature 298 K, how long will the pressure take to fall to 70 kPa?

21.11b A container of internal volume 22.0 m^3 was punctured, and a hole of radius 0.050 mm was formed. If the nitrogen pressure within the vehicle is initially 122 kPa and its temperature 293 K, how long will the pressure take to fall to 105 kPa?

21.12a Calculate the flux of energy arising from a temperature gradient of 2.5 K m^{-1} in a sample of argon in which the mean temperature is 273 K.

21.12b Calculate the flux of energy arising from a temperature gradient of 3.5 K m^{-1} in a sample of hydrogen in which the mean temperature is 260 K.

21.13a Use the experimental value of the thermal conductivity of neon (Table 21.2) to estimate the collision cross-section of Ne atoms at 273 K.

21.13b Use the experimental value of the thermal conductivity of nitrogen (Table 21.2) to estimate the collision cross-section of N_2 molecules at 298 K.

21.14a In a double-glazed window, the panes of glass are separated by 5.0 cm. What is the rate of transfer of heat by conduction from the warm room (25°C) to the cold exterior (-10°C) through a window of area 1.0 m^2 ? What power of heater is required to make good the loss of heat?

21.14b Two sheets of copper of area 1.50 m^2 are separated by 10.0 cm. What is the rate of transfer of heat by conduction from the warm sheet (50°C) to the cold sheet (-10°C). What is the rate of loss of heat?

21.15a Use the experimental value of the coefficient of viscosity for neon (Table 21.2) to estimate the collision cross-section of Ne atoms at 273 K.

21.15b Use the experimental value of the coefficient of viscosity for nitrogen (Table 21.2) to estimate the collision cross-section of the molecules at 273 K.

21.16a Calculate the inlet pressure required to maintain a flow rate of $9.5 \times 10^5\text{ dm}^3\text{ h}^{-1}$ of nitrogen at 293 K flowing through a pipe of length 8.50 m

and diameter 1.00 cm. The pressure of gas as it leaves the tube is 1.00 bar. The volume of the gas is measured at that pressure.

21.16b Calculate the inlet pressure required to maintain a flow rate of $8.70 \text{ cm}^3 \text{ s}^{-1}$ of nitrogen at 300 K flowing through a pipe of length 10.5 m and diameter 15 mm. The pressure of gas as it leaves the tube is 1.00 bar. The volume of the gas is measured at that pressure.

21.17a Calculate the viscosity of air at (a) 273 K, (b) 298 K, (c) 1000 K. Take $\sigma \approx 0.40 \text{ nm}^2$. (The experimental values are 173 μP at 273 K, 182 μP at 20°C, and 394 μP at 600°C.)

21.17b Calculate the viscosity of benzene vapour at (a) 273 K, (b) 298 K, (c) 1000 K. Take $\sigma \approx 0.88 \text{ nm}^2$.

21.18a Calculate the thermal conductivities of (a) argon, (b) helium at 300 K and 1.0 mbar. Each gas is confined in a cubic vessel of side 10 cm, one wall being at 310 K and the one opposite at 295 K. What is the rate of flow of energy as heat from one wall to the other in each case?

21.18b Calculate the thermal conductivities of (a) neon, (b) nitrogen at 300 K and 15 mbar. Each gas is confined in a cubic vessel of side 15 cm, one wall being at 305 K and the one opposite at 295 K. What is the rate of flow of energy as heat from one wall to the other in each case?

21.19a The viscosity of carbon dioxide was measured by comparing its rate of flow through a long narrow tube (using Poiseuille's formula) with that of argon. For the same pressure differential, the same volume of carbon dioxide passed through the tube in 55 s as argon in 83 s. The viscosity of argon at 25°C is 208 μP ; what is the viscosity of carbon dioxide? Estimate the molecular diameter of carbon dioxide.

21.19b The viscosity of a chlorofluorocarbon (CFC) was measured by comparing its rate of flow through a long narrow tube (using Poiseuille's formula) with that of argon. For the same pressure differential, the same volume of the CFC passed through the tube in 72.0 s as argon in 18.0 s. The viscosity of argon at 25°C is 208 μP ; what is the viscosity of the CFC? Estimate the molecular diameter of the CFC. Take $M = 200 \text{ g mol}^{-1}$.

21.20a Calculate the thermal conductivity of argon ($C_{V,m} = 12.5 \text{ J K}^{-1} \text{ mol}^{-1}$, $\sigma = 0.36 \text{ nm}^2$) at room temperature (20°C).

21.20b Calculate the thermal conductivity of nitrogen ($C_{V,m} = 20.8 \text{ J K}^{-1} \text{ mol}^{-1}$, $\sigma = 0.43 \text{ nm}^2$) at room temperature (20°C).

21.21a Calculate the diffusion constant of argon at 25°C and (a) 1.00 Pa, (b) 100 kPa, (c) 10.0 MPa. If a pressure gradient of 0.10 atm cm^{-1} is established in a pipe, what is the flow of gas due to diffusion?

21.21b Calculate the diffusion constant of nitrogen at 25°C and (a) 10.0 Pa, (b) 100 kPa, (c) 15.0 MPa. If a pressure gradient of 0.20 bar m^{-1} is established in a pipe, what is the flow of gas due to diffusion?

21.22a The mobility of a chloride ion in aqueous solution at 25°C is $7.91 \times 10^{-8} \text{ m}^2 \text{ s}^{-1} \text{ V}^{-1}$. Calculate the molar ionic conductivity.

21.22b The mobility of an acetate ion in aqueous solution at 25°C is $4.24 \times 10^{-8} \text{ m}^2 \text{ s}^{-1} \text{ V}^{-1}$. Calculate the molar ionic conductivity.

21.23a The mobility of a Rb^+ ion in aqueous solution is $7.92 \times 10^{-8} \text{ m}^2 \text{ s}^{-1} \text{ V}^{-1}$ at 25°C. The potential difference between two electrodes placed in the solution is 35.0 V. If the electrodes are 8.00 mm apart, what is the drift speed of the Rb^+ ion?

21.23b The mobility of a Li^+ ion in aqueous solution is $4.01 \times 10^{-8} \text{ m}^2 \text{ s}^{-1} \text{ V}^{-1}$ at 25°C. The potential difference between two electrodes placed in the solution is 12.0 V. If the electrodes are 1.00 cm apart, what is the drift speed of the ion?

21.24a What fraction of the total current is carried by Li^+ when current flows through an aqueous solution of LiBr at 25°C?

21.24b What fraction of the total current is carried by Cl^- when current flows through an aqueous solution of NaCl at 25°C?

21.25a The limiting molar conductivities of KCl , KNO_3 , and AgNO_3 are 14.99 $\text{mS m}^2 \text{ mol}^{-1}$, 14.50 $\text{mS m}^2 \text{ mol}^{-1}$, and 13.34 $\text{mS m}^2 \text{ mol}^{-1}$, respectively (all at 25°C). What is the limiting molar conductivity of AgCl at this temperature?

21.25b The limiting molar conductivities of NaI , NaCH_3CO_2 , and $\text{Mg}(\text{CH}_3\text{CO}_2)_2$ are 12.69 $\text{mS m}^2 \text{ mol}^{-1}$, 9.10 $\text{mS m}^2 \text{ mol}^{-1}$, and 18.78 $\text{mS m}^2 \text{ mol}^{-1}$, respectively (all at 25°C). What is the limiting molar conductivity of MgI_2 at this temperature?

21.26a At 25°C the molar ionic conductivities of Li^+ , Na^+ , and K^+ are 3.87 $\text{mS m}^2 \text{ mol}^{-1}$, 5.01 $\text{mS m}^2 \text{ mol}^{-1}$, and 7.35 $\text{mS m}^2 \text{ mol}^{-1}$, respectively. What are their mobilities?

21.26b At 25°C the molar ionic conductivities of F^- , Cl^- , and Br^- are 5.54 $\text{mS m}^2 \text{ mol}^{-1}$, 7.635 $\text{mS m}^2 \text{ mol}^{-1}$, and 7.81 $\text{mS m}^2 \text{ mol}^{-1}$, respectively. What are their mobilities?

21.27a The mobility of a NO_3^- ion in aqueous solution at 25°C is $7.40 \times 10^{-8} \text{ m}^2 \text{ s}^{-1} \text{ V}^{-1}$. Calculate its diffusion coefficient in water at 25°C.

21.27b The mobility of a CH_3CO_2^- ion in aqueous solution at 25°C is $4.24 \times 10^{-8} \text{ m}^2 \text{ s}^{-1} \text{ V}^{-1}$. Calculate its diffusion coefficient in water at 25°C.

21.28a The diffusion coefficient of CCl_4 in heptane at 25°C is $3.17 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$. Estimate the time required for a CCl_4 molecule to have a root mean square displacement of 5.0 mm.

21.28b The diffusion coefficient of I_2 in hexane at 25°C is $4.05 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$. Estimate the time required for an iodine molecule to have a root mean square displacement of 1.0 cm.

21.29a Estimate the effective radius of a sucrose molecule in water 25°C given that its diffusion coefficient is $5.2 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ and that the viscosity of water is 1.00 cP.

21.29b Estimate the effective radius of a glycine molecule in water at 25°C given that its diffusion coefficient is $1.055 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ and that the viscosity of water is 1.00 cP.

21.30a The diffusion coefficient for molecular iodine in benzene is $2.13 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$. How long does a molecule take to jump through about one molecular diameter (approximately the fundamental jump length for translational motion)?

21.30b The diffusion coefficient for CCl_4 in heptane is $3.17 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$. How long does a molecule take to jump through about one molecular diameter (approximately the fundamental jump length for translational motion)?

21.31a What are the root mean square distances travelled by an iodine molecule in benzene and by a sucrose molecule in water at 25°C in 1.0 s?

21.31b About how long, on average, does it take for the molecules in Exercise 21.31a to drift to a point (a) 1.0 mm, (b) 1.0 cm from their starting points?

Problems*

Numerical problems

21.1 Instead of the arrangement in Fig. 21.8, the speed of molecules can also be measured with a rotating slotted-disc apparatus, which consists of five coaxial 5.0 cm diameter discs separated by 1.0 cm, the slots in their rims being displaced by 2.0° between neighbours. The relative intensities, I , of the detected beam of Kr atoms for two different temperatures and at a series of rotation rates were as follows:

ν/Hz	20	40	80	100	120
$I(40\text{ K})$	0.846	0.513	0.069	0.015	0.002
$I(100\text{ K})$	0.592	0.485	0.217	0.119	0.057

Find the distributions of molecular velocities, $f(v_x)$, at these temperatures, and check that they conform to the theoretical prediction for a one-dimensional system.

21.2 Cars were timed by police radar as they passed in both directions below a bridge. Their velocities (kilometres per hour, numbers of cars in parentheses) to the east and west were as follows: 80 E (40), 85 E (62), 90 E (53), 95 E (12), 100 E (2); 80 W (38), 85 W (59), 90 W (50), 95 W (10), 100 W (2). What are (a) the mean velocity, (b) the mean speed, (c) the root mean square speed?

21.3 A population consists of people of the following heights (in metres, numbers of individuals in brackets): 1.80 (1), 1.82 (2), 1.84 (4), 1.86 (7), 1.88 (10), 1.90 (15), 1.92 (9), 1.94 (4), 1.96 (0), 1.98 (1). What are (a) the mean height, (b) the root mean square height of the population?

21.4 Calculate the ratio of the thermal conductivities of gaseous hydrogen at 300 K to gaseous hydrogen at 10 K. Be circumspect, and think about the modes of motion that are thermally active at the two temperatures.

21.5 A Knudsen cell was used to determine the vapour pressure of germanium at 1000°C . During an interval of 7200 s the mass loss through a hole of radius 0.50 mm amounted to 43 μg . What is the vapour pressure of germanium at 1000°C ? Assume the gas to be monatomic.

21.6 The nuclide ^{244}Bk (berkelium) decays by producing α particles, which capture electrons and form He atoms. Its half-life is 4.4 h. A sample of mass 1.0 mg was placed in a container of volume 1.0 cm^3 that was impermeable to α radiation, but there was also a hole of radius $2.0\text{ }\mu\text{m}$ in the wall. What is the pressure of helium at 298 K, inside the container after (a) 1.0 h, (b) 10 h?

21.7 An atomic beam is designed to function with (a) cadmium, (b) mercury. The source is an oven maintained at 380 K, there being a small slit of dimensions $1.0\text{ cm} \times 1.0 \times 10^{-3}\text{ cm}$. The vapour pressure of cadmium is 0.13 Pa and that of mercury is 12 Pa at this temperature. What is the atomic current (the number of atoms per unit time) in the beams?

21.8 Conductivities are often measured by comparing the resistance of a cell filled with the sample to its resistance when filled with some standard solution, such as aqueous potassium chloride. The conductivity of water is 76 mS m^{-1} at 25°C and the conductivity of $0.100\text{ mol dm}^{-3}\text{ KCl(aq)}$ is 1.1639 S m^{-1} . A cell had a resistance of $33.21\text{ }\Omega$ when filled with $0.100\text{ mol dm}^{-3}\text{ KCl(aq)}$ and $300.0\text{ }\Omega$ when filled with $0.100\text{ mol dm}^{-3}\text{ CH}_3\text{COOH}$. What is the molar conductivity of acetic acid at that concentration and temperature?

21.9 The resistances of a series of aqueous NaCl solutions, formed by successive dilution of a sample, were measured in a cell with cell constant (the constant C in the relation $\kappa = C/R$) equal to 0.2063 cm^{-1} . The following values were found:

$c/(\text{mol dm}^{-3})$	0.00050	0.0010	0.0050	0.010	0.020	0.050
R/Ω	3314	1669	342.1	174.1	89.08	37.14

Verify that the molar conductivity follows the Kohlrausch law and find the limiting molar conductivity. Determine the coefficient $\mathcal{K}$. Use the value of $\mathcal{K}$ (which should depend only on the nature, not the identity of the ions) and the information that $\lambda(\text{Na}^+) = 5.01\text{ mS m}^2\text{ mol}^{-1}$ and $\lambda(\text{I}^-) = 7.68\text{ mS m}^2\text{ mol}^{-1}$ to predict (a) the molar conductivity, (b) the conductivity, (c) the resistance it would show in the cell, of $0.010\text{ mol dm}^{-3}\text{ NaI(aq)}$ at 25°C .

21.10 After correction for the water conductivity, the conductivity of a saturated aqueous solution of AgCl at 25°C was found to be 0.1887 mS m^{-1} . What is the solubility of silver chloride at this temperature?

21.11 What are the drift speeds of Li^+ , Na^+ , and K^+ in water when a potential difference of 10 V is applied across a 1.00-cm conductivity cell? How long would it take an ion to move from one electrode to the other? In conductivity measurements it is normal to use alternating current: what are the displacements of the ions in (a) centimetres, (b) solvent diameters, about 300 pm, during a half cycle of 1.0 kHz applied potential?

21.12 The mobilities of H^+ and Cl^- at 25°C in water are $3.623 \times 10^{-7}\text{ m}^2\text{ s}^{-1}\text{ V}^{-1}$ and $7.91 \times 10^{-8}\text{ m}^2\text{ s}^{-1}\text{ V}^{-1}$, respectively. What proportion of the current is carried by the protons in 10^{-3} M HCl(aq) ? What fraction do they carry when the NaCl is added to the acid so that the solution is 1.0 mol dm^{-3} in the salt? Note how concentration as well as mobility governs the transport of current.

21.13 In a moving boundary experiment on KCl the apparatus consisted of a tube of internal diameter 4.146 mm, and it contained aqueous KCl at a concentration of 0.021 mol dm^{-3} . A steady current of 18.2 mA was passed, and the boundary advanced as follows:

$\Delta t/\text{s}$	200	400	600	800	1000
x/mm	64	128	192	254	318

Find the transport number of K^+ , its mobility, and its ionic conductivity.

21.14 The proton possesses abnormal mobility in water, but does it behave normally in liquid ammonia? To investigate this question, a moving-boundary technique was used to determine the transport number of NH_4^+ in liquid ammonia (the analogue of H_3O^+ in liquid water) at -40°C (J. Baldwin, J. Evans, and J.B. Gill, *J. Chem. Soc. A*, 3389 (1971)). A steady current of 5.000 mA was passed for 2500 s, during which time the boundary formed between mercury(II) iodide and ammonium iodide solutions in ammonia moved 286.9 mm in a $0.01365\text{ mol kg}^{-1}$ solution and 92.03 mm in a $0.04255\text{ mol kg}^{-1}$ solution. Calculate the transport number of NH_4^+ at these concentrations, and comment on the mobility of the proton in liquid ammonia. The bore of the tube is 4.146 mm and the density of liquid ammonia is 0.682 g cm^{-3} .

21.15 A dilute solution of potassium permanganate in water at 25°C was prepared. The solution was in a horizontal tube of length 10 cm, and at first there was a linear gradation of intensity of the purple solution from the left (where the concentration was 0.100 mol dm^{-3}) to the right (where the concentration was 0.050 mol dm^{-3}). What is the magnitude and sign of the thermodynamic force acting on the solute (a) close to the left face of the container, (b) in the middle, (c) close to the right face? Give the force per mole and force per molecule in each case.

* Problems denoted with the symbol ‡ were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

21.16 Estimate the diffusion coefficients and the effective hydrodynamic radii of the alkali metal cations in water from their mobilities at 25°C. Estimate the approximate number of water molecules that are dragged along by the cations. Ionic radii are given Table 20.3.

21.17 Nuclear magnetic resonance can be used to determine the mobility of molecules in liquids. A set of measurements on methane in carbon tetrachloride showed that its diffusion coefficient is $2.05 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ at 0°C and $2.89 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ at 25°C. Deduce what information you can about the mobility of methane in carbon tetrachloride.

21.18 A concentrated sucrose solution is poured into a cylinder of diameter 5.0 cm. The solution consisted of 10 g of sugar in 5.0 cm^3 of water. A further 1.0 dm^3 of water is then poured very carefully on top of the layer, without disturbing the layer. Ignore gravitational effects, and pay attention only to diffusional processes. Find the concentration at 5.0 cm above the lower layer after a lapse of (a) 10 s, (b) 1.0 y.

21.19 In a series of observations on the displacement of rubber latex spheres of radius $0.212 \text{ }\mu\text{m}$, the mean square displacements after selected time intervals were on average as follows:

t/s	30	60	90	120
$10^{12}\langle x^2 \rangle/\text{m}^2$	88.2	113.5	128	144

These results were originally used to find the value of Avogadro's constant, but there are now better ways of determining N_A , so the data can be used to find another quantity. Find the effective viscosity of water at the temperature of this experiment (25°C).

21.20† A.K. Srivastava, R.A. Samant, and S.D. Patankar (*J. Chem. Eng. Data* **41**, 431 (1996)) measured the conductance of several salts in a binary solvent mixture of water and a dipolar aprotic solvent 1,3-dioxolan-2-one (ethylene carbonate). They report the following conductances at 25°C in a solvent 80 per cent 1,3-dioxolan-2-one by mass:

NaI								
$\kappa/(\text{mmol dm}^{-3})$	32.02	20.28	12.06	8.64	2.85	1.24	0.83	
$\Lambda_m/(\text{S cm}^2 \text{ mol}^{-1})$	50.26	51.99	54.01	55.75	57.99	58.44	58.67	

KI								
$\kappa/(\text{mmol dm}^{-3})$	17.68	10.8	87.19	2.67	1.28	0.83	0.19	
$\Lambda_m/(\text{S cm}^2 \text{ mol}^{-1})$	42.45	45.91	47.53	51.81	54.09	55.78	57.42	

Calculate Λ_m° for NaI and KI in this solvent and $\lambda^\circ(\text{Na}) - \lambda^\circ(\text{K})$. Compare your results to the analogous quantities in aqueous solution using Table 21.5 in the *Data section*.

21.21† A. Fenghour, W.A. Wakeham, V. Vesovic, J.T.R. Watson, J. Millat, and E. Vogel (*J. Phys. Chem. Ref. Data* **24**, 1649 (1995)) have compiled an extensive table of viscosity coefficients for ammonia in the liquid and vapour phases. Deduce the effective molecular diameter of NH_3 based on each of the following vapour-phase viscosity coefficients: (a) $\eta = 9.08 \times 10^{-6} \text{ kg m}^{-1} \text{ s}^{-1}$ at 270 K and 1.00 bar; (b) $\eta = 1.749 \times 10^{-5} \text{ kg m}^{-1} \text{ s}^{-1}$ at 490 K and 10.0 bar.

21.22† G. Bakale, K. Lacmann, and W.F. Schmidt (*J. Phys. Chem.* **100**, 12477 (1996)) measured the mobility of singly charged C_{60}^- ions in a variety of nonpolar solvents. In cyclohexane at 22°C, the mobility is $1.1 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$. Estimate the effective radius of the C_{60}^- ion. The viscosity of the solvent is $0.93 \times 10^{-3} \text{ kg m}^{-1} \text{ s}^{-1}$. *Comment.* The researchers interpreted the substantial difference between this number and the van der Waals radius of neutral C_{60} in terms of a solvation layer around the ion.

Theoretical problems

21.23 Start from the Maxwell–Boltzmann distribution and derive an expression for the most probable speed of a gas of molecules at a temperature

T . Go on to demonstrate the validity of the equipartition conclusion that the average translational kinetic energy of molecules free to move in three dimensions is $\frac{3}{2}kT$.

21.24 Consider molecules that are confined to move in a plane (a two-dimensional gas). Calculate the distribution of speeds and determine the mean speed of the molecules at a temperature T .

21.25 A specially constructed velocity-selector accepts a beam of molecules from an oven at a temperature T but blocks the passage of molecules with a speed greater than the mean. What is the mean speed of the emerging beam, relative to the initial value, treated as a one-dimensional problem?

21.26 What is the proportion of gas molecules having (a) more than, (b) less than the root mean square speed? (c) What are the proportions having speeds greater and smaller than the mean speed?

21.27 Calculate the fractions of molecules in a gas that have a speed in a range Δv at the speed nc^* relative to those in the same range at c^* itself? This calculation can be used to estimate the fraction of very energetic molecules (which is important for reactions). Evaluate the ratio for $n = 3$ and $n = 4$.

21.28 Derive an expression that shows how the pressure of a gas inside an effusion oven (a heated chamber with a small hole in one wall) varies with time if the oven is not replenished as the gas escapes. Then show that $t_{1/2}$, the time required for the pressure to decrease to half its initial value, is independent of the initial pressure. *Hint.* Begin by setting up a differential equation relating dp/dt to $p = NkT/V$, and then integrating it.

21.29 Show how the ratio of two transport numbers t' and t'' for two cations in a mixture depends on their concentrations c' and c'' and their mobilities u' and u'' .

21.30 Confirm that eqn 21.72 is a solution of the diffusion equation with the correct initial value.

21.31 The diffusion equation is valid when many elementary steps are taken in the time interval of interest, but the random walk calculation lets us discuss distributions for short times as well as for long. Use eqn 21.84 to calculate the probability of being six paces from the origin (that is, at $x = 6\lambda$) after (a) four, (b) six, (c) twelve steps.

21.32 Use mathematical software to calculate P in a one-dimensional random walk, and evaluate the probability of being at $x = n\lambda$ for $n = 6, 10, 14, \dots, 60$. Compare the numerical value with the analytical value in the limit of a large number of steps. At what value of n is the discrepancy no more than 0.1 per cent?

21.33 Supply the intermediate mathematical steps in *Justification* 21.7.

21.34† A dilute solution of a weak (1,1)-electrolyte contains both neutral ion pairs and ions in equilibrium ($\text{AB} \rightleftharpoons \text{A}^+ + \text{B}^-$). Prove that molar conductivities are related to the degree of ionization by the equations:

$$\frac{1}{\Lambda_m} = \frac{1}{\Lambda_m(\alpha)} + \frac{(1-\alpha)\Lambda_m^\circ}{\alpha^2\Lambda_m(\alpha)^2} \quad \Lambda_m(\alpha) = \lambda_+ + \lambda_- = \Lambda_m^\circ - \mathcal{K}(\alpha)^{1/2}$$

where Λ_m° is the molar conductivity at infinite dilution and $\mathcal{K}$ is the constant in Kohlrausch's law (eqn 21.29).

Applications: to astrophysics and biochemistry

21.35 Calculate the escape velocity (the minimum initial velocity that will take an object to infinity) from the surface of a planet of radius R . What is the value for (a) the Earth, $R = 6.37 \times 10^6 \text{ m}$, $g = 9.81 \text{ m s}^{-2}$, (b) Mars, $R = 3.38 \times 10^6 \text{ m}$, $m_{\text{Mars}}/m_{\text{Earth}} = 0.108$. At what temperatures do H_2 , He, and O_2 molecules have mean speeds equal to their escape speeds? What proportion of the molecules have enough speed to escape when the temperature is (a) 240 K, (b) 1500 K? Calculations of this kind are very important in considering the composition of planetary atmospheres.

21.36† Interstellar space is a medium quite different from the gaseous environments we commonly encounter on Earth. For instance, a typical density of the medium is about 1 atom cm^{-3} and that atom is typically H; the effective temperature due to stellar background radiation is about 10 000 K. Estimate the diffusion coefficient and thermal conductivity of H under these conditions. *Comment.* Energy is in fact transferred much more effectively by radiation.

21.37 The principal components of the atmosphere of the Earth are diatomic molecules, which can rotate as well as translate. Given that the translational kinetic energy density of the atmosphere is 0.15 J cm^{-3} , what is the total kinetic energy density, including rotation?

21.38† In the *standard model* of stellar structure (I. Nicholson, *The sun*. Rand McNally, New York (1982)), the interior of the Sun is thought to consist of 36 per cent H and 64 per cent He by mass, at a density of 158 g cm^{-3} . Both atoms are completely ionized. The approximate dimensions of the nuclei can be calculated from the formula $r_{\text{nucleus}} = 1.4 \times 10^{-15} A^{1/3} \text{ m}$, where A is the mass number. The size of the free electron, $r_e \approx 10^{-18} \text{ m}$, is negligible compared to the size of the nuclei. (a) Calculate the excluded volume in 1.0 cm^3 of the stellar interior and on that basis decide upon the applicability of the perfect gas law to this system. (b) The standard model suggests that the pressure in the stellar interior is $2.5 \times 10^{11} \text{ atm}$. Calculate the temperature of the Sun's interior based on the perfect gas model. The generally accepted standard model value is 16 MK. (c) Would a van der Waals type of equation (with $a = 0$) give a better value for T ?

21.39 Enrico Fermi, the great Italian scientist, was a master at making good approximate calculations based on little or no actual data. Hence, such calculations are often called 'Fermi calculations'. Do a Fermi calculation on how long it would take for a gaseous air-borne cold virus of molar mass 100 kg mol^{-1} to travel the distance between two conversing people 1.0 m apart by diffusion in still air.

21.40 The diffusion coefficient of a particular kind of t-RNA molecule is $D = 1.0 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$ in the medium of a cell interior. How long does it take molecules produced in the cell nucleus to reach the walls of the cell at a distance $1.0 \text{ }\mu\text{m}$, corresponding to the radius of the cell?

21.41† In this problem, we examine a model for the transport of oxygen from air in the lungs to blood. First, show that, for the initial and boundary conditions $c(x, 0) = c(x, \infty) = c_0$, ($0 < x < \infty$) and $c(0, t) = c_s$, ($0 \leq t < \infty$) where c_0 and c_s are constants, the concentration, $c(x, t)$, of a species is given by

$$c(x, t) = c_0 + (c_s - c_0) \{1 - \text{erf} \xi\} \quad \xi(x, t) = \frac{x}{(4Dt)^{1/2}}$$

where $\text{erf} \xi$ is the error function (*Justification 9.4*) and the concentration $c(x, t)$ evolves by diffusion from the yz -plane of constant concentration, such as might occur if a condensed phase is absorbing a species from a gas phase. Now draw graphs of concentration profiles at several different times of your choice for the diffusion of oxygen into water at 298 K (when $D = 2.10 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$) on a spatial scale comparable to passage of oxygen from lungs through alveoli into the blood. Use $c_0 = 0$ and set c_s equal to the solubility of oxygen in water. *Hint.* Use mathematical software.

The rates of chemical reactions

22

This chapter is the first of a sequence that explores the rates of chemical reactions. The chapter begins with a discussion of the definition of reaction rate and outlines the techniques for its measurement. The results of such measurements show that reaction rates depend on the concentration of reactants (and products) in characteristic ways that can be expressed in terms of differential equations known as rate laws. The solutions of these equations are used to predict the concentrations of species at any time after the start of the reaction. The form of the rate law also provides insight into the series of elementary steps by which a reaction takes place. The key task in this connection is the construction of a rate law from a proposed mechanism and its comparison with experiment. Simple elementary steps have simple rate laws, and these rate laws can be combined together by invoking one or more approximations. These approximations include the concept of the rate-determining stage of a reaction, the steady-state concentration of a reaction intermediate, and the existence of a pre-equilibrium.

This chapter introduces the principles of **chemical kinetics**, the study of reaction rates, by showing how the rates of reactions may be measured and interpreted. The remaining chapters of this part of the text then develop this material in more detail and apply it to more complicated or more specialized cases. The rate of a chemical reaction might depend on variables under our control, such as the pressure, the temperature, and the presence of a catalyst, and we may be able to optimize the rate by the appropriate choice of conditions. The study of reaction rates also leads to an understanding of the **mechanisms** of reactions, their analysis into a sequence of elementary steps.

Empirical chemical kinetics

The first steps in the kinetic analysis of reactions are to establish the stoichiometry of the reaction and identify any side reactions. The basic data of chemical kinetics are then the concentrations of the reactants and products at different times after a reaction has been initiated. The rates of most chemical reactions are sensitive to the temperature, so in conventional experiments the temperature of the reaction mixture must be held constant throughout the course of the reaction. This requirement puts severe demands on the design of an experiment. Gas-phase reactions, for instance, are often carried out in a vessel held in contact with a substantial block of metal. Liquid-phase reactions, including flow reactions, must be carried out in an efficient thermostat. Special efforts have to be made to study reactions at low temperatures, as in the study of the kinds of reactions that take place in interstellar clouds. Thus, supersonic expansion of the reaction gas can be used to attain temperatures as low as

Discussion questions

Exercises

Problems

10 K. For work in the liquid phase and the solid phase, very low temperatures are often reached by flowing cold liquid or cold gas around the reaction vessel. Alternatively, the entire reaction vessel is immersed in a thermally insulated container filled with a cryogenic liquid, such as liquid helium (for work at around 4 K) or liquid nitrogen (for work at around 77 K). Non-isothermal conditions are sometimes employed. For instance, the shelf-life of an expensive pharmaceutical may be explored by slowly raising the temperature of a single sample.

22.1 Experimental techniques

The method used to monitor concentrations depends on the species involved and the rapidity with which their concentrations change. Many reactions reach equilibrium over periods of minutes or hours, and several techniques may then be used to follow the changing concentrations.

(a) Monitoring the progress of a reaction

A reaction in which at least one component is a gas might result in an overall change in pressure in a system of constant volume, so its progress may be followed by recording the variation of pressure with time.

Example 22.1 Monitoring the variation in pressure

Predict how the total pressure varies during the gas-phase decomposition $2\text{N}_2\text{O}_5(\text{g}) \rightarrow 4\text{NO}_2(\text{g}) + \text{O}_2(\text{g})$ in a constant-volume container.

Method The total pressure (at constant volume and temperature and assuming perfect gas behaviour) is proportional to the number of gas-phase molecules. Therefore, because each mole of N_2O_5 gives rise to $\frac{5}{2}$ mol of gas molecules, we can expect the pressure to rise to $\frac{5}{2}$ times its initial value. To confirm this conclusion, express the progress of the reaction in terms of the fraction, α , of N_2O_5 molecules that have reacted.

Answer Let the initial pressure be p_0 and the initial amount of N_2O_5 molecules present be n . When a fraction α of the N_2O_5 molecules has decomposed, the amounts of the components in the reaction mixture are:

	N_2O_5	NO_2	O_2	Total
Amount:	$n(1 - \alpha)$	$2\alpha n$	$\frac{1}{2}\alpha n$	$n(1 + \frac{3}{2}\alpha)$

When $\alpha = 0$ the pressure is p_0 , so at any stage the total pressure is

$$p = (1 + \frac{3}{2}\alpha)p_0$$

When the reaction is complete, the pressure will have risen to $\frac{5}{2}$ times its initial value.

Self-test 22.1 Repeat the calculation for $2\text{NOBr}(\text{g}) \rightarrow 2\text{NO}(\text{g}) + \text{Br}_2(\text{g})$.

$$[p = (1 + \frac{1}{2}\alpha)p_0]$$

Spectrophotometry, the measurement of absorption of radiation in a particular spectral region, is widely applicable, and is especially useful when one substance in the reaction mixture has a strong characteristic absorption in a conveniently accessible region of the electromagnetic spectrum. For example, the progress of the reaction

can be followed by measuring the absorption of visible light by bromine. A reaction that changes the number or type of ions present in a solution may be followed by monitoring the electrical conductivity of the solution. The replacement of neutral molecules by ionic products can result in dramatic changes in the conductivity, as in the reaction

If hydrogen ions are produced or consumed, the reaction may be followed by monitoring the pH of the solution.

Other methods of determining composition include emission spectroscopy, mass spectrometry, gas chromatography, nuclear magnetic resonance, and electron paramagnetic resonance (for reactions involving radicals or paramagnetic *d*-metal ions).

(b) Application of the techniques

In a **real-time analysis** the composition of the system is analysed while the reaction is in progress. Either a small sample is withdrawn or the bulk solution is monitored. In the **flow method** the reactants are mixed as they flow together in a chamber (Fig. 22.1). The reaction continues as the thoroughly mixed solutions flow through the outlet tube, and observation of the composition at different positions along the tube is equivalent to the observation of the reaction mixture at different times after mixing. The disadvantage of conventional flow techniques is that a large volume of reactant solution is necessary. This makes the study of fast reactions particularly difficult because to spread the reaction over a length of tube the flow must be rapid. This disadvantage is avoided by the **stopped-flow technique**, in which the reagents are mixed very quickly in a small chamber fitted with a syringe instead of an outlet tube (Fig. 22.2). The flow ceases when the plunger of the syringe reaches a stop, and the reaction continues in the mixed solutions. Observations, commonly using spectroscopic techniques such as ultraviolet–visible absorption, circular dichroism, and fluorescence emission, are made on the sample as a function of time. The technique allows for the study of reactions that occur on the millisecond to second timescale. The suitability of the stopped-flow method to the study of small samples means that it is appropriate for many biochemical reactions, and it has been widely used to study the kinetics of protein folding and enzyme action (see *Impact I22.1* later in the chapter).

Very fast reactions can be studied by **flash photolysis**, in which the sample is exposed to a brief flash of light that initiates the reaction and then the contents of the reaction chamber are monitored. Most work is now done with lasers with photolysis pulse widths that range from femtoseconds to nanoseconds (Section 14.5). The apparatus used for flash photolysis studies is based on the experimental design for time-resolved spectroscopy (Section 14.6). Reactions occurring on a picosecond or femtosecond timescale may be monitored by using electronic absorption or emission, infrared absorption, or Raman scattering. The spectra are recorded at a series of times following laser excitation. The laser pulse can initiate the reaction by forming a reactive species, such as an excited electronic state of a molecule, a radical, or an ion. We discuss examples of excited state reactions in Chapter 23. An example of radical generation is the light-induced dissociation of $\text{Cl}_2(\text{g})$ to yield Cl atoms that react with HBr to make HCl and Br according to the following sequence:

Fig. 22.1 The arrangement used in the flow technique for studying reaction rates. The reactants are injected into the mixing chamber at a steady rate. The location of the spectrometer corresponds to different times after initiation.

Fig. 22.2 In the stopped-flow technique the reagents are driven quickly into the mixing chamber by the driving syringes and then the time dependence of the concentrations is monitored.

Here HCl^* denotes a vibrationally excited HCl molecule and M is a body (an unreactive molecule or the wall of the container) that removes the excess energy stored in HCl . A so-called ‘third body’ (M) is not always necessary for heteronuclear diatomic molecules because they can discard energy radiatively, but homonuclear diatomic molecules are vibrationally and rotationally inactive, and can discard energy only by collision.

In contrast to real-time analysis, **quenching methods** are based on stopping, or quenching, the reaction after it has been allowed to proceed for a certain time. In this way the composition is analysed at leisure and reaction intermediates may be trapped. These methods are suitable only for reactions that are slow enough for there to be little reaction during the time it takes to quench the mixture. In the **chemical quench flow method**, the reactants are mixed in much the same way as in the flow method but the reaction is quenched by another reagent, such as solution of acid or base, after the mixture has travelled along a fixed length of the outlet tube. Different reaction times can be selected by varying the flow rate along the outlet tube. An advantage of the chemical quench flow method over the stopped-flow method is that spectroscopic fingerprints are not needed in order to measure the concentration of reactants and products. Once the reaction has been quenched, the solution may be examined by ‘slow’ techniques, such as gel electrophoresis, mass spectrometry, and chromatography. In the **freeze quench method**, the reaction is quenched by cooling the mixture within milliseconds and the concentrations of reactants, intermediates, and products are measured spectroscopically.

22.2 The rates of reactions

Reaction rates depend on the composition and the temperature of the reaction mixture. The next few sections look at these observations in more detail.

(a) The definition of rate

Consider a reaction of the form $A + 2B \rightarrow 3C + D$, in which at some instant the molar concentration of a participant J is $[J]$ and the volume of the system is constant. The instantaneous **rate of consumption** of one of the reactants at a given time is $-d[R]/dt$, where R is A or B . This rate is a positive quantity (Fig. 22.3). The **rate of formation** of one of the products (C or D , which we denote P) is $d[P]/dt$ (note the difference in sign). This rate is also positive.

It follows from the stoichiometry for the reaction $A + 2B \rightarrow 3C + D$ that

$$\frac{d[D]}{dt} = \frac{1}{3} \frac{d[C]}{dt} = -\frac{d[A]}{dt} = -\frac{1}{2} \frac{d[B]}{dt}$$

so there are several rates connected with the reaction. The undesirability of having different rates to describe the same reaction is avoided by using the extent of reaction, ξ (xi, the quantity introduced in Section 7.1):

$$\xi = \frac{n_J - n_{J,0}}{\nu_J} \quad (22.1)$$

where ν_J is the stoichiometric number of species J , and defining the unique **rate of reaction**, v , as the rate of change of the extent of reaction:

$$v = \frac{1}{V} \frac{d\xi}{dt} \quad [22.2]$$

It follows that

$$v = \frac{1}{\nu_J} \times \frac{1}{V} \frac{dn_J}{dt} \quad (22.3a)$$

Fig. 22.3 The definition of (instantaneous) rate as the slope of the tangent drawn to the curve showing the variation of concentration with time. For negative slopes, the sign is changed when reporting the rate, so all reaction rates are positive.

(Remember that v_j is negative for reactants and positive for products.) For a homogeneous reaction in a constant-volume system the volume V can be taken inside the differential and we use $[J] = n_j/V$ to write

$$v = \frac{1}{v_j} \frac{d[J]}{dt} \quad (22.3b)$$

For a heterogeneous reaction, we use the (constant) surface area, A , occupied by the species in place of V and use $\sigma_j = n_j/A$ to write

$$v = \frac{1}{v_j} \frac{d\sigma_j}{dt} \quad (22.3c)$$

In each case there is now a single rate for the entire reaction (for the chemical equation as written). With molar concentrations in moles per cubic decimetre and time in seconds, reaction rates of homogeneous reactions are reported in moles per cubic decimetre per second ($\text{mol dm}^{-3} \text{s}^{-1}$) or related units. For gas-phase reactions, such as those taking place in the atmosphere, concentrations are often expressed in molecules per cubic centimetre (molecules cm^{-3}) and rates in molecules per cubic centimetre per second ($\text{molecules cm}^{-3} \text{s}^{-1}$). For heterogeneous reactions, rates are expressed in moles per square metre per second ($\text{mol m}^{-2} \text{s}^{-1}$) or related units.

Illustration 22.1 Rates of formation and consumption

If the rate of formation of NO in the reaction $2 \text{NOBr(g)} \rightarrow 2 \text{NO(g)} + \text{Br}_2\text{(g)}$ is reported as $0.16 \text{ mmol dm}^{-3} \text{s}^{-1}$, we use $v_{\text{NO}} = +2$ to report that $v = 0.080 \text{ mmol dm}^{-3} \text{s}^{-1}$. Because $v_{\text{NOBr}} = -2$ it follows that $d[\text{NOBr}]/dt = -0.16 \text{ mmol dm}^{-3} \text{s}^{-1}$. The rate of consumption of NOBr is therefore $0.16 \text{ mmol dm}^{-3} \text{s}^{-1}$, or $9.6 \times 10^{16} \text{ molecules cm}^{-3} \text{s}^{-1}$.

Self-test 22.2 The rate of change of molar concentration of CH_3 radicals in the reaction $2 \text{CH}_3\text{(g)} \rightarrow \text{CH}_3\text{CH}_3\text{(g)}$ was reported as $d[\text{CH}_3]/dt = -1.2 \text{ mol dm}^{-3} \text{s}^{-1}$ under particular conditions. What is (a) the rate of reaction and (b) the rate of formation of CH_3CH_3 ? [(a) $0.60 \text{ mol dm}^{-3} \text{s}^{-1}$, (b) $0.60 \text{ mol dm}^{-3} \text{s}^{-1}$]

(b) Rate laws and rate constants

The rate of reaction is often found to be proportional to the concentrations of the reactants raised to a power. For example, the rate of a reaction may be proportional to the molar concentrations of two reactants A and B, so we write

$$v = k[A][B] \quad (22.4)$$

with each concentration raised to the first power. The coefficient k is called the **rate constant** for the reaction. The rate constant is independent of the concentrations but depends on the temperature. An experimentally determined equation of this kind is called the **rate law** of the reaction. More formally, a rate law is an equation that expresses the rate of reaction as a function of the concentrations of all the species present in the overall chemical equation for the reaction at some time:

$$v = f([A], [B], \dots) \quad [22.5a]$$

For homogeneous gas-phase reactions, it is often more convenient to express the rate law in terms of partial pressures, which are related to molar concentrations by $p_j = RT[J]$. In this case, we write

$$v = f(p_A, p_B, \dots) \quad [22.5b]$$

The rate law of a reaction is determined experimentally, and cannot in general be inferred from the chemical equation for the reaction. The reaction of hydrogen and bromine, for example, has a very simple stoichiometry, $\text{H}_2(\text{g}) + \text{Br}_2(\text{g}) \rightarrow 2 \text{HBr}(\text{g})$, but its rate law is complicated:

$$v = \frac{k[\text{H}_2][\text{Br}_2]^{3/2}}{[\text{Br}_2] + k'[\text{HBr}]} \quad (22.6)$$

In certain cases the rate law does reflect the stoichiometry of the reaction, but that is either a coincidence or reflects a feature of the underlying reaction mechanism (see later).

A practical application of a rate law is that, once we know the law and the value of the rate constant, we can predict the rate of reaction from the composition of the mixture. Moreover, as we shall see later, by knowing the rate law, we can go on to predict the composition of the reaction mixture at a later stage of the reaction. Moreover, a rate law is a guide to the mechanism of the reaction, for any proposed mechanism must be consistent with the observed rate law.

(c) Reaction order

Many reactions are found to have rate laws of the form

$$v = k[\text{A}]^a[\text{B}]^b \dots \quad (22.7)$$

The power to which the concentration of a species (a product or a reactant) is raised in a rate law of this kind is the **order** of the reaction with respect to that species. A reaction with the rate law in eqn 22.4 is **first-order** in A and first-order in B. The **overall order** of a reaction with a rate law like that in eqn 22.7 is the sum of the individual orders, $a + b + \dots$. The rate law in eqn 22.4 is therefore second-order overall.

A reaction need not have an integral order, and many gas-phase reactions do not. For example, a reaction having the rate law

$$v = k[\text{A}]^{1/2}[\text{B}] \quad (22.8)$$

is half-order in A, first-order in B, and three-halves-order overall. Some reactions obey a **zero-order rate law**, and therefore have a rate that is independent of the concentration of the reactant (so long as some is present). Thus, the catalytic decomposition of phosphine (PH_3) on hot tungsten at high pressures has the rate law

$$v = k \quad (22.9)$$

The PH_3 decomposes at a constant rate until it has almost entirely disappeared. Zero-order reactions typically occur when there is a bottle-neck of some kind in the mechanism, as in heterogeneous reactions when the surface is saturated and the subsequent reaction slow and in a number of enzyme reactions when there is a large excess of substrate relative to the enzyme.

When a rate law is not of the form in eqn 22.7, the reaction does not have an overall order and may not even have definite orders with respect to each participant. Thus, although eqn 22.6 shows that the reaction of hydrogen and bromine is first-order in H_2 , the reaction has an indefinite order with respect to both Br_2 and HBr and has no overall order.

These remarks point to three problems. First, we must see how to identify the rate law and obtain the rate constant from the experimental data. We concentrate on this aspect in this chapter. Second, we must see how to construct reaction mechanisms that are consistent with the rate law. We shall introduce the techniques of doing so in

this chapter and develop them further in Chapter 23. Third, we must account for the values of the rate constants and explain their temperature dependence. We shall see a little of what is involved in this chapter, but leave the details until Chapter 24.

(d) The determination of the rate law

The determination of a rate law is simplified by the **isolation method** in which the concentrations of all the reactants except one are in large excess. If B is in large excess, for example, then to a good approximation its concentration is constant throughout the reaction. Although the true rate law might be $v = k[A][B]$, we can approximate [B] by $[B]_0$, its initial value, and write

$$v = k'[A] \quad k' = k[B]_0 \quad (22.10)$$

which has the form of a first-order rate law. Because the true rate law has been forced into first-order form by assuming that the concentration of B is constant, eqn 22.10 is called a **pseudofirst-order rate law**. The dependence of the rate on the concentration of each of the reactants may be found by isolating them in turn (by having all the other substances present in large excess), and so constructing a picture of the overall rate law.

In the **method of initial rates**, which is often used in conjunction with the isolation method, the rate is measured at the beginning of the reaction for several different initial concentrations of reactants. We shall suppose that the rate law for a reaction with A isolated is $v = k[A]^a$; then its initial rate, v_0 , is given by the initial values of the concentration of A, and we write $v_0 = k[A]_0^a$. Taking logarithms gives:

$$\log v_0 = \log k + a \log [A]_0 \quad (22.11)$$

For a series of initial concentrations, a plot of the logarithms of the initial rates against the logarithms of the initial concentrations of A should be a straight line with slope a .

Example 22.2 Using the method of initial rates

The recombination of iodine atoms in the gas phase in the presence of argon was investigated and the order of the reaction was determined by the method of initial rates. The initial rates of reaction of $2 \text{ I(g)} + \text{Ar(g)} \rightarrow \text{I}_2\text{(g)} + \text{Ar(g)}$ were as follows:

$[\text{I}]_0 / (10^{-5} \text{ mol dm}^{-3})$	1.0	2.0	4.0	6.0
$v_0 / (\text{mol dm}^{-3} \text{ s}^{-1})$	(a) 8.70×10^{-4}	3.48×10^{-3}	1.39×10^{-2}	3.13×10^{-2}
	(b) 4.35×10^{-3}	1.74×10^{-2}	6.96×10^{-2}	1.57×10^{-1}
	(c) 8.69×10^{-3}	3.47×10^{-2}	1.38×10^{-1}	3.13×10^{-1}

The Ar concentrations are (a) 1.0 mmol dm^{-3} , (b) 5.0 mmol dm^{-3} , and (c) $10.0 \text{ mmol dm}^{-3}$. Determine the orders of reaction with respect to the I and Ar atom concentrations and the rate constant.

Method Plot the logarithm of the initial rate, $\log v_0$, against $\log [\text{I}]_0$ for a given concentration of Ar, and, separately, against $\log [\text{Ar}]_0$ for a given concentration of I. The slopes of the two lines are the orders of reaction with respect to I and Ar, respectively. The intercepts with the vertical axis give $\log k$.

Answer The plots are shown in Fig. 22.4. The slopes are 2 and 1, respectively, so the (initial) rate law is

$$v_0 = k[\text{I}]_0^2[\text{Ar}]_0$$

This rate law signifies that the reaction is second-order in [I], first-order in [Ar], and third-order overall. The intercept corresponds to $k = 9 \times 10^9 \text{ mol}^{-2} \text{ dm}^6 \text{ s}^{-1}$.

Fig. 22.4 The plot of $\log v_0$ against (a) $\log [I]_0$ for a given $[Ar]_0$, and (b) $\log [Ar]_0$ for a given $[I]_0$.

A note on good practice The units of k come automatically from the calculation, and are always such as to convert the product of concentrations to a rate in concentration/time (for example, $\text{mol dm}^{-3} \text{s}^{-1}$).

Self-test 22.3 The initial rate of a reaction depended on concentration of a substance J as follows:

$[J]_0 / (\text{mmol dm}^{-3})$	5.0	8.2	17	30
$v_0 / (10^{-7} \text{ mol dm}^{-3} \text{s}^{-1})$	3.6	9.6	41	130

Determine the order of the reaction with respect to J and calculate the rate constant.
 $[2, 1.4 \times 10^{-2} \text{ dm}^3 \text{mol}^{-1} \text{s}^{-1}]$

The method of initial rates might not reveal the full rate law, for once the products have been generated they might participate in the reaction and affect its rate. For example, products participate in the synthesis of HBr, because eqn 22.6 shows that the full rate law depends on the concentration of HBr. To avoid this difficulty, the rate law should be fitted to the data throughout the reaction. The fitting may be done, in simple cases at least, by using a proposed rate law to predict the concentration of any component at any time, and comparing it with the data. A law should also be tested by observing whether the addition of products or, for gas-phase reactions, a change in the surface-to-volume ratio in the reaction chamber affects the rate.

22.3 Integrated rate laws

Because rate laws are differential equations, we must integrate them if we want to find the concentrations as a function of time. Even the most complex rate laws may be integrated numerically. However, in a number of simple cases analytical solutions, known as **integrated rate laws**, are easily obtained, and prove to be very useful. We examine a few of these simple cases here.

(a) First-order reactions

As shown in the *Justification* below, the integrated form of the first-order rate law

$$\frac{d[A]}{dt} = -k[A] \quad (22.12a)$$

Synoptic table 22.1* Kinetic data for first-order reactions

Reaction	Phase	$\theta/^{\circ}\text{C}$	k/s^{-1}	$t_{1/2}$
$2\text{N}_2\text{O}_5 \rightarrow 4\text{NO}_2 + \text{O}_2$	g	25	3.38×10^{-5}	5.70 h
	$\text{Br}_2(\text{l})$	25	4.27×10^{-5}	4.51 h
$\text{C}_2\text{H}_6 \rightarrow 2\text{CH}_3$	g	700	5.36×10^{-4}	21.6 min

* More values are given in the Data section.

is

$$\ln\left(\frac{[\text{A}]}{[\text{A}]_0}\right) = -kt \quad [\text{A}] = [\text{A}]_0 e^{-kt} \quad (22.12b)$$

where $[\text{A}]_0$ is the initial concentration of A (at $t = 0$).

Justification 22.1 First-order integrated rate law

First, we rearrange eqn 22.12a into

$$\frac{d[\text{A}]}{[\text{A}]} = -k dt$$

This expression can be integrated directly because k is a constant independent of t . Initially (at $t = 0$) the concentration of A is $[\text{A}]_0$, and at a later time t it is $[\text{A}]$, so we make these values the limits of the integrals and write

$$\int_{[\text{A}]_0}^{[\text{A}]} \frac{d[\text{A}]}{[\text{A}]} = -k \int_0^t dt$$

Because the integral of $1/x$ is $\ln x$, eqn 22.12b is obtained immediately.

A note on good practice To set the limits of integration, identify the start time ($t = 0$) and the corresponding concentration of A ($[\text{A}]_0$), and write these quantities as the lower limits of their respective integrals. Then identify the time of interest (t) and the corresponding concentration ($[\text{A}]$), and write these quantities as the upper limits of their respective integrals.

Equation 22.12b shows that, if $\ln([\text{A}]/[\text{A}]_0)$ is plotted against t , then a first-order reaction will give a straight line of slope $-k$. Some rate constants determined in this way are given in Table 22.1. The second expression in eqn 22.12b shows that in a first-order reaction the reactant concentration decreases exponentially with time with a rate determined by k (Fig. 22.5).

Example 22.3 Analysing a first-order reaction

The variation in the partial pressure of azomethane with time was followed at 600 K, with the results given below. Confirm that the decomposition

is first-order in azomethane, and find the rate constant at 600 K.

t/s	0	1000	2000	3000	4000
p/Pa	10.9	7.63	5.32	3.71	2.59

Comment 22.1

The web site contains links to databases of rate constants of chemical reactions.

Fig. 22.5 The exponential decay of the reactant in a first-order reaction. The larger the rate constant, the more rapid the decay: here $k_{\text{large}} = 3k_{\text{small}}$.

Exploration For a first-order reaction of the form $\text{A} \rightarrow n\text{B}$ (with n possibly fractional), the concentration of the product varies with time as $[\text{B}] = n[\text{B}]_0(1 - e^{-kt})$. Plot the time dependence of $[\text{A}]$ and $[\text{B}]$ for the cases $n = 0.5, 1$, and 2 .

Fig. 22.6 The determination of the rate constant of a first-order reaction: a straight line is obtained when $\ln [A]$ (or, as here, $\ln p$) is plotted against t ; the slope gives k .

Method As indicated in the text, to confirm that a reaction is first-order, plot $\ln([A]/[A]_0)$ against time and expect a straight line. Because the partial pressure of a gas is proportional to its concentration, an equivalent procedure is to plot $\ln(p/p_0)$ against t . If a straight line is obtained, its slope can be identified with $-k$.

Answer We draw up the following table:

t/s	0	1000	2000	3000	4000
$\ln(p/p_0)$	1	-0.360	-0.720	-1.082	-1.441

Figure 22.6 shows the plot of $\ln(p/p_0)$ against t . The plot is straight, confirming a first-order reaction, and its slope is -3.6×10^{-4} . Therefore, $k = 3.6 \times 10^{-4} \text{ s}^{-1}$.

A note on good practice Because the horizontal and vertical axes of graphs are labelled with pure numbers, the slope of a graph is always dimensionless. For a graph of the form $y = b + mx$ we can write

$$y = b + (m \text{ units})(x/\text{units})$$

where ‘units’ are the units of x , and identify the (dimensionless) slope with ‘ m units’. Then

$$m = \text{slope}/\text{units}$$

In the present case, because the graph shown here is a plot of $\ln(p/p_0)$ against t/s (with ‘units’ = s) and k is the negative value of the slope of $\ln(p/p_0)$ against t itself,

$$k = -\text{slope}/s$$

Self-test 22.4 In a particular experiment, it was found that the concentration of N_2O_5 in liquid bromine varied with time as follows:

t/s	0	200	400	600	1000
$[\text{N}_2\text{O}_5]/(\text{mol dm}^{-3})$	0.110	0.073	0.048	0.032	0.014

Confirm that the reaction is first-order in N_2O_5 and determine the rate constant.

$$[k = 2.1 \times 10^{-3} \text{ s}^{-1}]$$

(b) Half-lives and time constants

A useful indication of the rate of a first-order chemical reaction is the **half-life**, $t_{1/2}$, of a substance, the time taken for the concentration of a reactant to fall to half its initial value. The time for $[A]$ to decrease from $[A]_0$ to $\frac{1}{2}[A]_0$ in a first-order reaction is given by eqn 22.12b as

$$kt_{1/2} = -\ln \left(\frac{\frac{1}{2}[A]_0}{[A]_0} \right) = -\ln \frac{1}{2} = \ln 2$$

Hence

$$t_{1/2} = \frac{\ln 2}{k} \quad (22.13)$$

($\ln 2 = 0.693$.) The main point to note about this result is that, for a first-order reaction, the half-life of a reactant is independent of its initial concentration. Therefore, if the concentration of A at some *arbitrary* stage of the reaction is $[A]$, then it will have fallen to $\frac{1}{2}[A]$ after a further interval of $(\ln 2)/k$. Some half-lives are given in Table 22.1.

Another indication of the rate of a first-order reaction is the **time constant**, τ (tau), the time required for the concentration of a reactant to fall to $1/e$ of its initial value. From eqn 22.12b it follows that

$$k\tau = -\ln\left(\frac{[A]_0/e}{[A]_0}\right) = -\ln\frac{1}{e} = 1$$

That is, the time constant of a first-order reaction is the reciprocal of the rate constant:

$$\tau = \frac{1}{k} \quad (22.14)$$

(c) Second-order reactions

We show in the *Justification* below that the integrated form of the second-order rate law

$$\frac{d[A]}{dt} = -k[A]^2 \quad (22.15a)$$

is either of the following two forms:

$$\frac{1}{[A]} - \frac{1}{[A]_0} = kt \quad (22.15b)$$

$$[A] = \frac{[A]_0}{1 + kt[A]_0} \quad (22.15c)$$

where $[A]_0$ is the initial concentration of A (at $t = 0$).

Justification 22.2 Second-order integrated rate law

To integrate eqn 22.15a we rearrange it into

$$\frac{d[A]}{[A]^2} = -kdt$$

The concentration of A is $[A]_0$ at $t = 0$ and $[A]$ at a general time t later. Therefore,

$$-\int_{[A]_0}^{[A]} \frac{d[A]}{[A]^2} = k \int_0^t dt$$

Because the integral of $1/x^2$ is $-1/x$, we obtain eqn 22.15b by substitution of the limits

$$\frac{1}{[A]} \Big|_{[A]_0}^{[A]} = \frac{1}{[A]} - \frac{1}{[A]_0} = kt$$

We can then rearrange this expression into eqn 22.15c.

Equation 22.15b shows that to test for a second-order reaction we should plot $1/[A]$ against t and expect a straight line. The slope of the graph is k . Some rate constants determined in this way are given in Table 22.2. The rearranged form, eqn 22.15c, lets us predict the concentration of A at any time after the start of the reaction. It shows that the concentration of A approaches zero more slowly than in a first-order reaction with the same initial rate (Fig. 22.7).

It follows from eqn 22.15b by substituting $t = t_{1/2}$ and $[A] = \frac{1}{2}[A]_0$ that the half-life of a species A that is consumed in a second-order reaction is

Fig. 22.7 The variation with time of the concentration of a reactant in a second-order reaction. The grey lines are the corresponding decays in a first-order reaction with the same initial rate. For this illustration, $k_{\text{large}} = 3k_{\text{small}}$.

Exploration For a second-order reaction of the form $A \rightarrow nB$ (with n possibly fractional), the concentration of the product varies with time as $[B] = nkt[A]_0^2/(1 + kt[A]_0)$. Plot the time dependence of $[A]$ and $[B]$ for the cases $n = 0.5, 1$, and 2 .

Synoptic table 22.2* Kinetic data for second-order reactions

Reaction	Phase	$\theta/^{\circ}\text{C}$	$k/(\text{dm}^3 \text{ mol}^{-1} \text{ s}^{-1})$
$2 \text{ NOBr} \rightarrow 2 \text{ NO} + \text{Br}_2$	g	10	0.80
$2 \text{ I} \rightarrow \text{I}_2$	g	23	7×10^9
$\text{CH}_3\text{Cl} + \text{CH}_3\text{O}^-$	$\text{CH}_3\text{OH}(\text{l})$	20	2.29×10^{-6}

* More values are given in the *Data section*.

$$t_{1/2} = \frac{1}{k[\text{A}]_0} \quad (22.16)$$

Therefore, unlike a first-order reaction, the half-life of a substance in a second-order reaction varies with the initial concentration. A practical consequence of this dependence is that species that decay by second-order reactions (which includes some environmentally harmful substances) may persist in low concentrations for long periods because their half-lives are long when their concentrations are low. In general, for an n th-order reaction of the form $\text{A} \rightarrow \text{products}$, the half-life is related to the rate constant and the initial concentration of A by

$$t_{1/2} = \frac{1}{k[\text{A}]^{n-1}} \quad (22.17)$$

(See Exercise 12.12a.)

Another type of second-order reaction is one that is first-order in each of two reactants A and B:

$$\frac{d[\text{A}]}{dt} = -k[\text{A}][\text{B}] \quad (22.18)$$

Such a rate law cannot be integrated until we know how the concentration of B is related to that of A. For example, if the reaction is $\text{A} + \text{B} \rightarrow \text{P}$, where P denotes products, and the initial concentrations are $[\text{A}]_0$ and $[\text{B}]_0$, then it is shown in the *Justification* below that, at a time t after the start of the reaction, the concentrations satisfy the relation

$$\ln \left(\frac{[\text{B}]/[\text{B}]_0}{[\text{A}]/[\text{A}]_0} \right) = ([\text{B}]_0 - [\text{A}]_0)kt \quad (22.19)$$

Therefore, a plot of the expression on the left against t should be a straight line from which k can be obtained.

Justification 22.3 Overall second-order rate law

It follows from the reaction stoichiometry that, when the concentration of A has fallen to $[\text{A}]_0 - x$, the concentration of B will have fallen to $[\text{B}]_0 - x$ (because each A that disappears entails the disappearance of one B). It follows that

$$\frac{d[\text{A}]}{dt} = -k([\text{A}]_0 - x)([\text{B}]_0 - x)$$

Because $[\text{A}] = [\text{A}]_0 - x$, it follows that $d[\text{A}]/dt = -dx/dt$ and the rate law may be written as

$$\frac{dx}{dt} = k([A]_0 - x)([B]_0 - x)$$

The initial condition is that $x = 0$ when $t = 0$; so the integration required is

$$\int_0^x \frac{dx}{([A]_0 - x)([B]_0 - x)} = k \int_0^t dt$$

The integral on the right is simply kt . The integral on the left is evaluated by using the method of partial fractions and by using $[A] = [A]_0$ and $[B] = [B]_0$ at $t = 0$ to give:

$$\int_0^x \frac{dx}{([A]_0 - x)([B]_0 - x)} = \frac{1}{[B]_0 - [A]_0} \left\{ \ln \left(\frac{[A]_0}{[A]_0 - x} \right) - \ln \left(\frac{[B]_0}{[B]_0 - x} \right) \right\}$$

This expression can be simplified and rearranged into eqn 22.19 by combining the two logarithms by using $\ln y - \ln z = \ln(y/z)$ and noting that $[A] = [A]_0 - x$ and $[B] = [B]_0 - x$.

Comment 22.2

To use the method of partial fractions to evaluate an integral of the form

$\int \frac{1}{(a-x)(b-x)} dx$, where a and b are constants, we write

$$\frac{1}{(a-x)(b-x)} = \frac{1}{b-a} \left(\frac{1}{a-x} - \frac{1}{b-x} \right)$$

and integrate the expression on the right. It follows that

$$\begin{aligned} \int \frac{dx}{(a-x)(b-x)} &= \frac{1}{b-a} \left[\int \frac{dx}{a-x} - \int \frac{dx}{b-x} \right] \\ &= \frac{1}{b-a} \left(\ln \frac{1}{a-x} - \ln \frac{1}{b-x} \right) + \text{constant} \end{aligned}$$

Similar calculations may be carried out to find the integrated rate laws for other orders, and some are listed in Table 22.3.

Table 22.3 Integrated rate laws

Order	Reaction	Rate law*	$t_{1/2}$
0	$A \rightarrow P$	$v = k$ $kt = x$ for $0 \leq x \leq [A]_0$	$[A]_0/2k$
1	$A \rightarrow P$	$v = k[A]$ $kt = \ln \frac{[A]_0}{[A]_0 - x}$	$(\ln 2)/k$
2	$A \rightarrow P$	$v = k[A]^2$ $kt = \frac{x}{[A]_0([A]_0 - x)}$	$1/k[A]_0$
	$A + B \rightarrow P$	$v = k[A][B]$ $kt = \frac{1}{[B]_0 - [A]_0} \ln \frac{[A]_0([B]_0 - x)}{([A]_0 - x)[B]_0}$	
	$A + 2B \rightarrow P$	$v = k[A][B]$ $kt = \frac{1}{[B]_0 - 2[A]_0} \ln \frac{[A]_0([B]_0 - 2x)}{([A]_0 - x)[B]_0}$	
	$A \rightarrow P$ with autocatalysis	$v = k[A][P]$ $kt = \frac{1}{[A]_0 + [P]_0} \ln \frac{[A]_0([P]_0 + x)}{([A]_0 - x)[P]_0}$	
3	$A + 2B \rightarrow P$	$v = k[A][B]^2$ $kt = \frac{2x}{(2[A]_0 - [B]_0)([B]_0 - 2x)[B]_0} + \frac{1}{(2[A]_0 - [B]_0)^2} \ln \frac{[A]_0([B]_0 - 2x)}{([A]_0 - x)[B]_0}$	
$n \geq 2$	$A \rightarrow P$	$v = k[A]^n$ $kt = \frac{1}{n-1} \left\{ \frac{1}{([A]_0 - x)^{n-1}} - \frac{1}{[A]_0^{n-1}} \right\}$	$\frac{2^{n-1} - 1}{(n-1)k[A]_0^{n-1}}$

* $x = [P]$ and $v = dx/dt$.

22.4 Reactions approaching equilibrium

Because all the laws considered so far disregard the possibility that the reverse reaction is important, none of them describes the overall rate when the reaction is close to equilibrium. At that stage the products may be so abundant that the reverse reaction must be taken into account. In practice, however, most kinetic studies are made on reactions that are far from equilibrium, and the reverse reactions are unimportant.

(a) First-order reactions close to equilibrium

We can explore the variation of the composition with time close to chemical equilibrium by considering the reaction in which A forms B and both forward and reverse reactions are first-order (as in some isomerizations). The scheme we consider is

The concentration of A is reduced by the forward reaction (at a rate $k[\text{A}]$) but it is increased by the reverse reaction (at a rate $k'[\text{B}]$). The net rate of change is therefore

$$\frac{d[\text{A}]}{dt} = -k[\text{A}] + k'[\text{B}] \quad (22.21)$$

If the initial concentration of A is $[\text{A}]_0$, and no B is present initially, then at all times $[\text{A}] + [\text{B}] = [\text{A}]_0$. Therefore,

$$\frac{d[\text{A}]}{dt} = -k[\text{A}] + k'([\text{A}]_0 - [\text{A}]) = -(k + k')[\text{A}] + k'[\text{A}]_0 \quad (22.22)$$

The solution of this first-order differential equation (as may be checked by differentiation) is

$$[\text{A}] = \frac{k' + ke^{-(k+k')t}}{k' + k} [\text{A}]_0 \quad (22.23)$$

Figure 22.8 shows the time dependence predicted by this equation.

As $t \rightarrow \infty$, the concentrations reach their equilibrium values, which are given by eqn 22.23 as:

$$[\text{A}]_{\text{eq}} = \frac{k'[\text{A}]_0}{k + k'} \quad [\text{B}]_{\text{eq}} = [\text{A}]_0 - [\text{A}]_{\text{eq}} = \frac{k[\text{A}]_0}{k + k'} \quad (22.24)$$

It follows that the equilibrium constant of the reaction is

$$K = \frac{[\text{B}]_{\text{eq}}}{[\text{A}]_{\text{eq}}} = \frac{k}{k'} \quad (22.25)$$

(This expression is only approximate because thermodynamic equilibrium constants are expressed in terms of activities, not concentrations.) Exactly the same conclusion can be reached—more simply, in fact—by noting that, at equilibrium, the forward and reverse rates must be the same, so

$$k[\text{A}]_{\text{eq}} = k'[\text{B}]_{\text{eq}} \quad (22.26)$$

This relation rearranges into eqn 22.25. The theoretical importance of eqn 22.25 is that it relates a thermodynamic quantity, the equilibrium constant, to quantities relating to rates. Its practical importance is that, if one of the rate constants can be measured, then the other may be obtained if the equilibrium constant is known.

Fig. 22.8 The approach of concentrations to their equilibrium values as predicted by eqn 22.23 for a reaction $\text{A} \rightleftharpoons \text{B}$ that is first-order in each direction, and for which $k = 2k'$.

Exploration Set up the rate equations and plot the corresponding graphs for the approach to and equilibrium of the form $\text{A} \rightleftharpoons 2\text{B}$.

For a more general reaction, the overall equilibrium constant can be expressed in terms of the rate constants for all the intermediate stages of the reaction mechanism:

$$K = \frac{k_a}{k'_a} \times \frac{k_b}{k'_b} \times \dots \quad (22.27)$$

where the k s are the rate constants for the individual steps and the k' s are those for the corresponding reverse steps.

(b) Relaxation methods

The term **relaxation** denotes the return of a system to equilibrium. It is used in chemical kinetics to indicate that an externally applied influence has shifted the equilibrium position of a reaction, normally suddenly, and that the reaction is adjusting to the equilibrium composition characteristic of the new conditions (Fig. 22.9). We shall consider the response of reaction rates to a **temperature jump**, a sudden change in temperature. We know from Section 7.4 that the equilibrium composition of a reaction depends on the temperature (provided $\Delta_r H^\circ$ is nonzero), so a shift in temperature acts as a perturbation on the system. One way of achieving a temperature jump is to discharge a capacitor through a sample made conducting by the addition of ions, but laser or microwave discharges can also be used. Temperature jumps of between 5 and 10 K can be achieved in about 1 μ s with electrical discharges. The high energy output of pulsed lasers (Section 14.5) is sufficient to generate temperature jumps of between 10 and 30 K within nanoseconds in aqueous samples. Some equilibria are also sensitive to pressure, and **pressure-jump techniques** may then also be used.

When a sudden temperature increase is applied to a simple $A \rightleftharpoons B$ equilibrium that is first-order in each direction, we show in the *Justification* below that the composition relaxes exponentially to the new equilibrium composition:

$$x = x_0 e^{-t/\tau} \quad \frac{1}{\tau} = k_a + k_b \quad (22.28)$$

where x_0 is the departure from equilibrium immediately after the temperature jump and x is the departure from equilibrium at the new temperature after a time t .

Fig. 22.9 The relaxation to the new equilibrium composition when a reaction initially at equilibrium at a temperature T_1 is subjected to a sudden change of temperature, which takes it to T_2 .

Justification 22.4 Relaxation to equilibrium

When the temperature of a system at equilibrium is increased suddenly, the rate constants change from their earlier values to the new values k_a and k_b characteristic of that temperature, but the concentrations of A and B remain for an instant at their old equilibrium values. As the system is no longer at equilibrium, it readjusts to the new equilibrium concentrations, which are now given by

$$k_a[A]_{\text{eq}} = k_b[B]_{\text{eq}}$$

and it does so at a rate that depends on the new rate constants. We write the deviation of $[A]$ from its new equilibrium value as x , so $[A] = x + [A]_{\text{eq}}$ and $[B] = [B]_{\text{eq}} - x$. The concentration of A then changes as follows:

$$\begin{aligned} \frac{d[A]}{dt} &= -k_a[A] + k_b[B] \\ &= -k_a([A]_{\text{eq}} + x) + k_b([B]_{\text{eq}} - x) \\ &= -(k_a + k_b)x \end{aligned}$$

because the two terms involving the equilibrium concentrations cancel. Because $d[A]/dt = dx/dt$, this equation is a first-order differential equation with the solution that resembles eqn 22.12b and is given in eqn 22.28.

Equation 22.28 shows that the concentrations of A and B relax into the new equilibrium at a rate determined by the sum of the two new rate constants. Because the equilibrium constant under the new conditions is $K \approx k_a/k_b$, its value may be combined with the relaxation time measurement to find the individual k_a and k_b .

Example 22.4 *Analysing a temperature-jump experiment*

The equilibrium constant for the autoprotolysis of water, $\text{H}_2\text{O}(\text{l}) \rightleftharpoons \text{H}^+(\text{aq}) + \text{OH}^-(\text{aq})$, is $K_w = a(\text{H}^+)a(\text{OH}^-) = 1.008 \times 10^{-14}$ at 298 K. After a temperature-jump, the reaction returns to equilibrium with a relaxation time of 37 μs at 298 K and $\text{pH} \approx 7$. Given that the forward reaction is first-order and the reverse is second-order overall, calculate the rate constants for the forward and reverse reactions.

Method We need to derive an expression for the relaxation time, τ (the time constant for return to equilibrium), in terms of k_1 (forward, first-order reaction) and k_2 (reverse, second-order reaction). We can proceed as above, but it will be necessary to make the assumption that the deviation from equilibrium (x) is so small that terms in x^2 can be neglected. Relate k_1 and k_2 through the equilibrium constant, but be careful with units because K_w is dimensionless.

Answer The forward rate at the final temperature is $k_1[\text{H}_2\text{O}]$ and the reverse rate is $k_2[\text{H}^+][\text{OH}^-]$. The net rate of deprotonation of H_2O is

$$\frac{d[\text{H}_2\text{O}]}{dt} = -k_1[\text{H}_2\text{O}] + k_2[\text{H}^+][\text{OH}^-]$$

We write $[\text{H}_2\text{O}] = [\text{H}_2\text{O}]_{\text{eq}} + x$, $[\text{H}^+] = [\text{H}^+]_{\text{eq}} - x$, and $[\text{OH}^-] = [\text{OH}^-]_{\text{eq}} - x$, and obtain

$$\begin{aligned} \frac{dx}{dt} &= -\{k_1 + k_2([\text{H}^+]_{\text{eq}} + [\text{OH}^-]_{\text{eq}})\}x - k_1[\text{H}_2\text{O}]_{\text{eq}} + k_2[\text{H}^+]_{\text{eq}}[\text{OH}^-]_{\text{eq}} + k_2x^2 \\ &\approx -\{k_1 + k_2([\text{H}^+]_{\text{eq}} + [\text{OH}^-]_{\text{eq}})\}x \end{aligned}$$

where we have neglected the term in x^2 and used the equilibrium condition

$$k_1[\text{H}_2\text{O}]_{\text{eq}} = k_2[\text{H}^+]_{\text{eq}}[\text{OH}^-]_{\text{eq}}$$

to eliminate the terms that are independent of x . It follows that

$$\frac{1}{\tau} = k_1 + k_2([\text{H}^+]_{\text{eq}} + [\text{OH}^-]_{\text{eq}})$$

At this point we note that

$$K_w = a(\text{H}^+)a(\text{OH}^-) \approx ([\text{H}^+]_{\text{eq}}/c^\ominus)([\text{OH}^-]_{\text{eq}}/c^\ominus) = [\text{H}^+]_{\text{eq}}[\text{OH}^-]_{\text{eq}}/c^{\ominus 2}$$

with $c^\ominus = 1 \text{ mol dm}^{-3}$. For this electrically neutral system, $[\text{H}^+] = [\text{OH}^-]$, so the concentration of each type of ion is $K_w^{1/2}c^\ominus$, and hence

$$\frac{1}{\tau} = k_1 + k_2(K_w^{1/2}c^\ominus + K_w^{1/2}c^\ominus) = k_2 \left\{ \frac{k_1}{k_2} + 2K_w^{1/2}c^\ominus \right\}$$

At this point we note that

$$\frac{k_1}{k_2} = \frac{[\text{H}^+]_{\text{eq}}[\text{OH}^-]_{\text{eq}}}{[\text{H}_2\text{O}]_{\text{eq}}} = \frac{K_w c^{\ominus 2}}{[\text{H}_2\text{O}]_{\text{eq}}}$$

The molar concentration of pure water is 55.6 mol dm^{-3} , so $[\text{H}_2\text{O}]_{\text{eq}}/c^\ominus = 55.6$. If we write $K = K_w/55.6 = 1.81 \times 10^{-16}$, we obtain

$$\frac{1}{\tau} = k_2 \{K + 2K_w^{1/2}\} c^\ominus$$

Hence,

$$k_2 = \frac{1}{\tau(K + 2K_w^{1/2})c^\ominus}$$

$$= \frac{1}{(3.7 \times 10^{-5} \text{ s}) \times (2.0 \times 10^{-7}) \times (1 \text{ mol dm}^{-3})} = 1.4 \times 10^{11} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

It follows that

$$k_1 = k_2 K c^\ominus = 2.4 \times 10^{-5} \text{ s}^{-1}$$

The reaction is faster in ice, where $k_2 = 8.6 \times 10^{12} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$.

A note on good practice Notice how we keep track of units through the use of $c^\ominus$: K and K_w are dimensionless; k_2 is expressed in $\text{dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ and k_1 is expressed in s^{-1} .

Self-test 22.5 Derive an expression for the relaxation time of a concentration when the reaction $\text{A} + \text{B} \rightleftharpoons \text{C} + \text{D}$ is second-order in both directions.

$$[1/\tau = k([A] + [B])_{\text{eq}} + k'([C] + [D])_{\text{eq}}]$$

22.5 The temperature dependence of reaction rates

The rate constants of most reactions increase as the temperature is raised. Many reactions in solution fall somewhere in the range spanned by the hydrolysis of methyl ethanoate (where the rate constant at 35°C is 1.82 times that at 25°C) and the hydrolysis of sucrose (where the factor is 4.13).

(a) The Arrhenius parameters

It is found experimentally for many reactions that a plot of $\ln k$ against $1/T$ gives a straight line. This behaviour is normally expressed mathematically by introducing two parameters, one representing the intercept and the other the slope of the straight line, and writing the **Arrhenius equation**

$$\ln k = \ln A - \frac{E_a}{RT} \quad (22.29)$$

The parameter A , which corresponds to the intercept of the line at $1/T = 0$ (at infinite temperature, Fig. 22.10), is called the **pre-exponential factor** or the ‘frequency factor’. The parameter E_a , which is obtained from the slope of the line ($-E_a/R$), is called the **activation energy**. Collectively the two quantities are called the **Arrhenius parameters** (Table 22.4).

Synoptic table 22.4* Arrhenius parameters

(1) First-order reactions	A/s^{-1}	$E_a/(\text{kJ mol}^{-1})$
$\text{CH}_3\text{NC} \rightarrow \text{CH}_3\text{CN}$	3.98×10^{13}	160
$2 \text{N}_2\text{O}_5 \rightarrow 4 \text{NO}_2 + \text{O}_2$	4.94×10^{13}	103.4
(2) Second-order reactions	$A/(\text{dm}^3 \text{ mol}^{-1} \text{ s}^{-1})$	$E_a/(\text{kJ mol}^{-1})$
$\text{OH} + \text{H}_2 \rightarrow \text{H}_2\text{O} + \text{H}$	8.0×10^{10}	42
$\text{NaC}_2\text{H}_5\text{O} + \text{CH}_3\text{I}$ in ethanol	2.42×10^{11}	81.6

* More values are given in the Data section.

Fig. 22.10 A plot of $\ln k$ against $1/T$ is a straight line when the reaction follows the behaviour described by the Arrhenius equation (eqn 22.29). The slope gives $-E_a/R$ and the intercept at $1/T = 0$ gives $\ln A$.

Fig. 22.11 The Arrhenius plot using the data in Example 22.5.

Example 22.5 Determining the Arrhenius parameters

The rate of the second-order decomposition of acetaldehyde (ethanal, CH_3CHO) was measured over the temperature range 700–1000 K, and the rate constants are reported below. Find E_a and A .

T/K	700	730	760	790	810	840	910	1000
$k/(\text{dm}^3 \text{mol}^{-1} \text{s}^{-1})$	0.011	0.035	0.105	0.343	0.789	2.17	20.0	145

Method According to eqn 22.29, the data can be analysed by plotting $\ln(k/\text{dm}^3 \text{mol}^{-1} \text{s}^{-1})$ against $1/(T/\text{K})$, or more conveniently $(10^3 \text{ K})/T$, and getting a straight line. As explained in Example 22.3, we obtain the activation energy from the dimensionless slope by writing $-E_a/R = \text{slope}/\text{units}$, where in this case ‘units’ = $1/(10^3 \text{ K})$, so $E_a = -\text{slope} \times R \times 10^3 \text{ K}$. The intercept at $T = 0$ is $\ln(A/\text{dm}^3 \text{mol}^{-1} \text{s}^{-1})$.

Answer We draw up the following table:

$(10^3 \text{ K})/T$	1.43	1.37	1.32	1.27	1.23	1.19	1.10	1.00
$\ln(k/\text{dm}^3 \text{mol}^{-1} \text{s}^{-1})$	−4.51	−3.35	−2.25	−1.07	−0.24	0.77	3.00	4.98

Now plot $\ln k$ against $1/T$ (Fig. 22.11). The least-squares fit is to a line with slope -22.7 and intercept 27.7 . Therefore,

$$E_a = 22.7 \times (8.3145 \text{ J K}^{-1} \text{mol}^{-1}) \times 10^3 \text{ K} = 189 \text{ kJ mol}^{-1}$$

$$A = e^{27.7} \text{ dm}^3 \text{mol}^{-1} \text{s}^{-1} = 1.1 \times 10^{12} \text{ dm}^3 \text{mol}^{-1} \text{s}^{-1}$$

A note on good practice Note that A has the same units as k . In practice, A is obtained from one of the mid-range data values rather than using a lengthy extrapolation.

Self-test 22.6 Determine A and E_a from the following data:

T/K	300	350	400	450	500
$k/(\text{dm}^3 \text{mol}^{-1} \text{s}^{-1})$	7.9×10^6	3.0×10^7	7.9×10^7	1.7×10^8	3.2×10^8
	$[8 \times 10^{10} \text{ dm}^3 \text{mol}^{-1} \text{s}^{-1}, 23 \text{ kJ mol}^{-1}]$				

The fact that E_a is given by the slope of the plot of $\ln k$ against $1/T$ means that, the higher the activation energy, the stronger the temperature dependence of the rate constant (that is, the steeper the slope). *A high activation energy signifies that the rate constant depends strongly on temperature.* If a reaction has zero activation energy, its rate is independent of temperature. In some cases the activation energy is negative, which indicates that the rate decreases as the temperature is raised. We shall see that such behaviour is a signal that the reaction has a complex mechanism.

The temperature dependence of some reactions is non-Arrhenius, in the sense that a straight line is not obtained when $\ln k$ is plotted against $1/T$. However, it is still possible to define an activation energy at any temperature as

$$E_a = RT^2 \left(\frac{d \ln k}{dT} \right) \quad [22.30]$$

This definition reduces to the earlier one (as the slope of a straight line) for a temperature-independent activation energy. However, the definition in eqn 22.30 is more general than eqn 22.29, because it allows E_a to be obtained from the slope (at the

temperature of interest) of a plot of $\ln k$ against $1/T$ even if the Arrhenius plot is not a straight line. Non-Arrhenius behaviour is sometimes a sign that quantum mechanical tunnelling is playing a significant role in the reaction (Section 22.7f).

(b) The interpretation of the parameters

For the present chapter we shall regard the Arrhenius parameters as purely empirical quantities that enable us to discuss the variation of rate constants with temperature; however, it is useful to have an interpretation in mind and write eqn 22.29 as

$$k = Ae^{-E_a/RT} \quad (22.31)$$

To interpret E_a we consider how the molecular potential energy changes in the course of a chemical reaction that begins with a collision between molecules of A and molecules of B (Fig. 22.12).

As the reaction event proceeds, A and B come into contact, distort, and begin to exchange or discard atoms. The **reaction coordinate** is the collection of motions, such as changes in interatomic distances and bond angles, that are directly involved in the formation of products from reactants. (The reaction coordinate is essentially a geometrical concept and quite distinct from the extent of reaction.) The potential energy rises to a maximum and the cluster of atoms that corresponds to the region close to the maximum is called the **activated complex**. After the maximum, the potential energy falls as the atoms rearrange in the cluster and reaches a value characteristic of the products. The climax of the reaction is at the peak of the potential energy, which corresponds to the activation energy E_a . Here two reactant molecules have come to such a degree of closeness and distortion that a small further distortion will send them in the direction of products. This crucial configuration is called the **transition state** of the reaction. Although some molecules entering the transition state might revert to reactants, if they pass through this configuration then it is inevitable that products will emerge from the encounter.

We also conclude from the preceding discussion that, for a reaction involving the collision of two molecules, *the activation energy is the minimum kinetic energy that reactants must have in order to form products*. For example, in a gas-phase reaction there are numerous collisions each second, but only a tiny proportion are sufficiently energetic to lead to reaction. The fraction of collisions with a kinetic energy in excess of an energy E_a is given by the Boltzmann distribution as $e^{-E_a/RT}$. Hence, we can interpret the exponential factor in eqn 22.31 as the fraction of collisions that have enough kinetic energy to lead to reaction.

The pre-exponential factor is a measure of the rate at which collisions occur irrespective of their energy. Hence, the product of A and the exponential factor, $e^{-E_a/RT}$, gives the rate of *successful* collisions. We shall develop these remarks in Chapter 24 and see that they have their analogues for reactions that take place in liquids.

Fig. 22.12 A potential energy profile for an exothermic reaction. The height of the barrier between the reactants and products is the activation energy of the reaction.

Comment 22.3

The terms *activated complex* and *transition state* are often used as synonyms; however, we shall preserve a distinction.

Accounting for the rate laws

We now move on to the second stage of the analysis of kinetic data, their explanation in terms of a postulated reaction mechanism.

22.6 Elementary reactions

Most reactions occur in a sequence of steps called **elementary reactions**, each of which involves only a small number of molecules or ions. A typical elementary reaction is

Note that the phase of the species is not specified in the chemical equation for an elementary reaction, and the equation represents the specific process occurring to individual molecules. This equation, for instance, signifies that an H atom attacks a Br_2 molecule to produce an HBr molecule and a Br atom. The **molecularity** of an elementary reaction is the number of molecules coming together to react in an elementary reaction. In a **unimolecular reaction**, a single molecule shakes itself apart or its atoms into a new arrangement, as in the isomerization of cyclopropane to propene. In a **bimolecular reaction**, a pair of molecules collide and exchange energy, atoms, or groups of atoms, or undergo some other kind of change. It is most important to distinguish molecularity from order: reaction order is an empirical quantity, and obtained from the experimental rate law; molecularity refers to an elementary reaction proposed as an individual step in a mechanism.

The rate law of a unimolecular elementary reaction is first-order in the reactant:

$$\text{A} \rightarrow \text{P} \quad \frac{d[\text{A}]}{dt} = -k[\text{A}] \quad (22.32)$$

where P denotes products (several different species may be formed). A unimolecular reaction is first-order because the number of A molecules that decay in a short interval is proportional to the number available to decay. (Ten times as many decay in the same interval when there are initially 1000 A molecules as when there are only 100 present.) Therefore, the rate of decomposition of A is proportional to its molar concentration.

An elementary bimolecular reaction has a second-order rate law:

$$\text{A} + \text{B} \rightarrow \text{P} \quad \frac{d[\text{A}]}{dt} = -k[\text{A}][\text{B}] \quad (22.33)$$

A bimolecular reaction is second-order because its rate is proportional to the rate at which the reactant species meet, which in turn is proportional to their concentrations. Therefore, if we have evidence that a reaction is a single-step, bimolecular process, we can write down the rate law (and then go on to test it). Bimolecular elementary reactions are believed to account for many homogeneous reactions, such as the dimerizations of alkenes and dienes and reactions such as

(where 'alc' signifies alcohol solution). There is evidence that the mechanism of this reaction is a single elementary step

This mechanism is consistent with the observed rate law

$$v = k[\text{CH}_3\text{I}][\text{CH}_3\text{CH}_2\text{O}^-] \quad (22.34)$$

We shall see below how to combine a series of simple steps together into a mechanism and how to arrive at the corresponding rate law. For the present we emphasize that, *if the reaction is an elementary bimolecular process, then it has second-order kinetics, but if the kinetics are second-order, then the reaction might be complex*. The postulated mechanism can be explored only by detailed detective work on the system, and by investigating whether side products or intermediates appear during the course of the reaction. Detailed analysis of this kind was one of the ways, for example, in which the reaction $\text{H}_2(\text{g}) + \text{I}_2(\text{g}) \rightarrow 2 \text{HI}(\text{g})$ was shown to proceed by a complex mechanism. For

many years the reaction had been accepted on good, but insufficiently meticulous evidence as a fine example of a simple bimolecular reaction, $\text{H}_2 + \text{I}_2 \rightarrow \text{HI} + \text{HI}$, in which atoms exchanged partners during a collision.

22.7 Consecutive elementary reactions

Some reactions proceed through the formation of an intermediate (I), as in the consecutive unimolecular reactions

An example is the decay of a radioactive family, such as

(The times are half-lives.) We can discover the characteristics of this type of reaction by setting up the rate laws for the net rate of change of the concentration of each substance.

(a) The variation of concentrations with time

The rate of unimolecular decomposition of A is

$$\frac{d[\text{A}]}{dt} = -k_a[\text{A}] \quad (22.35)$$

and A is not replenished. The intermediate I is formed from A (at a rate $k_a[\text{A}]$) but decays to P (at a rate $k_b[\text{I}]$). The net rate of formation of I is therefore

$$\frac{d[\text{I}]}{dt} = k_a[\text{A}] - k_b[\text{I}] \quad (22.36)$$

The product P is formed by the unimolecular decay of I:

$$\frac{d[\text{P}]}{dt} = k_b[\text{I}] \quad (22.37)$$

We suppose that initially only A is present, and that its concentration is $[\text{A}]_0$.

The first of the rate laws, eqn 22.35, is an ordinary first-order decay, so we can write

$$[\text{A}] = [\text{A}]_0 e^{-k_a t} \quad (22.38)$$

When this equation is substituted into eqn 22.36, we obtain after rearrangement

$$\frac{d[\text{I}]}{dt} + k_b[\text{I}] = k_a[\text{A}]_0 e^{-k_a t} \quad (22.39)$$

This differential equation has a standard form and, after setting $[\text{I}]_0 = 0$, the solution is

$$[\text{I}] = \frac{k_a}{k_b - k_a} (e^{-k_a t} - e^{-k_b t}) [\text{A}]_0 \quad (22.40)$$

At all times $[\text{A}] + [\text{I}] + [\text{P}] = [\text{A}]_0$, so it follows that

$$[\text{P}] = \left\{ 1 + \frac{k_a e^{-k_b t} - k_b e^{-k_a t}}{k_b - k_a} \right\} [\text{A}]_0 \quad (22.41)$$

The concentration of the intermediate I rises to a maximum and then falls to zero (Fig. 22.13). The concentration of the product P rises from zero towards $[\text{A}]_0$.

Comment 22.4

The solution of a first-order differential equation with the form

$$\frac{dy}{dx} + yf(x) = g(x)$$

is

$$e^{\int f(x) dx} y = \int e^{\int f(x) dx} g(x) dx + \text{constant}$$

Equation 22.39 is a special case of this standard form, with $f(x) = \text{constant}$.

Fig. 22.13 The concentrations of A, I, and P in the consecutive reaction scheme $\text{A} \rightarrow \text{I} \rightarrow \text{P}$. The curves are plots of eqns 22.38, 22.40, and 21.41 with $k_a = 10k_b$. If the intermediate I is in fact the desired product, it is important to be able to predict when its concentration is greatest; see Example 22.6.

Exploration Use mathematical software, an electronic spreadsheet, or the applets found in the *Living graphs* section of the text's web site to investigate the effects on $[\text{A}]$, $[\text{I}]$, $[\text{P}]$, and t_{max} of changing the ratio k_a/k_b from 10 (as in Fig. 22.13) to 0.01. Compare your results with those shown in Fig. 22.15.

Example 22.6 *Analysing consecutive reactions*

Suppose that in an industrial batch process a substance A produces the desired compound I which goes on to decay to a worthless product C, each step of the reaction being first-order. At what time will I be present in greatest concentration?

Method The time-dependence of the concentration of I is given by eqn 22.40. We can find the time at which [I] passes through a maximum, $t_{\max}$, by calculating $d[I]/dt$ and setting the resulting rate equal to zero.

Answer It follows from eqn 22.40 that

$$\frac{d[I]}{dt} = -\frac{k_a[A]_0(k_a e^{-k_a t} - k_b e^{-k_b t})}{k_b - k_a}$$

This rate is equal to zero when

$$k_a e^{-k_a t} = k_b e^{-k_b t}$$

Therefore,

$$t_{\max} = \frac{1}{k_a - k_b} \ln \frac{k_a}{k_b}$$

For a given value of k_a , as k_b increases both the time at which [I] is a maximum and the yield of I decrease.

Self-test 22.7 Calculate the maximum concentration of I and justify the last remark.

$$[[I]_{\max}/[A]_0 = (k_a/k_b)^c, \quad c = k_b/(k_b - k_a)]$$

Fig. 22.14 The basis of the steady-state approximation. It is supposed that the concentrations of intermediates remain small and hardly change during most of the course of the reaction.

(b) The steady-state approximation

One feature of the calculation so far has probably not gone unnoticed: there is a considerable increase in mathematical complexity as soon as the reaction mechanism has more than a couple of steps. A reaction scheme involving many steps is nearly always unsolvable analytically, and alternative methods of solution are necessary. One approach is to integrate the rate laws numerically (see *Appendix 2*). An alternative approach, which continues to be widely used because it leads to convenient expressions and more readily digestible results, is to make an approximation.

The **steady-state approximation** (which is also widely called the **quasi-steady-state approximation**, QSSA, to distinguish it from a true steady state) assumes that, after an initial **induction period**, an interval during which the concentrations of intermediates, I, rise from zero, and during the major part of the reaction, the rates of change of concentrations of all reaction intermediates are negligibly small (Fig. 22.14):

$$\frac{d[I]}{dt} \approx 0 \quad (22.42)$$

This approximation greatly simplifies the discussion of reaction schemes. For example, when we apply the approximation to the consecutive first-order mechanism, we set $d[I]/dt = 0$ in eqn 22.36, which then becomes

$$k_a[A] - k_b[I] \approx 0$$

Then

$$[I] \approx (k_a/k_b)[A] \quad (22.43)$$

For this expression to be consistent with eqn 22.42, we require $k_a/k_b \ll 1$ (so that, even though $[A]$ does depend on the time, the dependence of $[I]$ on the time is negligible). On substituting this value of $[I]$ into eqn 22.37, that equation becomes

$$\frac{d[P]}{dt} = k_b[I] \approx k_a[A] \quad (22.44)$$

and we see that P is formed by a first-order decay of A , with a rate constant k_a , the rate-constant of the slower, rate-determining, step. We can write down the solution of this equation at once by substituting the solution for $[A]$, eqn 22.38, and integrating:

$$[P] = k_a[A]_0 \int_0^t e^{-k_a t} dt = (1 - e^{-k_a t})[A]_0 \quad (22.45)$$

This is the same (approximate) result as before, eqn 22.41, but much more quickly obtained. Figure 22.15 compares the approximate solutions found here with the exact solutions found earlier; k_b does not have to be very much bigger than k_a for the approach to be reasonably accurate.

Fig. 22.15 A comparison of the exact result for the concentrations of a consecutive reaction and the concentrations obtained by using the steady-state approximation (red lines) for $k_b = 20k_a$. (The curve for $[A]$ is unchanged.)

Example 22.7 Using the steady-state approximation

Devise the rate law for the decomposition of N_2O_5 ,

on the basis of the following mechanism:

A note on good practice Note that when writing the equation for an elementary reaction all the species are displayed individually; so we write $A \rightarrow B + B$, for instance, not $A \rightarrow 2 B$.

Method First identify the intermediates (species that occur in the reaction steps but do not appear in the overall reaction) and write expressions for their net rates of formation. Then, all net rates of change of the concentrations of intermediates are set equal to zero and the resulting equations are solved algebraically.

Answer The intermediates are NO and NO_3 ; the net rates of change of their concentrations are

$$\frac{d[NO]}{dt} = k_b[NO_2][NO_3] - k_c[NO][N_2O_5] \approx 0$$

$$\frac{d[NO_3]}{dt} = k_a[N_2O_5] - k'_a[NO_2][NO_3] - k_b[NO_2][NO_3] \approx 0$$

The net rate of change of concentration of N_2O_5 is

$$\frac{d[N_2O_5]}{dt} = -k_a[N_2O_5] + k'_a[NO_2][NO_3] - k_c[NO][N_2O_5]$$

Fig. 22.16 In these diagrams of reaction schemes, heavy arrows represent fast steps and light arrows represent slow steps. (a) The first step is rate-determining; (b) the second step is rate-determining; (c) although one step is slow, it is not rate-determining because there is a fast route that circumvents it.

Fig. 22.17 The reaction profile for a mechanism in which the first step (RDS) is rate-determining.

and replacing the concentrations of the intermediates by using the equations above gives

$$\frac{d[\text{N}_2\text{O}_5]}{dt} = -\frac{2k_a k_b [\text{N}_2\text{O}_5]}{k'_a + k_b}$$

Self-test 22.8 Derive the rate law for the decomposition of ozone in the reaction $2 \text{O}_3(\text{g}) \rightarrow 3 \text{O}_2(\text{g})$ on the basis of the (incomplete) mechanism

$$[d[\text{O}_3]/dt = -k_a k_b [\text{O}_3]^2 / (k'_a [\text{O}_2] + k_b [\text{O}_3])]$$

(c) The rate-determining step

Equation 22.45 shows that, when $k_b \gg k_a$, then the formation of the final product P depends on only the *smaller* of the two rate constants. That is, the rate of formation of P depends on the rate at which I is formed, not on the rate at which I changes into P. For this reason, the step $\text{A} \rightarrow \text{I}$ is called the ‘rate-determining step’ of the reaction. Its existence has been likened to building a six-lane highway up to a single-lane bridge: the traffic flow is governed by the rate of crossing the bridge. Similar remarks apply to more complicated reaction mechanisms, and in general the **rate-determining step** is the slowest step in a mechanism and controls the overall rate of the reaction. However, the rate-determining step is not just the slowest step: it must be slow *and* be a crucial gateway for the formation of products. If a faster reaction can also lead to products, then the slowest step is irrelevant because the slow reaction can then be side-stepped (Fig. 22.16).

The rate law of a reaction that has a rate-determining step can often be written down almost by inspection. If the first step in a mechanism is rate-determining, then the rate of the overall reaction is equal to the rate of the first step because all subsequent steps are so fast that once the first intermediate is formed it results immediately in the formation of products. Figure 22.17 shows the reaction profile for a mechanism of this kind in which the slowest step is the one with the highest activation energy. Once over the initial barrier, the intermediates cascade into products. However, a rate-determining step may also stem from the low concentration of a crucial reactant and need not correspond to the step with highest activation barrier.

(d) Kinetic and thermodynamic control of reactions

In some cases reactants can give rise to a variety of products, as in nitrations of mono-substituted benzene, when various proportions of the *ortho*-, *meta*-, and *para*-substituted products are obtained, depending on the directing power of the original substituent. Suppose two products, P_1 and P_2 , are produced by the following competing reactions:

The relative proportion in which the two products have been produced at a given stage of the reaction (before it has reached equilibrium) is given by the ratio of the two rates, and therefore of the two rate constants:

$$\frac{[P_2]}{[P_1]} = \frac{k_2}{k_1} \quad (22.46)$$

This ratio represents the **kinetic control** over the proportions of products, and is a common feature of the reactions encountered in organic chemistry where reactants are chosen that facilitate pathways favouring the formation of a desired product. If a reaction is allowed to reach equilibrium, then the proportion of products is determined by thermodynamic rather than kinetic considerations, and the ratio of concentrations is controlled by considerations of the standard Gibbs energies of all the reactants and products.

(e) Pre-equilibria

From a simple sequence of consecutive reactions we now turn to a slightly more complicated mechanism in which an intermediate I reaches an equilibrium with the reactants A and B:

The rate constants are k_a and k'_a for the forward and reverse reactions of the equilibrium and k_b for the final step. This scheme involves a **pre-equilibrium**, in which an intermediate is in equilibrium with the reactants. A pre-equilibrium can arise when the rate of decay of the intermediate back into reactants is much faster than the rate at which it forms products; thus, the condition is possible when $k'_a \gg k_b$ but not when $k_b \gg k'_a$. Because we assume that A, B, and I are in equilibrium, we can write

$$K = \frac{[I]}{[A][B]} \quad K = \frac{k_a}{k'_a} \quad (22.48)$$

In writing these equations, we are presuming that the rate of reaction of I to form P is too slow to affect the maintenance of the pre-equilibrium (see the example below). The rate of formation of P may now be written:

$$\frac{d[P]}{dt} = k_b[I] = k_b K [A][B] \quad (22.49)$$

This rate law has the form of a second-order rate law with a composite rate constant:

$$\frac{d[P]}{dt} = k[A][B] \quad k = k_b K = \frac{k_a k_b}{k'_a} \quad (22.50)$$

Example 22.8 Analysing a pre-equilibrium

Repeat the pre-equilibrium calculation but without ignoring the fact that I is slowly leaking away as it forms P.

Method Begin by writing the net rates of change of the concentrations of the substances and then invoke the steady-state approximation for the intermediate I. Use the resulting expression to obtain the rate of change of the concentration of P.

Answer The net rates of change of P and I are

$$\frac{d[P]}{dt} = k_b[I]$$

$$\frac{d[I]}{dt} = k_a[A][B] - k'_a[I] - k_b[I] \approx 0$$

The second equation solves to

$$[I] \approx \frac{k_a[A][B]}{k'_a + k_b}$$

When we substitute this result into the expression for the rate of formation of P, we obtain

$$\frac{d[P]}{dt} \approx k[A][B] \quad k = \frac{k_a k_b}{k'_a + k_b}$$

This expression reduces to that in eqn 22.50 when the rate constant for the decay of I into products is much smaller than that for its decay into reactants, $k_b \ll k'_a$.

Self-test 22.9 Show that the pre-equilibrium mechanism in which $2A \rightleftharpoons I$ (K) followed by $I + B \rightarrow P$ (k_b) results in an overall third-order reaction.

$$[d[P]/dt = k_b K[A]^2[B]]$$

(f) The kinetic isotope effect

The postulation of a plausible mechanism requires careful analysis of many experiments designed to determine the fate of atoms during the formation of products. Observation of the **kinetic isotope effect**, a decrease in the rate of a chemical reaction upon replacement of one atom in a reactant by a heavier isotope, facilitates the identification of bond-breaking events in the rate-determining step. A **primary kinetic isotope effect** is observed when the rate-determining step requires the scission of a bond involving the isotope. A **secondary kinetic isotope effect** is the reduction in reaction rate even though the bond involving the isotope is not broken to form product. In both cases, the effect arises from the change in activation energy that accompanies the replacement of an atom by a heavier isotope on account of changes in the zero-point vibrational energies (Section 13.9).

First, we consider the origin of the primary kinetic isotope effect in a reaction in which the rate-determining step is the scission of a C—H bond. The reaction coordinate corresponds to the stretching of the C—H bond and the potential energy profile is shown in Fig. 22.18. On deuteration, the dominant change is the reduction of the zero-point energy of the bond (because the deuterium atom is heavier). The whole reaction profile is not lowered, however, because the relevant vibration in the activated complex has a very low force constant, so there is little zero-point energy associated with the reaction coordinate in either isotopomeric form of the activated complex.

We assume that, to a good approximation, a change in the activation energy arises only from the change in zero-point energy of the stretching vibration, so

$$E_a(\text{C—D}) - E_a(\text{C—H}) = N_A \left\{ \frac{1}{2} h c \tilde{\nu}(\text{C—H}) - \frac{1}{2} h c \tilde{\nu}(\text{C—D}) \right\} \quad (22.51)$$

where $\tilde{\nu}$ is the relevant vibrational wavenumber. From Section 13.9, we know that $\tilde{\nu}(\text{C—D}) = (\mu_{\text{CH}}/\mu_{\text{CD}})^{1/2} \tilde{\nu}(\text{C—H})$, where μ is the relevant effective mass. It follows that

$$E_a(\text{C—D}) - E_a(\text{C—H}) = \frac{1}{2} N_A h c \tilde{\nu}(\text{C—H}) \left\{ 1 - \left(\frac{\mu_{\text{CH}}}{\mu_{\text{CD}}} \right)^{1/2} \right\} \quad (22.52)$$

If we assume further that the pre-exponential factor does not change upon deuteration, then the rate constants for the two species should be in the ratio

Fig. 22.18 Changes in the reaction profile when a C—H bond undergoing cleavage is deuterated. In this illustration, the C—H and C—D bonds are modelled as simple harmonic oscillators. The only significant change is in the zero-point energy of the reactants, which is lower for C—D than for C—H. As a result, the activation energy is greater for C—D cleavage than for C—H cleavage.

$$\frac{k(\text{C-D})}{k(\text{C-H})} = e^{-\lambda} \quad \text{with} \quad \lambda = \frac{hc\tilde{\nu}(\text{C-H})}{2kT} \left\{ 1 - \left(\frac{\mu_{\text{CH}}}{\mu_{\text{CD}}} \right)^{1/2} \right\} \quad (22.53)$$

Note that $\lambda > 0$ because $\mu_{\text{CD}} > \mu_{\text{CH}}$ and that $k(\text{C-D})/k(\text{C-H})$ decreases with decreasing temperature.

Illustration 22.2 Assessing the primary kinetic isotope effect

From infrared spectra, the fundamental vibrational wavenumber for stretching of a C–H bond is about 3000 cm^{-1} . From $\mu_{\text{CH}}/\mu_{\text{CD}} = 0.538$ and eqn 22.53, it follows that $k(\text{C-D})/k(\text{C-H}) = 0.145$ at 298 K. We predict that at room temperature C–H cleavage should be about seven times faster than C–D cleavage, other conditions being equal. However, experimental values of $k(\text{C-D})/k(\text{C-H})$ can differ significantly from those predicted by eqn 22.53 on account of the severity of the assumptions in the model.

In some cases, substitution of deuterium for hydrogen results in values of $k(\text{C-D})/k(\text{C-H})$ that are too low to be accounted for by eqn 22.53, even when more complete models are used to predict ratios of rate constants. Such abnormal kinetic isotope effects are evidence for a path in which quantum mechanical tunnelling of hydrogen atoms takes place through the activation barrier (Fig. 22.19). We saw in Section 9.3 that the probability of tunnelling through a barrier decreases as the mass of the particle increases, so deuterium tunnels less efficiently through a barrier than hydrogen and its reactions are correspondingly slower. Quantum mechanical tunnelling can be the dominant process in reactions involving hydrogen atom or proton transfer when the temperature is so low that very few reactant molecules can overcome the activation energy barrier. We shall see in Chapter 23 that, because m_e is so small, tunnelling is also a very important contributor to the rates of electron transfer reactions.

Now consider the secondary isotope effect, which arises from differences in the zero-point energies between reactants and an activated complex with a significantly different structure. The activation energy of the undeuterated compound is

$$E_a(\text{H}) = E_a + E_{\text{vib},0}^{\ddagger}(\text{H}) - E_{\text{vib},0}(\text{H})$$

where E_a is the difference between the minima of the molecular potential energy curves of the activated complex and the ground state of the reactant and $E_{\text{vib},0}^{\ddagger}(\text{H})$ and $E_{\text{vib},0}(\text{H})$ are the zero-point vibrational energies of the two states (Fig. 22.20). For the deuterated compound

$$E_a(\text{D}) = E_a + E_{\text{vib},0}^{\ddagger}(\text{D}) - E_{\text{vib},0}(\text{D})$$

The difference in activation energies is therefore

$$E_a(\text{D}) - E_a(\text{H}) = \{E_{\text{vib},0}^{\ddagger}(\text{D}) - E_{\text{vib},0}(\text{D})\} - \{E_{\text{vib},0}^{\ddagger}(\text{H}) - E_{\text{vib},0}(\text{H})\}$$

We now suppose that the difference in zero-point energies is due solely to the vibration of a single C–H (or C–D) bond, and so write

$$E_a(\text{D}) - E_a(\text{H}) = \frac{1}{2}N_A hc\{\tilde{\nu}^{\ddagger}(\text{C-D}) - \tilde{\nu}(\text{C-D})\} - \frac{1}{2}N_A hc\{\tilde{\nu}^{\ddagger}(\text{C-H}) - \tilde{\nu}(\text{C-H})\} \quad (22.54)$$

where $\tilde{\nu}^{\ddagger}$ and $\tilde{\nu}$ denote vibrational wavenumbers in the activated complex and reactant, respectively. With $\tilde{\nu}^{\ddagger}(\text{C-D}) = (\mu_{\text{CH}}/\mu_{\text{CD}})^{1/2}\tilde{\nu}^{\ddagger}(\text{C-H})$ and $\tilde{\nu}(\text{C-D}) = (\mu_{\text{CH}}/\mu_{\text{CD}})^{1/2}\tilde{\nu}(\text{C-H})$, it follows that

Fig. 22.19 A proton can tunnel through the activation energy barrier that separates reactants from products, so the effective height of the barrier is reduced and the rate of the proton transfer reaction increases. The effect is represented by drawing the wavefunction of the proton near the barrier. Proton tunnelling is important only at low temperatures, when most of the reactants are trapped on the left of the barrier.

Fig. 22.20 The difference in zero-point vibrational energies used to explain the secondary isotope effect.

$$E_a(\text{D}) - E_a(\text{H}) = \frac{1}{2}N_A h c \{ \bar{\nu}^\ddagger(\text{C-H}) - \bar{\nu}(\text{C-H}) \} \left\{ \left(\frac{\mu_{\text{CH}}}{\mu_{\text{CD}}} \right)^{1/2} - 1 \right\} \quad (22.55)$$

and

$$\frac{k(\text{D})}{k(\text{H})} = e^{-\lambda} \quad \text{with} \quad \lambda = \frac{h c \{ \bar{\nu}^\ddagger(\text{C-H}) - \bar{\nu}(\text{C-H}) \}}{2kT} \left\{ \left(\frac{\mu_{\text{CH}}}{\mu_{\text{CD}}} \right)^{1/2} - 1 \right\} \quad (22.56)$$

Because $\mu_{\text{CH}}/\mu_{\text{CD}} < 1$, provided the vibrational wavenumber of the activated complex is less than that of the reactant, $\lambda > 1$ and the deuterated form reacts more slowly than the undeuterated compound.

Illustration 22.3 Assessing the secondary kinetic isotope effect

In the heterolytic dissociation $\text{CHCl}_3 \rightarrow \text{CHCl}_2^+ + \text{Cl}^-$ the activated complex resembles the product CHCl_2^+ . From infrared spectra, the fundamental vibrational wavenumber for a bending motion involving the C–H group is about 1350 cm^{-1} in CHCl_3 and about 800 cm^{-1} in CHCl_2^+ . Assuming that $\bar{\nu}^\ddagger(\text{C-H}) = 800 \text{ cm}^{-1}$ on account of the structural similarity between CHCl_2^+ and the activated complex, it follows from $\mu_{\text{CH}}/\mu_{\text{CD}} = 0.538$ and eqn 22.56 that $k(\text{D})/k(\text{H}) = 0.709$ at 298 K. We predict that at room temperature the dissociation of CHCl_3 should be about 40 per cent faster than dissociation of CDCl_3 . Comparison with the result from *Illustration 22.2* shows that the secondary kinetic isotope effect leads to higher values of $k(\text{D})/k(\text{H})$ than does the primary kinetic isotope effect. This conclusion is supported by a number of experimental observations.

IMPACT ON BIOCHEMISTRY

I22.1 Kinetics of the helix–coil transition in polypeptides

We saw in *Impact I16.1* that a simple statistical model accounts for the thermodynamic aspects of the helix–coil transition in polypeptides. The unfolding of a helix begins somewhere in the middle of the chain with a nucleation step, which is less favourable than the remaining helix-to-coil conversions, and continues in a cooperative fashion, in which the polymer becomes increasingly more susceptible to structural changes as more conversions occur. Here we examine the kinetics of the helix–coil transition, focusing primarily on experimental strategies and some recent results.

Earlier work on folding and unfolding of small polypeptides and large proteins relied primarily on rapid mixing and stopped-flow techniques. In a typical stopped-flow experiment, a sample of the protein with a high concentration of a chemical denaturant, such as urea or guanidinium hydrochloride, is mixed with a solution containing a much lower concentration of the same denaturant. Upon entering the mixing chamber, the denaturant is diluted and the protein re-folds. Unfolding is observed by mixing a sample of folded protein with a solution containing a high concentration of denaturant. These experiments are ideal for sorting out events in the millisecond timescale, such as the formation of contacts between helical segments in a large protein. However, the available data also indicate that, in a number of proteins, a significant portion of the folding process occurs in less than 1 ms, a time range not accessible by the stopped-flow technique. More recent temperature-jump and flash photolysis experiments have uncovered faster events. For example, at ambient temperature the formation of a loop between helical or sheet segments may be as fast as $1 \mu\text{s}$ and the formation of tightly packed cores with significant tertiary structure occurs in the

10–100 μs range. Among the fastest events are the formation and denaturation of helices and sheets from fully unfolded peptide chains and we examine how the laser-induced temperature-jump technique has been used in the study of the helix–coil transition.

The laser-induced temperature-jump technique takes advantage of the fact that proteins unfold, or melt, at high temperatures and each protein has a characteristic melting temperature (Section 19.10). Proteins also lose their native structures at very low temperatures, a process known as *cold denaturation*, and re-fold when the temperature is increased but kept significantly below the melting temperature. Hence, a temperature-jump experiment can be configured to monitor either folding or unfolding of a polypeptide, depending on the initial and final temperatures of the sample. The challenge of using melting or cold denaturation as the basis of kinetic measurements lies in increasing the temperature of the sample very quickly so fast relaxation process can be monitored. A number of clever strategies have been employed. In one example, a pulsed laser excites dissolved dye molecules that decay largely by internal conversion, or heat transfer to the solution. Another variation makes use of direct excitation of overtones of the O–H or O–D stretching modes of H_2O or D_2O , respectively, with a pulsed infrared laser. The latter strategy leads to temperature jumps in a small irradiated volume of about 20 K in less than 100 ps. Relaxation of the sample can then be probed by a variety of spectroscopic techniques, including absorption, emission, or Raman scattering. For example, the infrared absorption spectrum of a polypeptide is sensitive to polypeptide conformation, as the N–H stretching vibrations in the range $1630\text{--}1670\text{ cm}^{-1}$ are significantly different in the helix and coil forms.

Much of the kinetic work on the helix–coil transition has been conducted in small synthetic polypeptides rich in alanine, an amino acid that is known to stabilize helical structures. Both experimental results and statistical mechanical calculations suggest that the mechanism of unfolding consists of at least two steps: a very fast step in which amino acids at either end of a helical segment undergo transitions to coil regions and a slower rate-determining step that corresponds to the cooperative melting of the rest of the chain and loss of helical content. Using *h* and *c* to denote an amino acid residue belonging to a helical and coil region, respectively, the mechanism may be summarized as follows:

The rate-determining step is thought to account for the relaxation time of 160 ns measured with a laser-induced temperature jump between 282.5 K and 300.6 K in an alanine-rich polypeptide containing 21 amino acids. It is thought that the limitation on the rate of the helix–coil transition in this peptide arises from an activation energy barrier of 1.7 kJ mol^{-1} associated with nucleation events of the form $\dots hhhh \dots \rightarrow \dots hhch \dots$ in the middle of the chain. Therefore, nucleation is not only thermodynamically unfavourable but also kinetically slow. Models that use concepts of statistical thermodynamics also suggest that a $hhhh \dots \rightarrow chhh \dots$ transition at either end of a helical segment has a significantly lower activation energy on account of the converting amino acid not being flanked by *h* regions.

The time constant for the helix–coil transition has also been measured in proteins. In apomyoglobin (myoglobin lacking the haem cofactor), the unfolding of the helices appears to have a relaxation time of about 50 ns, even shorter than in synthetic peptides. It is difficult to interpret these results because we do not yet know how the amino acid sequence or interactions between helices in a folded protein affect the helix–coil relaxation time.

Fig. 22.21 A representation of the Lindemann-Hinshelwood mechanism of unimolecular reactions. The species A is excited by collision with A, and the excited A molecule (A^*) may either be deactivated by a collision with A or go on to decay by a unimolecular process to form products.

22.8 Unimolecular reactions

A number of gas-phase reactions follow first-order kinetics, as in the isomerization of cyclopropane mentioned earlier:

The problem with the interpretation of first-order rate laws is that presumably a molecule acquires enough energy to react as a result of its collisions with other molecules. However, collisions are simple bimolecular events, so how can they result in a first-order rate law? First-order gas-phase reactions are widely called ‘unimolecular reactions’ because they also involve an elementary unimolecular step in which the reactant molecule changes into the product. This term must be used with caution, though, because the overall mechanism has bimolecular as well as unimolecular steps.

(a) The Lindemann-Hinshelwood mechanism

The first successful explanation of unimolecular reactions was provided by Frederick Lindemann in 1921 and then elaborated by Cyril Hinshelwood. In the **Lindemann-Hinshelwood mechanism** it is supposed that a reactant molecule A becomes energetically excited by collision with another A molecule (Fig. 22.21):

The energized molecule (A^*) might lose its excess energy by collision with another molecule:

Alternatively, the excited molecule might shake itself apart and form products P. That is, it might undergo the unimolecular decay

If the unimolecular step is slow enough to be the rate-determining step, the overall reaction will have first-order kinetics, as observed. This conclusion can be demonstrated explicitly by applying the steady-state approximation to the net rate of formation of A^* :

$$\frac{d[\text{A}^*]}{dt} = k_a[\text{A}]^2 - k'_a[\text{A}][\text{A}^*] - k_b[\text{A}^*] \approx 0 \quad (22.61)$$

This equation solves to

$$[\text{A}^*] = \frac{k_a[\text{A}]^2}{k_b + k'_a[\text{A}]} \quad (22.62)$$

so the rate law for the formation of P is

$$\frac{d[\text{P}]}{dt} = k_b[\text{A}^*] = \frac{k_a k_b [\text{A}]^2}{k_b + k'_a[\text{A}]} \quad (22.63)$$

At this stage the rate law is not first-order. However, if the rate of deactivation by (A^*, A) collisions is much greater than the rate of unimolecular decay, in the sense that

$$k'_a[\text{A}][\text{A}] \gg k_b[\text{A}^*] \quad \text{or} \quad k'_a[\text{A}] \gg k_b$$

then we can neglect k_b in the denominator and obtain

$$\frac{d[P]}{dt} = k[A] \quad k = \frac{k_a k_b}{k'_a} \quad (22.64)$$

Equation 22.64 is a first-order rate law, as we set out to show.

The Lindemann–Hinshelwood mechanism can be tested because it predicts that, as the concentration (and therefore the partial pressure) of A is reduced, the reaction should switch to overall second-order kinetics. Thus, when $k'_a[A] \ll k_b$, the rate law in eqn 22.63 is

$$\frac{d[P]}{dt} \approx k_a[A]^2 \quad (22.65)$$

The physical reason for the change of order is that at low pressures the rate-determining step is the bimolecular formation of A^* . If we write the full rate law in eqn 22.63 as

$$\frac{d[P]}{dt} = k[A] \quad k = \frac{k_a k_b [A]}{k_b + k'_a [A]} \quad (22.66)$$

then the expression for the effective rate constant, k , can be rearranged to

$$\frac{1}{k} = \frac{k'_a}{k_a k_b} + \frac{1}{k_a [A]} \quad (22.67)$$

Hence, a test of the theory is to plot $1/k$ against $1/[A]$, and to expect a straight line.

(b) The RRK model

Whereas the Lindemann–Hinshelwood mechanism agrees in general with the switch in order of unimolecular reactions, it does not agree in detail. Figure 22.22 shows a typical graph of $1/k$ against $1/[A]$. The graph has a pronounced curvature, corresponding to a larger value of k (a smaller value of $1/k$) at high pressures (low $1/[A]$) than would be expected by extrapolation of the reasonably linear low pressure (high $1/[A]$) data.

An improved model was proposed in 1926 by O.K. Rice and H.C. Ramsperger and almost simultaneously by L.S. Kassel, and is now known as the **Rice–Ramsperger–Kassel model** (RRK model). The model has been elaborated, largely by R.A. Marcus, into the RRKM model. Here we outline Kassel's original approach to the RRK model: the details are set out in *Further information 22.1* at the end of the chapter. The essential feature of the model is that, although a molecule might have enough energy to react, that energy is distributed over all the modes of motion of the molecule, and reaction will occur only when enough of that energy has migrated into a particular location (such as a bond) in the molecule. Provided the rate constant is proportional to this probability, which we show in *Further information 22.1* is

$$P = \left(1 - \frac{E^*}{E}\right)^{s-1} \quad (22.68a)$$

where s is the number of modes of motion over which the energy may be dissipated and E^* is the energy required for the bond of interest to break, we can write the **Kassel form** of the unimolecular rate constant for the decay of A^* to products as

$$k_b(E) = \left(1 - \frac{E^*}{E}\right)^{s-1} k_b \quad \text{for } E \geq E^* \quad (22.68b)$$

where k_b is the rate constant used in the original Lindemann theory.

Fig. 22.22 The pressure dependence of the unimolecular isomerization of *trans*-CHD=CHD showing a pronounced departure from the straight line predicted by eqn 22.67 based on the Lindemann–Hinshelwood mechanism.

Fig. 22.23 The energy dependence of the rate constant given by eqn 22.68 for three values of s .

The energy dependence of the rate constant given by eqn 22.68 is shown in Fig. 22.23 for various values of s . We see that the rate constant is smaller at a given excitation energy if s is large, as it takes longer for the excitation energy to migrate through all the oscillators of a large molecule and accumulate in the critical mode. As E becomes very large, however, the term in parentheses approaches 1, and $k_b(E)$ becomes independent of the energy and the number of oscillators in the molecule, as there is now enough energy to accumulate immediately in the critical mode regardless of the size of the molecule.

(c) The activation energy of a composite reaction

Although the rate of each step of a complex mechanism might increase with temperature and show Arrhenius behaviour, is that true of a composite reaction? To answer this question, we consider the high-pressure limit of the Lindemann–Hinshelwood mechanism as expressed in eqn 22.64. If each of the rate constants has an Arrhenius-like temperature dependence, we can use eqn 22.31 for each of them, and write

$$k = \frac{k_a k_b}{k'_a} = \frac{(A_a e^{-E_a(a)/RT})(A_b e^{-E_a(b)/RT})}{(A'_a e^{-E'_a(a)/RT})} \quad (22.69)$$

$$= \frac{A_a A_b}{A'_a} e^{-\{E_a(a) + E_a(b) - E'_a(a)\}/RT}$$

That is, the composite rate constant k has an Arrhenius-like form with activation energy

$$E_a = E_a(a) + E_a(b) - E'_a(a) \quad (22.70)$$

Provided $E_a(a) + E_a(b) > E'_a(a)$, the activation energy is positive and the rate increases with temperature. However, it is conceivable that $E_a(a) + E_a(b) < E'_a(a)$ (Fig. 22.24), in which case the activation energy is negative and the rate will *decrease* as the temperature is raised. There is nothing remarkable about this behaviour: all it means is that the reverse reaction (corresponding to the deactivation of A^*) is so sensitive to temperature that its rate increases sharply as the temperature is raised, and depletes the steady-state concentration of A^* . The Lindemann–Hinshelwood mechanism is an unlikely candidate for this type of behaviour because the deactivation of A^* has only a small activation energy, but there are reactions with analogous mechanisms in which a negative activation energy is observed.

When we examine the general rate law given in eqn 22.63, it is clear that the temperature dependence may be difficult to predict because each rate constant in the

Fig. 22.24 For a reaction with a pre-equilibrium, there are three activation energies to take into account, two referring to the reversible steps of the pre-equilibrium and one for the final step. The relative magnitudes of the activation energies determine whether the overall activation energy is (a) positive or (b) negative.

expression for k increases with temperature, and the outcome depends on whether the terms in the numerator dominate those in the denominator, or vice versa. The fact that so many reactions do show Arrhenius-like behaviour with positive activation energies suggests that their rate laws are in a 'simple' regime, like eqn 22.65 rather than eqn 22.64, and that the temperature dependence is dominated by the activation energy of the rate-determining stage.

Checklist of key ideas

- ☐ 1. The rates of chemical reactions are measured by using techniques that monitor the concentrations of species present in the reaction mixture. Examples include real-time and quenching procedures, flow and stopped-flow techniques, and flash photolysis.
- ☐ 2. The instantaneous rate of a reaction is the slope of the tangent to the graph of concentration against time (expressed as a positive quantity).
- ☐ 3. A rate law is an expression for the reaction rate in terms of the concentrations of the species that occur in the overall chemical reaction.
- ☐ 4. For a rate law of the form $v = k[A]^a[B]^b \dots$, the rate constant is k , the order with respect to A is a , and the overall order is $a + b + \dots$.
- ☐ 5. An integrated rate law is an expression for the concentration of a reactant or product as a function of time (Table 22.3).
- ☐ 6. The half-life $t_{1/2}$ of a reaction is the time it takes for the concentration of a species to fall to half its initial value. The time constant τ is the time required for the concentration of a reactant to fall to $1/e$ of its initial value. For a first-order reaction, $t_{1/2} = (\ln 2)/k$ and $\tau = 1/k$.
- ☐ 7. The equilibrium constant for a reaction is equal to the ratio of the forward and reverse rate constants, $K = k/k'$.
- ☐ 8. In relaxation methods of kinetic analysis, the equilibrium position of a reaction is first shifted suddenly and then allowed to readjust the equilibrium composition characteristic of the new conditions.
- ☐ 9. The temperature dependence of the rate constant of a reaction typically follows the Arrhenius equation, $\ln k = \ln A - E_a/RT$.
- ☐ 10. The activation energy, the parameter E_a in the Arrhenius equation, is the minimum kinetic energy for reaction during a molecular encounter. The larger the activation energy, the more sensitive the rate constant is to the temperature.
- ☐ 11. The mechanism of reaction is the sequence of elementary steps involved in a reaction.
- ☐ 12. The molecularity of an elementary reaction is the number of molecules coming together to react. An elementary unimolecular reaction has first-order kinetics; an elementary bimolecular reaction has second-order kinetics.
- ☐ 13. The rate-determining step is the slowest step in a reaction mechanism that controls the rate of the overall reaction.
- ☐ 14. In the steady-state approximation, it is assumed that the concentrations of all reaction intermediates remain constant and small throughout the reaction.
- ☐ 15. Provided a reaction has not reached equilibrium, the products of competing reactions are controlled by kinetics, with $[P_2]/[P_1] = k_2/k_1$.
- ☐ 16. Pre-equilibrium is a state in which an intermediate is in equilibrium with the reactants and which arises when the rates of formation of the intermediate and its decay back into reactants are much faster than its rate of formation of products.
- ☐ 17. The kinetic isotope effect is the decrease in the rate of a chemical reaction upon replacement of one atom in a reactant by a heavier isotope. A primary kinetic isotope effect is observed when the rate-determining step requires the scission of a bond involving the isotope. A secondary kinetic isotope effect is the reduction in reaction rate even though the bond involving the isotope is not broken to form product.
- ☐ 18. The Lindemann–Hinshelwood mechanism and the RRKM model of 'unimolecular' reactions account for the first-order kinetics of gas-phase reactions.

However, because $s - 1$ is small (in the sense $s - 1 \ll n - n^*$), we can approximate this expression by

$$P \approx \frac{(n - n^*)(n - n^*) \dots (n - n^*)_{s-1 \text{ factors}}}{(n)(n) \dots (n)_{s-1 \text{ factors}}} = \left(\frac{n - n^*}{n} \right)^{s-1}$$

Because the energy of the excited molecule is $E = nh\nu$ and the critical energy is $E^* = n^*h\nu$, this expression may be written

$$P = \left(1 - \frac{E^*}{E} \right)^{s-1}$$

as in eqn 22.68a. The dispersal of the energy of the collision reduces the rate constant below its simple 'Lindemann' form, and to obtain the observed rate constant we should multiply the latter by the probability that the energy will in fact be localized in the bond of interest, which gives eqn 22.68b.

Discussion questions

22.1 Consult literature sources and list the observed timescales during which the following processes occur: radiative decay of excited electronic states, molecular rotational motion, molecular vibrational motion, proton transfer reactions, the initial event of vision, energy transfer in photosynthesis, the initial electron transfer events in photosynthesis, the helix-to-coil transition in polypeptides, and collisions in liquids.

22.2 Write a brief report on a recent research article in which at least one of the following techniques was used to study the kinetics of a chemical reaction: stopped-flow techniques, flash photolysis, chemical quench-flow methods, freeze quench methods, temperature-jump methods, or pressure-jump methods. Your report should be similar in content and size to one of the *Impact* sections found throughout this text.

22.3 Describe the main features, including advantages and disadvantages, of the following experimental methods for determining the rate law of a reaction: the isolation method, the method of initial rates, and fitting data to integrated rate law expressions.

22.4 Distinguish between reaction order and molecularity.

22.5 Assess the validity of the following statement: the rate-determining step is the slowest step in a reaction mechanism.

22.6 Distinguish between a pre-equilibrium approximation and a steady-state approximation.

22.7 Distinguish between kinetic and thermodynamic control of a reaction.

22.8 Define the terms in and limit the generality of the expression $\ln k = \ln A - E_a/RT$.

22.9 Distinguish between a primary and a secondary kinetic isotope effect. Discuss how kinetic isotope effects in general can provide insight into the mechanism of a reaction.

22.10 Discuss the limitations of the generality of the expression $k = k_a k_b [A] / (k_b + k'_a [A])$ for the effective rate constant of a unimolecular reaction $A \rightarrow P$ with the following mechanism: $A + A \rightleftharpoons A^* + A$ (k_a, k'_a), $A^* \rightarrow P$ (k_b). Suggest an experimental procedure that may either support or refute the mechanism.

Exercises

22.1a The rate of the reaction $A + 2B \rightarrow 3C + D$ was reported as $1.0 \text{ mol dm}^{-3} \text{ s}^{-1}$. State the rates of formation and consumption of the participants.

22.1b The rate of the reaction $A + 3B \rightarrow C + 2D$ was reported as $1.0 \text{ mol dm}^{-3} \text{ s}^{-1}$. State the rates of formation and consumption of the participants.

22.2a The rate of formation of C in the reaction $2A + B \rightarrow 2C + 3D$ is $1.0 \text{ mol dm}^{-3} \text{ s}^{-1}$. State the reaction rate, and the rates of formation or consumption of A, B, and D.

22.2b The rate of consumption of B in the reaction $A + 3B \rightarrow C + 2D$ is $1.0 \text{ mol dm}^{-3} \text{ s}^{-1}$. State the reaction rate, and the rates of formation or consumption of A, C, and D.

22.3a The rate law for the reaction in Exercise 22.1a was found to be $v = k[A][B]$. What are the units of k ? Express the rate law in terms of the rates of formation and consumption of (a) A, (b) C.

22.3b The rate law for the reaction in Exercise 22.1b was found to be $v = k[A][B]^2$. What are the units of k ? Express the rate law in terms of the rates of formation and consumption of (a) A, (b) C.

22.4a The rate law for the reaction in Exercise 22.2a was reported as $d[C]/dt = k[A][B][C]$. Express the rate law in terms of the reaction rate; what are the units for k in each case?

22.4b The rate law for the reaction in Exercise 22.2b was reported as $d[C]/dt = k[A][B][C]^{-1}$. Express the rate law in terms of the reaction rate; what are the units for k in each case?

22.5a At 518°C , the rate of decomposition of a sample of gaseous acetaldehyde, initially at a pressure of 363 Torr, was 1.07 Torr s^{-1} when 5.0 per cent had reacted and 0.76 Torr s^{-1} when 20.0 per cent had reacted. Determine the order of the reaction.

22.5b At 400 K, the rate of decomposition of a gaseous compound initially at a pressure of 12.6 kPa, was 9.71 Pa s^{-1} when 10.0 per cent had reacted and 7.67 Pa s^{-1} when 20.0 per cent had reacted. Determine the order of the reaction.

22.6a At 518°C , the half-life for the decomposition of a sample of gaseous acetaldehyde (ethanal) initially at 363 Torr was 410 s. When the pressure was 169 Torr, the half-life was 880 s. Determine the order of the reaction.

22.6b At 400 K, the half-life for the decomposition of a sample of a gaseous compound initially at 55.5 kPa was 340 s. When the pressure was 28.9 kPa, the half-life was 178 s. Determine the order of the reaction.

22.7a The rate constant for the first-order decomposition of N_2O_5 in the reaction $2\text{N}_2\text{O}_5(\text{g}) \rightarrow 4\text{NO}_2(\text{g}) + \text{O}_2(\text{g})$ is $k = 3.38 \times 10^{-5} \text{ s}^{-1}$ at 25°C . What is the half-life of N_2O_5 ? What will be the pressure, initially 500 Torr, at (a) 10 s, (b) 10 min after initiation of the reaction?

22.7b The rate constant for the first-order decomposition of a compound A in the reaction $2A \rightarrow P$ is $k = 2.78 \times 10^{-7} \text{ s}^{-1}$ at 25°C . What is the half-life of A? What will be the pressure, initially 32.1 kPa, at (a) 10 s, (b) 10 min after initiation of the reaction?

22.8a A second-order reaction of the type $A + B \rightarrow P$ was carried out in a solution that was initially $0.050 \text{ mol dm}^{-3}$ in A and $0.080 \text{ mol dm}^{-3}$ in B. After 1.0 h the concentration of A had fallen to $0.020 \text{ mol dm}^{-3}$. (a) Calculate the rate constant. (b) What is the half-life of the reactants?

22.8b A second-order reaction of the type $A + 2B \rightarrow P$ was carried out in a solution that was initially $0.075 \text{ mol dm}^{-3}$ in A and $0.030 \text{ mol dm}^{-3}$ in B. After 1.0 h the concentration of A had fallen to $0.045 \text{ mol dm}^{-3}$. (a) Calculate the rate constant. (b) What is the half-life of the reactants?

22.9a If the rate laws are expressed with (a) concentrations in moles per decimetre cubed, (b) pressures in kilopascals, what are the units of the second-order and third-order rate constants?

22.9b If the rate laws are expressed with (a) concentrations in molecules per metre cubed, (b) pressures in newtons per metre squared, what are the units of the second-order and third-order rate constants?

22.10a The second-order rate constant for the reaction

is $0.11 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$. What is the concentration of ester after (a) 10 s, (b) 10 min when ethyl acetate is added to sodium hydroxide so that the initial concentrations are $[\text{NaOH}] = 0.050 \text{ mol dm}^{-3}$ and $[\text{CH}_3\text{COOC}_2\text{H}_5] = 0.100 \text{ mol dm}^{-3}$?

22.10b The second-order rate constant for the reaction $A + 2B \rightarrow C + D$ is $0.21 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$. What is the concentration of C after (a) 10 s, (b) 10 min when the reactants are mixed with initial concentrations of $[A] = 0.025 \text{ mol dm}^{-3}$ and $[B] = 0.150 \text{ mol dm}^{-3}$?

22.11a A reaction $2A \rightarrow P$ has a second-order rate law with $k = 3.50 \times 10^{-4} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$. Calculate the time required for the concentration of A to change from $0.260 \text{ mol dm}^{-3}$ to $0.011 \text{ mol dm}^{-3}$.

22.11b A reaction $2A \rightarrow P$ has a third-order rate law with $k = 3.50 \times 10^{-4} \text{ dm}^6 \text{ mol}^{-2} \text{ s}^{-1}$. Calculate the time required for the concentration of A to change from $0.077 \text{ mol dm}^{-3}$ to $0.021 \text{ mol dm}^{-3}$.

22.12a Show that $t_{1/2} \propto 1/[A]^{n-1}$ for a reaction that is n th-order in A.

22.12b Deduce an expression for the time it takes for the concentration of a substance to fall to one-third its initial value in an n th-order reaction.

22.13a The $\text{p}K_a$ of NH_4^+ is 9.25 at 25°C . The rate constant at 25°C for the reaction of NH_4^+ and OH^- to form aqueous NH_3 is $4.0 \times 10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$. Calculate the rate constant for proton transfer to NH_3 . What relaxation time would be observed if a temperature jump were applied to a solution of $0.15 \text{ mol dm}^{-3} \text{ NH}_3(\text{aq})$ at 25°C ?

22.13b The equilibrium $A \rightleftharpoons B + C$ at 25°C is subjected to a temperature jump that slightly increases the concentrations of B and C. The measured relaxation time is $3.0 \mu\text{s}$. The equilibrium constant for the system is 2.0×10^{-16} at 25°C , and the equilibrium concentrations of B and C at 25°C are both $2.0 \times 10^{-4} \text{ mol dm}^{-3}$. Calculate the rate constants for steps (1) and (2).

22.14a The rate constant for the decomposition of a certain substance is $2.80 \times 10^{-3} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ at 30°C and $1.38 \times 10^{-2} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ at 50°C . Evaluate the Arrhenius parameters of the reaction.

22.14b The rate constant for the decomposition of a certain substance is $1.70 \times 10^{-2} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ at 24°C and $2.01 \times 10^{-2} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ at 37°C . Evaluate the Arrhenius parameters of the reaction.

22.15a The base-catalysed bromination of nitromethane- d_3 in water at room temperature (298 K) proceeds 4.3 times more slowly than the bromination of the undeuterated material. Account for this difference. Use $k_f(\text{C}-\text{H}) = 450 \text{ N m}^{-1}$.

22.15b Predict the order of magnitude of the isotope effect on the relative rates of displacement of (a) ^1H and ^3H , (b) ^{16}O and ^{18}O . Will raising the temperature enhance the difference? Take $k_f(\text{C}-\text{H}) = 450 \text{ N m}^{-1}$, $k_f(\text{C}-\text{O}) = 1750 \text{ N m}^{-1}$.

22.16a The effective rate constant for a gaseous reaction that has a Lindemann–Hinshelwood mechanism is $2.50 \times 10^{-4} \text{ s}^{-1}$ at 1.30 kPa and $2.10 \times 10^{-5} \text{ s}^{-1}$ at 12 Pa. Calculate the rate constant for the activation step in the mechanism.

22.16b The effective rate constant for a gaseous reaction that has a Lindemann–Hinshelwood mechanism is $1.7 \times 10^{-3} \text{ s}^{-1}$ at 1.09 kPa and $2.2 \times 10^{-4} \text{ s}^{-1}$ at 25 Pa. Calculate the rate constant for the activation step in the mechanism.

Problems*

Numerical problems

22.1 The data below apply to the formation of urea from ammonium cyanate, $\text{NH}_4\text{CNO} \rightarrow \text{NH}_2\text{CONH}_2$. Initially 22.9 g of ammonium cyanate was dissolved in enough water to prepare 1.00 dm^3 of solution. Determine the order of the reaction, the rate constant, and the mass of ammonium cyanate left after 300 min.

t/min	0	20.0	50.0	65.0	150
$m(\text{urea})/\text{g}$	0	7.0	12.1	13.8	17.7

22.2 The data below apply to the reaction, $(\text{CH}_3)_3\text{CBr} + \text{H}_2\text{O} \rightarrow (\text{CH}_3)_3\text{COH} + \text{HBr}$. Determine the order of the reaction, the rate constant, and the molar concentration of $(\text{CH}_3)_3\text{CBr}$ after 43.8 h.

t/h	0	3.15	6.20	10.00	18.30	30.80
$[(\text{CH}_3)_3\text{CBr}]/(10^{-2} \text{ mol dm}^{-3})$	10.39	8.96	7.76	6.39	3.53	2.07

22.3 The thermal decomposition of an organic nitrile produced the following data:

$t/(10^3 \text{ s})$	0	2.00	4.00	6.00	8.00	10.00	12.00	∞
$[\text{nitrile}]/(\text{mol dm}^{-3})$	1.10	0.86	0.67	0.52	0.41	0.32	0.25	0

Determine the order of the reaction and the rate constant.

22.4 The following data have been obtained for the decomposition of $\text{N}_2\text{O}_5(\text{g})$ at 67°C according to the reaction $2 \text{N}_2\text{O}_5(\text{g}) \rightarrow 4 \text{NO}_2(\text{g}) + \text{O}_2(\text{g})$. Determine the order of the reaction, the rate constant, and the half-life. It is not necessary to obtain the result graphically, you may do a calculation using estimates of the rates of change of concentration.

t/min	0	1	2	3	4	5
$[\text{N}_2\text{O}_5]/(\text{mol dm}^{-3})$	1.000	0.705	0.497	0.349	0.246	0.173

22.5 A first-order decomposition reaction is observed to have the following rate constants at the indicated temperatures. Estimate the activation energy.

$k/(10^{-3} \text{ s}^{-1})$	2.46	45.1	576
$\theta/^\circ\text{C}$	0	20.0	40.0

* Problems denoted with the symbol ‡ were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

22.6 The gas-phase decomposition of acetic acid at 1189 K proceeds by way of two parallel reactions:

What is the maximum percentage yield of the ketene CH_2CO obtainable at this temperature?

22.7 Sucrose is readily hydrolysed to glucose and fructose in acidic solution. The hydrolysis is often monitored by measuring the angle of rotation of plane-polarized light passing through the solution. From the angle of rotation the concentration of sucrose can be determined. An experiment on the hydrolysis of sucrose in 0.50 M HCl(aq) produced the following data:

t/min	0	14	39	60	80	110	140	170	210
$[\text{sucrose}]/(\text{mol dm}^{-3})$	0.316	0.300	0.274	0.256	0.238	0.211	0.190	0.170	0.146

Determine the rate constant of the reaction and the half-life of a sucrose molecule. What is the average lifetime of a sucrose molecule?

22.8 The composition of a liquid-phase reaction $2\text{A} \rightarrow \text{B}$ was followed by a spectrophotometric method with the following results:

t/min	0	10	20	30	40	∞
$[\text{B}]/(\text{mol dm}^{-3})$	0	0.089	0.153	0.200	0.230	0.312

Determine the order of the reaction and its rate constant.

22.9 The ClO radical decays rapidly by way of the reaction, $2\text{ClO} \rightarrow \text{Cl}_2 + \text{O}_2$. The following data have been obtained:

$t/(10^{-3} \text{ s})$	0.12	0.62	0.96	1.60	3.20	4.00	5.75
$[\text{ClO}]/(10^{-6} \text{ mol dm}^{-3})$	8.49	8.09	7.10	5.79	5.20	4.77	3.95

Determine the rate constant of the reaction and the half-life of a ClO radical.

22.10 Cyclopropane isomerizes into propene when heated to 500°C in the gas phase. The extent of conversion for various initial pressures has been followed by gas chromatography by allowing the reaction to proceed for a time with various initial pressures:

p_0/Torr	200	200	400	400	600	600
t/s	100	200	100	200	100	200
p/Torr	186	173	373	347	559	520

where p_0 is the initial pressure and p is the final pressure of cyclopropane. What are the order and rate constant for the reaction under these conditions?

22.11 The addition of hydrogen halides to alkenes has played a fundamental role in the investigation of organic reaction mechanisms. In one study (M.J. Haugh and D.R. Dalton, *J. Amer. Chem. Soc.* **97**, 5674 (1975)), high pressures of hydrogen chloride (up to 25 atm) and propene (up to 5 atm) were examined over a range of temperatures and the amount of 2-chloropropane formed was determined by NMR. Show that, if the reaction $\text{A} + \text{B} \rightarrow \text{P}$ proceeds for a short time δt , the concentration of product follows $[\text{P}]/[\text{A}] = k[\text{A}]^{m-1}[\text{B}]^n\delta t$ if the reaction is m th-order in A and n th-order in B. In a series of runs the ratio of [chloropropane] to [propene] was independent of [propene] but the ratio of [chloropropane] to $[\text{HCl}]$ for constant amounts of propene depended on $[\text{HCl}]$. For $\delta t \approx 100 \text{ h}$ (which is short on the timescale of the reaction) the latter ratio rose from zero to 0.05, 0.03, 0.01 for $p(\text{HCl}) = 10 \text{ atm}$, 7.5 atm, 5.0 atm, respectively. What are the orders of the reaction with respect to each reactant?

22.12 Use mathematical software or an electronic spreadsheet to examine the time dependence of $[\text{I}]$ in the reaction mechanism $\text{A} \rightarrow \text{I} \rightarrow \text{P}$ (k_1, k_2). You may either integrate eqn 22.39 numerically (see Appendix 2) or use eqn 22.40 directly. In all the following calculations, use $[\text{A}]_0 = 1 \text{ mol dm}^{-3}$ and a time range of 0 to 5 s. (a) Plot $[\text{I}]$ against t for $k_1 = 10 \text{ s}^{-1}$ and $k_2 = 1 \text{ s}^{-1}$. (b) Increase the ratio k_2/k_1 steadily by decreasing the value of k_1 and examine the plot of $[\text{I}]$ against t at each turn. What approximation about $d[\text{I}]/dt$ becomes increasingly valid?

22.13 Show that the following mechanism can account for the rate law of the reaction in Problem 22.11:

What further tests could you apply to verify this mechanism?

22.14 Consider the dimerization $2\text{A} \rightleftharpoons \text{A}_2$, with forward rate constant k_a and backward rate constant k_b . (a) Derive the following expression for the relaxation time in terms of the total concentration of protein, $[\text{A}]_{\text{tot}} = [\text{A}] + 2[\text{A}_2]$:

$$\frac{1}{\tau^2} = k_b^2 + 8k_a k_b [\text{A}]_{\text{tot}}$$

(b) Describe the computational procedures that lead to the determination of the rate constants k_a and k_b from measurements of τ for different values of $[\text{A}]_{\text{tot}}$. (c) Use the data provided below and the procedure you outlined in part (b) to calculate the rate constants k_a and k_b , and the equilibrium constant K for formation of hydrogen-bonded dimers of 2-pyridone:

$[\text{A}]_{\text{tot}}/(\text{mol dm}^{-3})$	0.500	0.352	0.251	0.151	0.101
τ/ns	2.3	2.7	3.3	4.0	5.3

22.15 In the experiments described in Problems 22.11 and 22.13 an inverse temperature dependence of the reaction rate was observed, the overall rate of reaction at 70°C being roughly one-third that at 19°C . Estimate the apparent activation energy and the activation energy of the rate-determining step given that the enthalpies of the two equilibria are both of the order of -14 kJ mol^{-1} .

22.16 The second-order rate constants for the reaction of oxygen atoms with aromatic hydrocarbons have been measured (R. Atkinson and J.N. Pitts, *J. Phys. Chem.* **79**, 295 (1975)). In the reaction with benzene the rate constants are $1.44 \times 10^7 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ at 300.3 K , $3.03 \times 10^7 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ at 341.2 K , and $6.9 \times 10^7 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ at 392.2 K . Find the pre-exponential factor and activation energy of the reaction.

22.17 In Problem 22.10 the isomerization of cyclopropane over a limited pressure range was examined. If the Lindemann mechanism of first-order reactions is to be tested we also need data at low pressures. These have been obtained (H.O. Pritchard, R.G. Sowden, and A.F. Trotman-Dickenson, *Proc. R. Soc. A* **217**, 563 (1953)):

p/Torr	84.1	11.0	2.89	0.569	0.120	0.067
$10^4 k_{\text{eff}}/\text{s}^{-1}$	2.98	2.23	1.54	0.857	0.392	0.303

Test the Lindemann theory with these data.

22.18† P.W. Seakins, M.J. Pilling, L.T. Niiranen, D. Gutman, and L.N. Krasnoperov (*J. Phys. Chem.* **96**, 9847 (1992)) measured the forward and reverse rate constants for the gas-phase reaction $\text{C}_2\text{H}_5(\text{g}) + \text{HBr}(\text{g}) \rightarrow \text{C}_2\text{H}_6(\text{g}) + \text{Br}(\text{g})$ and used their findings to compute thermodynamic parameters for C_2H_5 . The reaction is bimolecular in both directions with Arrhenius parameters $A = 1.0 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$, $E_a = -4.2 \text{ kJ mol}^{-1}$ for the forward reaction and $k' = 1.4 \times 10^{11} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$, $E_a = 53.3 \text{ kJ mol}^{-1}$ for the reverse reaction. Compute $\Delta_f H^\circ$, S_m° , and $\Delta_f G^\circ$ of C_2H_5 at 298 K .

22.19 Two products are formed in reactions in which there is kinetic control of the ratio of products. The activation energy for the reaction leading to Product 1 is greater than that leading to Product 2. Will the ratio of product concentrations $[\text{P}_1]/[\text{P}_2]$ increase or decrease if the temperature is raised?

Theoretical problems

22.20 The reaction mechanism

involves an intermediate A. Deduce the rate law for the reaction.

22.21 The equilibrium $A \rightleftharpoons B$ is first-order in both directions. Derive an expression for the concentration of A as a function of time when the initial molar concentrations of A and B are $[A]_0$ and $[B]_0$. What is the final composition of the system?

22.22 Derive an integrated expression for a second-order rate law $v = k[A][B]$ for a reaction of stoichiometry $2A + 3B \rightarrow P$.

22.23 Derive the integrated form of a third-order rate law $v = k[A]^2[B]$ in which the stoichiometry is $2A + B \rightarrow P$ and the reactants are initially present in (a) their stoichiometric proportions, (b) with B present initially in twice the amount.

22.24 Set up the rate equations for the reaction mechanism:

Show that the mechanism is equivalent to

under specified circumstances.

22.25 Show that the ratio $t_{1/2}/t_{3/4}$, where $t_{1/2}$ is the half-life and $t_{3/4}$ is the time for the concentration of A to decrease to $\frac{3}{4}$ of its initial value (implying that $t_{3/4} < t_{1/2}$) can be written as a function of n alone, and can therefore be used as a rapid assessment of the order of a reaction.

22.26 Derive an equation for the steady-state rate of the sequence of reactions $A \rightleftharpoons B \rightleftharpoons C \rightleftharpoons D$, with $[A]$ maintained at a fixed value and the product D removed as soon as it is formed.

22.27† For a certain second-order reaction $A + B \rightarrow \text{Products}$, the rate of reaction, v , may be written

$$v = \frac{dx}{dt} = k([A]_0 - x)([B]_0 + x)$$

where x is the decrease in concentration of A or B as a result of reaction. Find an expression for the maximum rate and the conditions under which it applies. Draw a graph of v against x , and noting that v and x cannot be negative, identify the portion of the curve that corresponds to reality.

22.28 Consider the dimerization $A \rightleftharpoons A_2$ with forward rate constant k_a and backward rate constant k_b . Show that the relaxation time is:

$$\tau = \frac{1}{k_b + 4k_a[A]_{\text{eq}}}$$

Applications: to archaeology, biochemistry, and environmental science

22.29 The half-life for the (first-order) radioactive decay of ^{14}C is 5730 y (it emits β rays with an energy of 0.16 MeV). An archaeological sample contained wood that had only 72 per cent of the ^{14}C found in living trees. What is its age?

22.30 One of the hazards of nuclear explosions is the generation of ^{90}Sr and its subsequent incorporation in place of calcium in bones. This nuclide emits β rays of energy 0.55 MeV, and has a half-life of 28.1 y. Suppose 1.00 μg was absorbed by a newly born child. How much will remain after (a) 18 y, (b) 70 y if none is lost metabolically?

22.31 Pharmacokinetics is the study of the rates of absorption and elimination of drugs by organisms. In most cases, elimination is slower than absorption and is a more important determinant of availability of a drug for binding to its target. A drug can be eliminated by many mechanisms, such as metabolism in the liver, intestine, or kidney followed by excretion of breakdown products through urine or faeces. As an example of pharmacokinetic analysis, consider the elimination of beta adrenergic blocking agents (beta blockers), drugs used in the treatment of hypertension.

After intravenous administration of a beta blocker, the blood plasma of a patient was analysed for remaining drug and the data are shown below, where c is the drug concentration measured at a time t after the injection.

t/min	30	60	120	150	240	360	480
$c/(\text{ng cm}^{-3})$	699	622	413	292	152	60	24

(a) Is removal of the drug a first- or second-order process? (b) Calculate the rate constant and half-life of the process. *Comment.* An essential aspect of drug development is the optimization of the half-life of elimination, which needs to be long enough to allow the drug to find and act on its target organ but not so long that harmful side-effects become important.

22.32 The absorption and elimination of a drug in the body may be modelled with a mechanism consisting of two consecutive reactions:

where the rate constants of absorption ($A \rightarrow B$) and elimination are, respectively, k_1 and k_2 . (a) Consider a case in which absorption is so fast that it may be regarded as instantaneous so that a dose of A at an initial concentration $[A]_0$ immediately leads to a drug concentration in blood of $[B]_0$. Also, assume that elimination follows first-order kinetics. Show that, after the administration of n equal doses separated by a time interval τ , the peak concentration of drug B in the blood, $[P]_n$, rises beyond the value of $[B]_0$ and eventually reaches a constant, maximum peak value given by

$$[P]_{\infty} = [B]_0(1 - e^{-k_2\tau})^{-1}$$

where $[P]_n$ is the (peak) concentration of B immediately after administration of the n th dose and $[P]_{\infty}$ is the value at very large n . Also, write a mathematical expression for the residual concentration of B, $[R]_n$, which we define to be the concentration of drug B immediately before the administration of the $(n+1)$ th dose. $[R]_n$ is always smaller than $[P]_n$ on account of drug elimination during the period τ between drug administrations. Show that $[P]_{\infty} - [R]_{\infty} = [B]_0$. (b) Consider a drug for which $k_2 = 0.0289 \text{ h}^{-1}$. (i) Calculate the value of τ required to achieve $[P]_{\infty}/[B]_0 = 10$. Prepare a graph that plots both $[P]_n/[B]_0$ and $[R]_n/[B]_0$ against n . (ii) How many doses must be administered to achieve a $[P]_n$ value that is 75 per cent of the maximum value? What time has passed during the administration of these doses? (iii) What actions can be taken to reduce the variation $[P]_{\infty} - [R]_{\infty}$ while maintaining the same value of $[P]_{\infty}$? (c) Now consider the administration of a single dose $[A]_0$ for which absorption follows first-order kinetics and elimination follows zero-order kinetics. Show that with the initial concentration $[B]_0 = 0$, the concentration of drug in the blood is given by

$$[B] = [A]_0(1 - e^{-k_1 t}) - k_2 t$$

Plot $[B]/[A]_0$ against t for the case $k_1 = 10 \text{ h}^{-1}$, $k_2 = 4.0 \times 10^{-3} \text{ mmol dm}^{-3} \text{ h}^{-1}$, and $[A]_0 = 0.1 \text{ mmol dm}^{-3}$. Comment on the shape of the curve. (d) Using the model from part (c), set $d[B]/dt = 0$ and show that the maximum value of

$[B]$ occurs at the time $t_{\text{max}} = \frac{1}{k_1} \ln \left(\frac{k_1[A]_0}{k_2} \right)$. Also, show that the maximum concentration of drug in blood is given by $[B]_{\text{max}} = [A]_0 - k_2/k_1 - k_2 t_{\text{max}}$.

22.33 Consider a mechanism for the helix-coil transition in which nucleation occurs in the middle of the chain:

We saw in *Impact 122.1* that this type of nucleation is relatively slow, so neither step may be rate-determining. (a) Set up the rate equations for this mechanism. (b) Apply the steady-state approximation and show that, under these circumstances, the mechanism is equivalent to $hhhh \dots \rightleftharpoons cccc \dots$.

(c) Use your knowledge of experimental techniques and your results from parts (a) and (b) to support or refute the following statement: It is very difficult to obtain experimental evidence for intermediates in protein folding by performing simple rate measurements and one must resort to special flow, relaxation, or trapping techniques to detect intermediates directly.

22.34 Propose a set of experiments in which analysis of the line-shapes of NMR transitions (Section 15.7) can be used to monitor fast events in protein folding and unfolding. What are the disadvantages and disadvantages of this NMR method over methods that use electronic and vibrational spectroscopy?

22.35 Consider the following mechanism for renaturation of a double helix from its strands A and B:

Derive the rate equation for the formation of the double helix and express the rate constant of the renaturation reaction in terms of the rate constants of the individual steps.

22.36† Prebiotic reactions are reactions that might have occurred under the conditions prevalent on the Earth before the first living creatures emerged and which can lead to analogues of molecules necessary for life as we now know it. To qualify, a reaction must proceed with favourable rates and equilibria. M.P. Robertson and S.I. Miller (*Science* **268**, 702 (1995)) have studied the prebiotic synthesis of 5-substituted uracils, among them 5-hydroxymethyluracil (HMU). Amino acid analogues can be formed from HMU under prebiotic conditions by reaction with various nucleophiles, such as H_2S , HCN , indole, imidazole, etc. For the synthesis of HMU (the uracil analogue of serine) from uracil and formaldehyde (HCHO), the rate of addition is given by $\log \{k/(\text{dm}^3 \text{mol}^{-1} \text{s}^{-1})\} = 11.75 - 5488/(T/\text{K})$ (at $\text{pH} = 7$), and $\log K = -1.36 + 1794/(T/\text{K})$. For this reaction, calculate the rates and equilibrium constants over a range of temperatures corresponding to possible prebiotic conditions, such as 0 – 50°C , and plot them against temperature. Also, calculate the activation energy and the standard reaction Gibbs energy and enthalpy at 25°C . Prebiotic conditions are not likely to be standard conditions. Speculate about how the actual values of the reaction Gibbs energy and enthalpy might differ from the standard values. Do you expect that the reaction would still be favourable?

22.37† Methane is a by-product of a number of natural processes (such as digestion of cellulose in ruminant animals, anaerobic decomposition of organic waste matter) and industrial processes (such as food production and fossil fuel use). Reaction with the hydroxyl radical OH is the main path by which CH_4 is removed from the lower atmosphere. T. Gierczak, R.K.

Talukdar, S.C. Herndon, G.L. Vaghjiani, and A.R. Ravishankara (*J. Phys. Chem. A* **101**, 3125 (1997)) measured the rate constants for the elementary bimolecular gas-phase reaction of methane with the hydroxyl radical over a range of temperatures of importance to atmospheric chemistry. Deduce the Arrhenius parameters A and E_a from the following measurements:

T/K	295	223	218	213	206	200	195
$k/(\text{dm}^3 \text{mol}^{-1} \text{s}^{-1})$	3.55	0.494	0.452	0.379	0.295	0.241	0.217

22.38† As we saw in Problem 22.37, reaction with the hydroxyl radical OH is the main path by which CH_4 , a by-product of many natural and industrial processes, is removed from the lower atmosphere. T. Gierczak, R.K. Talukdar, S.C. Herndon, G.L. Vaghjiani, and A.R. Ravishankara (*J. Phys. Chem. A* **101**, 3125 (1997)) measured the rate constants for the bimolecular gas-phase reaction $\text{CH}_4(\text{g}) + \text{OH}(\text{g}) \rightarrow \text{CH}_3(\text{g}) + \text{H}_2\text{O}(\text{g})$ and found $A = 1.13 \times 10^9 \text{ dm}^3 \text{mol}^{-1} \text{s}^{-1}$ and $E_a = 14.1 \text{ kJ mol}^{-1}$ for the Arrhenius parameters. (a) Estimate the rate of consumption of CH_4 . Take the average OH concentration to be $1.5 \times 10^{-21} \text{ mol dm}^{-3}$, that of CH_4 to be $4.0 \times 10^{-8} \text{ mol dm}^{-3}$, and the temperature to be -10°C . (b) Estimate the global annual mass of CH_4 consumed by this reaction (which is slightly less than the amount introduced to the atmosphere) given an effective volume for the Earth's lower atmosphere of $4 \times 10^{21} \text{ dm}^3$.

22.39† T. Gierczak, R.K. Talukdar, S.C. Herndon, G.L. Vaghjiani, and A.R. Ravishankara (*J. Phys. Chem. A* **101**, 3125 (1997)) measured the rate constants for the bimolecular gas-phase reaction of methane with the hydroxyl radical in several isotopic variations. From their data, the following Arrhenius parameters can be obtained:

	$A/(\text{dm}^3 \text{mol}^{-1} \text{s}^{-1})$	$E_a/(\text{kJ mol}^{-1})$
$\text{CH}_4 + \text{OH} \rightarrow \text{CH}_3 + \text{H}_2\text{O}$	1.13×10^9	14.1
$\text{CD}_4 + \text{OH} \rightarrow \text{CD}_3 + \text{DOH}$	6.0×10^8	17.5
$\text{CH}_4 + \text{OD} \rightarrow \text{CH}_3 + \text{DOH}$	1.01×10^9	13.6

Compute the rate constants at 298 K , and interpret the kinetic isotope effects.

22.40† The oxidation of HSO_3^- by O_2 in aqueous solution is a reaction of importance to the processes of acid rain formation and flue gas desulfurization. R.E. Connick, Y.-X. Zhang, S. Lee, R. Adamic, and P. Chieng (*Inorg. Chem.* **34**, 4543 (1995)) report that the reaction $2 \text{HSO}_3^- + \text{O}_2 \rightarrow 2 \text{SO}_4^{2-} + 2 \text{H}^+$ follows the rate law $v = k[\text{HSO}_3^-]^2[\text{H}^+]^2$. Given a pH of 5.6 and an oxygen molar concentration of $2.4 \times 10^{-4} \text{ mol dm}^{-3}$ (both presumed constant), an initial HSO_3^- molar concentration of $5 \times 10^{-5} \text{ mol dm}^{-3}$, and a rate constant of $3.6 \times 10^6 \text{ dm}^9 \text{mol}^{-3} \text{s}^{-1}$, what is the initial rate of reaction? How long would it take for HSO_3^- to reach half its initial concentration?

Problems

This chapter extends the material introduced in Chapter 22 by showing how to deal with complex reaction mechanisms. First, we consider chain reactions and see that either complicated or simple rate laws can be obtained, depending on the conditions. Under certain circumstances, a chain reaction can become explosive, and we see some of the reasons for this behaviour. An important application of these more complicated techniques is to the kinetics of polymerization reactions. There are two major classes of polymerization process and the average molar mass of the product varies with time in distinctive ways. Second, we describe homogeneous catalysis and apply the associated concepts to enzyme-catalysed reactions. Finally, we describe the principles of photochemistry and apply them to problems in environmental science, biochemistry, and medicine.

Many reactions take place by mechanisms that involve several elementary steps. Some take place at a useful rate only after absorption of light or if a catalyst is present. In this chapter we see how to develop the ideas introduced in Chapter 22 to deal with these special kinds of reactions.

Chain reactions

Many gas-phase reactions and liquid-phase polymerization reactions are **chain reactions**. In a chain reaction, a reaction intermediate produced in one step generates an intermediate in a subsequent step, then that intermediate generates another intermediate, and so on. The intermediates in a chain reaction are called **chain carriers**. In a **radical chain reaction** the chain carriers are radicals (species with unpaired electrons). Ions may also act as chain carriers. In nuclear fission the chain carriers are neutrons.

23.1 The rate laws of chain reactions

A chain reaction can have a simple rate law. As a first example, consider the **pyrolysis**, or thermal decomposition in the absence of air, of acetaldehyde (ethanal, CH_3CHO), which is found to be three-halves order in CH_3CHO :

Some ethane is also detected. The **Rice–Herzfeld mechanism** for this reaction is as follows (the dot signifies an unpaired electron and marks a radical):

The chain carriers $\cdot\text{CH}_3$ and $\cdot\text{CHO}$ are formed initially in the **initiation step**. To simplify the treatment, we shall ignore the subsequent reactions of $\cdot\text{CHO}$, except to note that they give rise to the formation of CO and of the by-product H_2 . The chain carrier $\cdot\text{CH}_3$ attacks other reactant molecules in the **propagation steps**, and each attack gives rise to a new carrier. Radicals combine and end the chain in the **termination step**.

To test the proposed mechanism we need to show that it leads to the observed rate law. According to the steady-state approximation (Section 22.7b), the net rate of change of the intermediates ($\cdot\text{CH}_3$ and $\text{CH}_3\text{CO}\cdot$) may be set equal to zero:

$$\frac{d[\cdot\text{CH}_3]}{dt} = k_i[\text{CH}_3\text{CHO}] - k_p[\cdot\text{CH}_3][\text{CH}_3\text{CHO}] + k'_p[\text{CH}_3\text{CO}\cdot] - 2k_t[\cdot\text{CH}_3]^2 = 0$$

$$\frac{d[\text{CH}_3\text{CO}\cdot]}{dt} = k_p[\cdot\text{CH}_3][\text{CH}_3\text{CHO}] - k'_p[\text{CH}_3\text{CO}\cdot] = 0$$

The sum of the two equations is

$$k_i[\text{CH}_3\text{CHO}] - 2k_t[\cdot\text{CH}_3]^2 = 0$$

which shows that the steady-state approximation also implies that the rate of chain initiation is equal to the rate of chain termination. The steady-state concentration of $\cdot\text{CH}_3$ radicals is

$$[\cdot\text{CH}_3] = \left(\frac{k_i}{2k_t} \right)^{1/2} [\text{CH}_3\text{CHO}]^{1/2} \quad (23.2)$$

It follows that the rate of formation of CH_4 is

$$\frac{d[\text{CH}_4]}{dt} = k_p[\cdot\text{CH}_3][\text{CH}_3\text{CHO}] = k_p \left(\frac{k_i}{2k_t} \right)^{1/2} [\text{CH}_3\text{CHO}]^{3/2} \quad (23.3)$$

which is in agreement with the three-halves order observed experimentally (eqn 23.1). However, this mechanism does not accommodate the formation of various known reaction by-products, such as propanone (CH_3COCH_3) and propanal ($\text{CH}_3\text{CH}_2\text{CHO}$).

In many cases, a chain reaction leads to a complicated rate law. An example is the **hydrogen–bromine reaction**:

The following mechanism has been proposed to account for this rate law (Fig. 23.1):

where M is either Br_2 or H_2 . This step is an example of a **thermolysis**, a reaction initiated by heat, which stimulates vigorous intermolecular collisions.

A **retardation step** reduces the net rate of formation of product. In this case, the chain carrier $\text{H}\cdot$ attacks a molecule of HBr , the product. In the termination step, the third body M removes the energy of recombination. Other possible termination steps include the recombination of H atoms to form H_2 and combination of H and Br atoms. However, it turns out that only Br atom recombination is important because Br atoms propagate the chain more slowly and thus live longer than H atoms. The net rate of formation of the product HBr is

Fig. 23.1 A schematic representation of the mechanism of the reaction between hydrogen and bromine. Note how the reactants and products are shown as arms to the circle, but the intermediates (H and Br) occur only on the circle. Similar diagrams are used to depict the action of catalysts.

$$\frac{d[\text{HBr}]}{dt} = k_p[\text{Br}\cdot][\text{H}_2] + k'_p[\text{H}\cdot][\text{Br}_2] - k_r[\text{H}\cdot][\text{HBr}]$$

We can now either analyse the rate equations numerically (see *Appendix 2* and *Further reading*) or look for approximate solutions and see if they agree with the empirical rate law. The following example illustrates the latter approach.

Example 23.1 Deriving the rate equation of a chain reaction

Derive the rate law for the formation of HBr according to the mechanism given above.

Method Make the steady-state approximation for the concentrations of any intermediates ($\text{H}\cdot$ and $\text{Br}\cdot$ in the present case) by setting the net rates of change of their concentrations equal to zero. Solve the resulting equations for the concentrations of the intermediates, and then use the resulting expressions in the equation for the net rate of formation of HBr.

Answer The net rates of formation of the two intermediates are

$$\frac{d[\text{H}\cdot]}{dt} = k_p[\text{Br}\cdot][\text{H}_2] - k'_p[\text{H}\cdot][\text{Br}_2] - k_r[\text{H}\cdot][\text{HBr}] = 0$$

$$\begin{aligned} \frac{d[\text{Br}\cdot]}{dt} &= 2k_i[\text{Br}_2][\text{M}] - k_p[\text{Br}\cdot][\text{H}_2] + k'_p[\text{H}\cdot][\text{Br}_2] + k_r[\text{H}\cdot][\text{HBr}] - 2k_t[\text{Br}\cdot]^2[\text{M}] \\ &= 0 \end{aligned}$$

The steady-state concentrations of the intermediates are obtained by solving these two simultaneous equations and are

$$[\text{Br}\cdot] = \left(\frac{k_i}{k_t}\right)^{1/2} [\text{Br}_2]^{1/2} \quad [\text{H}\cdot] = \frac{k_p(k_i/k_t)^{1/2} [\text{H}_2][\text{Br}_2]^{1/2}}{k'_p[\text{Br}_2] + k_r[\text{HBr}]}$$

Note that $[\text{M}]$ has cancelled. When we substitute these concentrations into the expression for $d[\text{HBr}]/dt$, we obtain

$$\frac{d[\text{HBr}]}{dt} = \frac{2k_p(k_i/k_t)^{1/2} [\text{H}_2][\text{Br}_2]^{3/2}}{[\text{Br}_2] + (k_r/k'_p)[\text{HBr}]}$$

This equation has the same form as the empirical rate law (eqn 23.4), so the two empirical rate constants can be identified as

$$k = 2k_p \left(\frac{k_i}{k_t}\right)^{1/2} \quad k' = \frac{k_r}{k'_p}$$

The rate law shows that the reaction slows down as HBr forms, or as the $[\text{HBr}]/[\text{Br}_2]$ ratio increases. This effect occurs because Br_2 molecules compete with HBr molecules for $\text{H}\cdot$ atoms, with the propagation step $\text{H}\cdot + \text{Br}_2 \rightarrow \text{HBr} + \text{Br}\cdot$ yielding product (HBr) and the retardation step $\text{H}\cdot + \text{HBr} \rightarrow \text{H}_2 + \text{Br}\cdot$ converting HBr back into reactant (H_2). Numerical integration of the rate law with mathematical software shows the predicted time dependence of the concentration of HBr for this mechanism (Fig. 23.2).

Self-test 23.1 Deduce the rate law for the production of HBr when the initiation step is the photolysis, or light-induced decomposition, of Br_2 into two bromine atoms, $\text{Br}\cdot$. Let the photolysis rate be $v = I_{\text{abs}}$, where I_{abs} is the intensity of absorbed radiation. [See eqn 23.39 below]

Fig. 23.2 The numerical integration of the HBr rate law, Example 23.1, can be used to explore how the concentration of HBr changes with time. These runs began with stoichiometric proportions of H_2 and Br_2 ; the curves are labelled with the value of $2k' - 1$.

Exploration Use mathematical software or the interactive applets found in the *Living graphs* section of the text's web site to plot the concentrations of the radicals $\text{H}\cdot$ and $\text{Br}\cdot$ against time. Find a combination of rate constants that results in steady states for these intermediates.

23.2 Explosions

A **thermal explosion** is a very rapid reaction arising from a rapid increase of reaction rate with increasing temperature. The temperature of the system rises if the energy released by an exothermic reaction cannot escape, and the reaction goes faster. The acceleration of the rate results in an even faster rise of temperature, so the reaction becomes catastrophically fast. A **chain-branching explosion** occurs when the number of chain centres grows exponentially.

An example of both types of explosion is the reaction between hydrogen and oxygen:

Although the net reaction is very simple, the mechanism is very complex and has not yet been fully elucidated. A chain reaction is involved, and the chain carriers include $\text{H}\cdot$, $\cdot\text{O}\cdot$, and $\cdot\text{OH}$. Some steps involving $\text{H}\cdot$ are:

A **branching step** is an elementary reaction that produces more than one chain carrier. Recall that an O atom, with the ground-state configuration $[\text{He}]2s^22p^4$, has two unpaired electrons. The same is true of an O_2 molecule, with 12 valence electrons and a ground-state configuration $1\sigma_g^21\sigma_u^22\sigma_g^21\pi_u^41\pi_g^2$.

The occurrence of an explosion depends on the temperature and pressure of the system, and the **explosion regions** for the reaction, the conditions under which explosion occurs, are shown in Fig. 23.3. At very low pressures the system is outside the explosion region and the mixture reacts smoothly. At these pressures the chain carriers produced in the branching steps can reach the walls of the container where they combine. Increasing the pressure along a vertical line in the illustration takes the system through the **first explosion limit** (provided the temperature is greater than about 730 K). The chain carriers react before reaching the walls and the branching reactions are explosively efficient. The reaction is smooth when the pressure is above the **second explosion limit**. The concentration of third-body M molecules is then so high compared to the concentrations of chain carriers that the combination of $\text{H}\cdot$ atoms with O_2 molecules to form relatively unreactive $\text{HO}_2\cdot$ molecules becomes faster than the branching reaction between $\text{H}\cdot$ atoms and O_2 molecules. These long-lived $\text{HO}_2\cdot$ molecules then diffuse to the walls and are removed there, in what amounts to another termination step. When the pressure is increased to above the **third explosion limit**, diffusion of $\text{HO}_2\cdot$ molecules to the walls becomes so slow that they can react with H_2 molecules (now at very high concentrations) to regenerate H atoms and H_2O_2 molecules.

Fig. 23.3 The explosion limits of the $\text{H}_2 + \text{O}_2$ reaction. In the explosive regions the reaction proceeds explosively when heated homogeneously.

Example 23.2 Examining the explosion behaviour of a chain reaction

For the reaction of hydrogen and oxygen described above, show that an explosion occurs when the rate of chain branching exceeds that of chain termination.

Method Identify the onset of explosion with the rapid increase in the concentration of radicals, and for simplicity identify that concentration with the concentration of

Fig. 23.4 The concentration of radicals in the fuel-rich regime of the hydrogen–oxygen reaction (a) under steady combustion conditions, (b) in the explosive region. For this graph, $\Delta k = k_{\text{branch}} - k_{\text{term}}$.

Exploration Using mathematical software, an electronic spreadsheet, or the interactive applets found in the *Living graphs* section of the text's web site, explore the effect of changing the parameter $\Delta k = k_{\text{branch}} - k_{\text{term}}$ on the shapes of the curves in Figs. 23.4a and 23.4b.

$\text{H}\cdot$ atoms, which probably outnumber the highly reactive $\cdot\text{OH}$ and $\cdot\text{O}\cdot$ radicals. Set up the corresponding rate laws for the reaction intermediates and then apply the steady-state approximation.

Answer The rate of formation of radicals, v_{rad} , is identified with $d[\text{H}\cdot]/dt$; therefore we write

$$v_{\text{rad}} = v_{\text{init}} + k_p[\cdot\text{OH}][\text{H}_2] - k_b[\text{H}\cdot][\text{O}_2] + k'_b[\cdot\text{O}\cdot][\text{H}_2] - k_t[\text{H}\cdot] - k'_t[\text{H}\cdot][\text{O}_2][\text{M}]$$

Applying the steady-state approximation to $\cdot\text{OH}$ and $\cdot\text{O}\cdot$ gives

$$\frac{d[\cdot\text{OH}]}{dt} = -k_p[\cdot\text{OH}][\text{H}_2] + k_b[\text{H}\cdot][\text{O}_2] + k'_b[\cdot\text{O}\cdot][\text{H}_2] = 0$$

$$\frac{d[\cdot\text{O}\cdot]}{dt} = k_b[\text{H}\cdot][\text{O}_2] - k'_b[\cdot\text{O}\cdot][\text{H}_2] = 0$$

The solutions of these two algebraic equations are

$$[\cdot\text{O}\cdot] = \frac{k_b[\text{H}\cdot][\text{O}_2]}{k'_b[\text{H}_2]} \quad [\cdot\text{OH}] = \frac{2k_b[\text{H}\cdot][\text{O}_2]}{k_p[\text{H}_2]}$$

The rate of formation of radicals is therefore

$$v_{\text{rad}} = v_{\text{init}} + (2k_b[\text{O}_2] - k_t - k'_t[\text{O}_2][\text{M}])[\text{H}\cdot]$$

We write $k_{\text{branch}} = 2k_b[\text{O}_2]$, a measure of the rate of the more important chain-branching step, and $k_{\text{term}} = k_t + k'_t[\text{O}_2][\text{M}]$, a measure of the rate of chain termination. Then,

$$\frac{d[\text{H}\cdot]}{dt} = v_{\text{init}} + (k_{\text{branch}} - k_{\text{term}})[\text{H}\cdot]$$

There are two solutions. At low O_2 concentrations, termination dominates branching, so $k_{\text{term}} > k_{\text{branch}}$. Then,

$$[\text{H}\cdot] = \frac{v_{\text{init}}}{k_{\text{term}} - k_{\text{branch}}} (1 - e^{-(k_{\text{term}} - k_{\text{branch}})t})$$

As can be seen from Fig. 23.4a, in this regime there is steady combustion of hydrogen. At high O_2 concentrations, branching dominates termination, or $k_{\text{branch}} > k_{\text{term}}$. Then,

$$[\text{H}\cdot] = \frac{v_{\text{init}}}{k_{\text{branch}} - k_{\text{term}}} (e^{(k_{\text{branch}} - k_{\text{term}})t} - 1)$$

There is now an explosive increase in the concentration of radicals (Fig. 23.4b).

Although the steady-state approximation does not hold under explosive conditions, the calculation at least gives an indication of the basis for the transition from smooth combustion to explosion.

Self-test 23.2 Calculate the variation in radical composition when the rates of branching and termination are equal. $[[\text{H}\cdot] = v_{\text{init}}t]$

Not all explosions are due to chain reactions. Solid-state explosions, such as the explosion of ammonium nitrate or TNT (2,4,6-trinitrotoluene), for instance, are simply decompositions that occur very rapidly with the production of large amounts of gas phase molecules.

Polymerization kinetics

In **stepwise polymerization** any two monomers present in the reaction mixture can link together at any time and growth of the polymer is not confined to chains that are already forming (Fig. 23.5). As a result, monomers are removed early in the reaction and, as we shall see, the average molar mass of the product grows with time. In **chain polymerization** an activated monomer, M , attacks another monomer, links to it, then that unit attacks another monomer, and so on. The monomer is used up as it becomes linked to the growing chains (Fig. 23.6). High polymers are formed rapidly and only the yield, not the average molar mass, of the polymer is increased by allowing long reaction times.

23.3 Stepwise polymerization

Stepwise polymerization commonly proceeds by a condensation reaction, in which a small molecule (typically H_2O) is eliminated in each step. Stepwise polymerization is the mechanism of production of polyamides, as in the formation of nylon-66:

Fig. 23.5 In stepwise polymerization, growth can start at any pair of monomers, and so new chains begin to form throughout the reaction.

Fig. 23.6 The process of chain polymerization. Chains grow as each chain acquires additional monomers.

Polyesters and polyurethanes are formed similarly (the latter without elimination). A polyester, for example, can be regarded as the outcome of the stepwise condensation of a hydroxyacid $\text{HO}-\text{M}-\text{COOH}$. We shall consider the formation of a polyester from such a monomer, and measure its progress in terms of the concentration of the $-\text{COOH}$ groups in the sample (which we denote A), for these groups gradually disappear as the condensation proceeds. Because the condensation reaction can occur between molecules containing any number of monomer units, chains of many different lengths can grow in the reaction mixture.

In the absence of a catalyst, we can expect the condensation to be overall second-order in the concentration of the $-\text{OH}$ and $-\text{COOH}$ (or A) groups, and write

$$\frac{d[A]}{dt} = -k[\text{OH}][A] \quad (23.5a)$$

However, because there is one $-\text{OH}$ group for each $-\text{COOH}$ group, this equation is the same as

$$\frac{d[A]}{dt} = -k[A]^2 \quad (23.5b)$$

If we assume that the rate constant for the condensation is independent of the chain length, then k remains constant throughout the reaction. The solution of this rate law is given by eqn 22.15, and is

$$[A] = \frac{[A]_0}{1 + kt[A]_0} \quad (23.6)$$

The fraction, p , of $-\text{COOH}$ groups that have condensed at time t is, after application of eqn 23.6:

$$p = \frac{[A]_0 - [A]}{[A]_0} = \frac{kt[A]_0}{1 + kt[A]_0} \quad (23.7)$$

Next, we calculate the **degree of polymerization**, which is defined as the average number of monomer residues per polymer molecule. This quantity is the ratio of the initial concentration of A , $[A]_0$, to the concentration of end groups, $[A]$, at the time of interest, because there is one $-A$ group per polymer molecule. For example, if there were initially 1000 A groups and there are now only 10, each polymer must be 100 units long on average. Because we can express $[A]$ in terms of p (eqn 23.7), the average number of monomers per polymer molecule, $\langle n \rangle$, is

$$\langle n \rangle = \frac{[A]_0}{[A]} = \frac{1}{1 - p} \quad (23.8a)$$

This result is illustrated in Fig. 23.7. When we express p in terms of the rate constant k (eqn 23.7), we find

$$\langle n \rangle = 1 + kt[A]_0 \quad (23.8b)$$

The average length grows linearly with time. Therefore, the longer a stepwise polymerization proceeds, the higher the average molar mass of the product.

23.4 Chain polymerization

Chain polymerization occurs by addition of monomers to a growing polymer, often by a radical chain process. It results in the rapid growth of an individual polymer

Fig. 23.7 The average chain length of a polymer as a function of the fraction of reacted monomers, p . Note that p must be very close to 1 for the chains to be long.

Exploration Plot the variation of p with time for a range of k values of your choosing (take $[A]_0 = 1.0 \text{ mol dm}^{-3}$).

chain for each activated monomer. Examples include the addition polymerizations of ethene, methyl methacrylate, and styrene, as in

and subsequent reactions. The central feature of the kinetic analysis (which is summarized in the *Justification* below) is that the rate of polymerization is proportional to the square root of the initiator concentration:

$$v = k[\text{I}]^{1/2}[\text{M}] \quad (23.9)$$

Justification 23.1 *The rate of chain polymerization*

There are three basic types of reaction step in a chain polymerization process:

(a) Initiation:

where I is the initiator, R· the radical I forms, and ·M₁ is a monomer radical. We have shown a reaction in which a radical is produced, but in some polymerizations the initiation step leads to the formation of an ionic chain carrier. The rate-determining step is the formation of the radicals R· by homolysis of the initiator, so the rate of initiation is equal to the v_i given above.

(b) Propagation:

If we assume that the rate of propagation is independent of chain size for sufficiently large chains, then we can use only the equation given above to describe the propagation process. Consequently, for sufficiently large chains, the rate of propagation is equal to the overall rate of polymerization.

Because this chain of reactions propagates quickly, the rate at which the total concentration of radicals grows is equal to the rate of the rate-determining initiation step. It follows that

$$\left(\frac{d[\cdot\text{M}]}{dt} \right)_{\text{production}} = 2fk_i[\text{I}] \quad (23.10)$$

where f is the fraction of radicals R· that successfully initiate a chain.

(c) Termination:

In **mutual termination** two growing radical chains combine. In termination by **disproportionation** a hydrogen atom transfers from one chain to another, corresponding to the oxidation of the donor and the reduction of the acceptor. In **chain transfer**, a new chain initiates at the expense of the one currently growing.

Here we suppose that only mutual termination occurs. If we assume that the rate of termination is independent of the length of the chain, the rate law for termination is

$$v_t = k_t[\cdot\text{M}]^2$$

and the rate of change of radical concentration by this process is

$$\left(\frac{d[\cdot M]}{dt} \right)_{\text{depletion}} = -2k_t[\cdot M]^2$$

The steady-state approximation gives:

$$\frac{d[\cdot M]}{dt} = 2fk_i[I] - 2k_t[\cdot M]^2 = 0$$

The steady-state concentration of radical chains is therefore

$$[\cdot M] = \left(\frac{fk_i}{k_t} \right)^{1/2} [I]^{1/2} \quad (23.11)$$

Because the rate of propagation of the chains is the negative of the rate at which the monomer is consumed, we can write $v_p = -d[M]/dt$ and

$$v_p = k_p[\cdot M][M] = k_p \left(\frac{fk_i}{k_t} \right)^{1/2} [I]^{1/2} [M] \quad (23.12)$$

This rate is also the rate of polymerization, which has the form of eqn 23.9.

The **kinetic chain length**, v , is the ratio of the number of monomer units consumed per activated centre produced in the initiation step:

$$v = \frac{\text{number of monomer units consumed}}{\text{number of activated centres produced}} \quad (23.13)$$

The kinetic chain length can be expressed in terms of the rate expressions in *Justification 23.1*. To do so, we recognize that monomers are consumed at the rate that chains propagate. Then,

$$v = \frac{\text{rate of propagation of chains}}{\text{rate of production of radicals}}$$

By making the steady-state approximation, we set the rate of production of radicals equal to the termination rate. Therefore, we can write the expression for the kinetic chain length as

$$v = \frac{k_p[\cdot M][M]}{2k_t[\cdot M]^2} = \frac{k_p[M]}{2k_t[\cdot M]}$$

When we substitute the steady-state expression, eqn 23.11, for the radical concentration, we obtain

$$v = k[M][I]^{-1/2} \quad k = \frac{1}{2}k_p(fk_i k_t)^{-1/2} \quad (23.14)$$

Consider a polymer produced by a chain mechanism with mutual termination. In this case, the average number of monomers in a polymer molecule, $\langle n \rangle$, produced by the reaction is the sum of the numbers in the two combining polymer chains. The average number of units in each chain is v . Therefore,

$$\langle n \rangle = 2v = 2k[M][I]^{-1/2} \quad (23.15)$$

with k given in eqn 23.14. We see that, the slower the initiation of the chain (the smaller the initiator concentration and the smaller the initiation rate constant), the greater the kinetic chain length, and therefore the higher the average molar mass of the polymer. Some of the consequences of molar mass for polymers were explored in Chapter 19; now we have seen how we can exercise kinetic control over them.

Homogeneous catalysis

A **catalyst** is a substance that accelerates a reaction but undergoes no net chemical change. The catalyst lowers the activation energy of the reaction by providing an alternative path that avoids the slow, rate-determining step of the uncatalysed reaction (Fig. 23.8). Catalysts can be very effective; for instance, the activation energy for the decomposition of hydrogen peroxide in solution is 76 kJ mol^{-1} , and the reaction is slow at room temperature. When a little iodide ion is added, the activation energy falls to 57 kJ mol^{-1} and the rate constant increases by a factor of 2000. **Enzymes**, which are biological catalysts, are very specific and can have a dramatic effect on the reactions they control. For example, the enzyme catalase reduces the activation energy for the decomposition of hydrogen peroxide to 8 kJ mol^{-1} , corresponding to an acceleration of the reaction by a factor of 10^{15} at 298 K.

A **homogeneous catalyst** is a catalyst in the same phase as the reaction mixture. For example, the decomposition of hydrogen peroxide in aqueous solution is catalysed by bromide ion or catalase (Sections 23.5 and 23.6). A **heterogeneous catalyst** is a catalyst in a different phase from the reaction mixture. For example, the hydrogenation of ethene to ethane, a gas-phase reaction, is accelerated in the presence of a solid catalyst such as palladium, platinum, or nickel. The metal provides a surface upon which the reactants bind; this binding facilitates encounters between reactants and increases the rate of the reaction. We examine heterogeneous catalysis in Chapter 25 and consider only homogeneous catalysis here.

Fig. 23.8 A catalyst provides a different path with a lower activation energy. The result is an increase in the rate of formation of products.

23.5 Features of homogeneous catalysis

We can obtain some idea of the mode of action of homogeneous catalysts by examining the kinetics of the bromide-catalysed decomposition of hydrogen peroxide:

The reaction is believed to proceed through the following pre-equilibrium:

where we have set the activity of H_2O in the equilibrium constant equal to 1 and assumed that the thermodynamic properties of the other substances are ideal. The second step is rate-determining. Therefore, we can obtain the rate law of the overall reaction by setting the overall rate equal to the rate of the second step and using the equilibrium constant to express the concentration of H_3O_2^+ in terms of the reactants. The result is

$$\frac{d[\text{O}_2]}{dt} = k_{\text{eff}}[\text{H}_2\text{O}_2][\text{H}_3\text{O}^+][\text{Br}^-]$$

with $k_{\text{eff}} = kK$, in agreement with the observed dependence of the rate on the Br^- concentration and the pH of the solution. The observed activation energy is that of the effective rate constant kK .

In **acid catalysis** the crucial step is the transfer of a proton to the substrate:

Acid catalysis is the primary process in the solvolysis of esters and keto–enol tautomerism. In **base catalysis**, a proton is transferred from the substrate to a base:

Base catalysis is the primary step in the isomerization and halogenation of organic compounds, and of the Claisen and aldol condensation reactions.

23.6 Enzymes

Fig. 23.9 Two models that explain the binding of a substrate to the active site of an enzyme. In the lock-and-key model, the active site and substrate have complementary three-dimensional structures and dock perfectly without the need for major atomic rearrangements. In the induced fit model, binding of the substrate induces a conformational change in the active site. The substrate fits well in the active site after the conformational change has taken place.

Enzymes are homogeneous biological catalysts. These ubiquitous compounds are special proteins or nucleic acids that contain an **active site**, which is responsible for binding the **substrates**, the reactants, and processing them into products. As is true of any catalyst, the active site returns to its original state after the products are released. Many enzymes consist primarily of proteins, some featuring organic or inorganic co-factors in their active sites. However, certain RNA molecules can also be biological catalysts, forming **ribozymes**. A very important example of a ribozyme is the **ribosome**, a large assembly of proteins and catalytically active RNA molecules responsible for the synthesis of proteins in the cell.

The structure of the active site is specific to the reaction that it catalyses, with groups in the substrate interacting with groups in the active site by intermolecular interactions, such as hydrogen bonding, electrostatic, or van der Waals interactions. Figure 23.9 shows two models that explain the binding of a substrate to the active site of an enzyme. In the **lock-and-key model**, the active site and substrate have complementary three-dimensional structures and dock perfectly without the need for major atomic rearrangements. Experimental evidence favours the **induced fit model**, in which binding of the substrate induces a conformational change in the active site. Only after the change does the substrate fit snugly in the active site.

Enzyme-catalysed reactions are prone to inhibition by molecules that interfere with the formation of product. Many drugs for the treatment of disease function by inhibiting enzymes. For example, an important strategy in the treatment of acquired immune deficiency syndrome (AIDS) involves the steady administration of a specially designed protease inhibitor. The drug inhibits an enzyme that is key to the formation of the protein envelope surrounding the genetic material of the human immunodeficiency virus (HIV). Without a properly formed envelope, HIV cannot replicate in the host organism.

(a) The Michaelis–Menten mechanism of enzyme catalysis

Experimental studies of enzyme kinetics are typically conducted by monitoring the initial rate of product formation in a solution in which the enzyme is present at very low concentration. Indeed, enzymes are such efficient catalysts that significant accelerations may be observed even when their concentration is more than three orders of magnitude smaller than that of the substrate.

The principal features of many enzyme-catalysed reactions are as follows:

- 1 For a given initial concentration of substrate, $[\text{S}]_0$, the initial rate of product formation is proportional to the total concentration of enzyme, $[\text{E}]_0$.
- 2 For a given $[\text{E}]_0$ and low values of $[\text{S}]_0$, the rate of product formation is proportional to $[\text{S}]_0$.
- 3 For a given $[\text{E}]_0$ and high values of $[\text{S}]_0$, the rate of product formation becomes independent of $[\text{S}]_0$, reaching a maximum value known as the **maximum velocity**, v_{max} .

The **Michaelis–Menten mechanism** accounts for these features. According to this mechanism, an enzyme–substrate complex is formed in the first step and either the substrate is released unchanged or after modification to form products:

We show in the following *Justification* that this mechanism leads to the **Michaelis–Menten equation** for the rate of product formation

$$v = \frac{k_b[\text{E}]_0}{1 + K_M/[S]_0} \quad (23.17)$$

where $K_M = (k'_a + k_b)/k_a$ is the **Michaelis constant**, characteristic of a given enzyme acting on a given substrate.

Justification 23.2 The Michaelis–Menten equation

The rate of product formation according to the Michaelis–Menten mechanism is

$$v = k_b[\text{ES}] \quad (23.18)$$

We can obtain the concentration of the enzyme–substrate complex by invoking the steady-state approximation and writing

$$\frac{d[\text{ES}]}{dt} = k_a[\text{E}][\text{S}] - k'_a[\text{ES}] - k_b[\text{ES}] = 0$$

It follows that

$$[\text{ES}] = \left(\frac{k_a}{k'_a + k_b} \right) [\text{E}][\text{S}] \quad (23.19)$$

where $[\text{E}]$ and $[\text{S}]$ are the concentrations of *free* enzyme and substrate, respectively. Now we define the Michaelis constant as

$$K_M = \frac{k'_a + k_b}{k_a} = \frac{[\text{E}][\text{S}]}{[\text{ES}]}$$

and note that K_M has the same units as molar concentration. To express the rate law in terms of the concentrations of enzyme and substrate added, we note that $[\text{E}]_0 = [\text{E}] + [\text{ES}]$. Moreover, because the substrate is typically in large excess relative to the enzyme, the free substrate concentration is approximately equal to the initial substrate concentration and we can write $[\text{S}] \approx [\text{S}]_0$. It then follows that:

$$[\text{ES}] = \frac{[\text{E}]_0}{1 + K_M/[S]_0}$$

We obtain eqn 23.17 when we substitute this expression for $[\text{ES}]$ into that for the rate of product formation ($v = k_b[\text{ES}]$).

Equation 23.17 shows that, in accord with experimental observations (Fig. 23.10):

- 1 When $[\text{S}]_0 \ll K_M$, the rate is proportional to $[\text{S}]_0$:

$$v = \frac{k_a}{K_M} [\text{S}]_0 [\text{E}]_0 \quad (23.20a)$$

- 2 When $[\text{S}]_0 \gg K_M$, the rate reaches its maximum value and is independent of $[\text{S}]_0$:

$$v = v_{\max} = k_b[\text{E}]_0 \quad (23.20b)$$

Fig. 23.10 The variation of the rate of an enzyme-catalysed reaction with substrate concentration. The approach to a maximum rate, $v_{\max}$, for large $[\text{S}]$ is explained by the Michaelis–Menten mechanism.

Exploration Use the Michaelis–Menten equation to generate two families of curves showing the dependence of v on $[\text{S}]$: one in which K_M varies but $v_{\max}$ is constant, and another in which $v_{\max}$ varies but K_M is constant.

Fig. 23.11 A Lineweaver–Burk plot for the analysis of an enzyme-catalysed reaction that proceeds by a Michaelis–Menten mechanism and the significance of the intercepts and the slope.

Substitution of the definitions of K_M and $v_{\max}$ into eqn 23.17 gives:

$$v = \frac{v_{\max}}{1 + K_M/[S]_0} \quad (23.21)$$

We can rearrange this expression into a form that is amenable to data analysis by linear regression:

$$\frac{1}{v} = \frac{1}{v_{\max}} + \left(\frac{K_M}{v_{\max}} \right) \frac{1}{[S]_0} \quad (23.22)$$

A **Lineweaver–Burk plot** is a plot of $1/v$ against $1/[S]_0$, and according to eqn 23.22 it should yield a straight line with slope of $K_M/v_{\max}$, a y -intercept at $1/v_{\max}$, and an x -intercept at $-1/K_M$ (Fig. 23.11). The value of k_b is then calculated from the y -intercept and eqn 23.20b. However, the plot cannot give the individual rate constants k_a and k'_a that appear in the expression for K_M . The stopped-flow technique described in Section 22.1b can give the additional data needed, because we can find the rate of formation of the enzyme–substrate complex by monitoring the concentration after mixing the enzyme and substrate. This procedure gives a value for k_a , and k'_a is then found by combining this results with the values of k_b and K_M .

(b) The catalytic efficiency of enzymes

The **turnover frequency**, or **catalytic constant**, of an enzyme, k_{cat} , is the number of catalytic cycles (turnovers) performed by the active site in a given interval divided by the duration of the interval. This quantity has units of a first-order rate constant and, in terms of the Michaelis–Menten mechanism, is numerically equivalent to k_b , the rate constant for release of product from the enzyme–substrate complex. It follows from the identification of k_{cat} with k_b and from eqn 23.20b that

$$k_{\text{cat}} = k_b = \frac{v_{\max}}{[E]_0} \quad (23.23)$$

The **catalytic efficiency**, ε (epsilon), of an enzyme is the ratio k_{cat}/K_M . The higher the value of ε , the more efficient is the enzyme. We can think of the catalytic activity as the effective rate constant of the enzymatic reaction. From $K_M = (k'_a + k_b)/k_a$ and eqn 23.23, it follows that

$$\varepsilon = \frac{k_{\text{cat}}}{K_M} = \frac{k_a k_b}{k'_a + k_b} \quad (23.24)$$

The efficiency reaches its maximum value of k_a when $k_b \gg k'_a$. Because k_a is the rate constant for the formation of a complex from two species that are diffusing freely in solution, the maximum efficiency is related to the maximum rate of diffusion of E and S in solution. This limit (which is discussed further in Section 24.2) leads to rate constants of about 10^8 – $10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ for molecules as large as enzymes at room temperature. The enzyme catalase has $\varepsilon = 4.0 \times 10^8 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ and is said to have attained ‘catalytic perfection’, in the sense that the rate of the reaction it catalyses is controlled only by diffusion: it acts as soon as a substrate makes contact.

Comment 23.1

The web site contains links to databases of enzymes.

Example 23.3 Determining the catalytic efficiency of an enzyme

The enzyme carbonic anhydrase catalyses the hydration of CO_2 in red blood cells to give bicarbonate (hydrogencarbonate) ion:

The following data were obtained for the reaction at pH = 7.1, 273.5 K, and an enzyme concentration of 2.3 nmol dm^{-3} :

$[\text{CO}_2]/(\text{mmol dm}^{-3})$	1.25	2.5	5	20
rate/ $(\text{mmol dm}^{-3} \text{ s}^{-1})$	2.78×10^{-2}	5.00×10^{-2}	8.33×10^{-2}	1.67×10^{-1}

Determine the catalytic efficiency of carbonic anhydrase at 273.5 K.

Method Prepare a Lineweaver–Burk plot and determine the values of K_M and $v_{\max}$ by linear regression analysis. From eqn 23.23 and the enzyme concentration, calculate k_{cat} and the catalytic efficiency from eqn 23.24.

Answer We draw up the following table:

$1/([\text{CO}_2]/(\text{mmol dm}^{-3}))$	0.800	0.400	0.200	0.0500
$1/(v/(\text{mmol dm}^{-3} \text{ s}^{-1}))$	36.0	20.0	12.0	6.0

Figure 23.12 shows the Lineweaver–Burk plot for the data. The slope is 40.0 and the y -intercept is 4.00. Hence,

$$v_{\max}/(\text{mmol dm}^{-3} \text{ s}^{-1}) = \frac{1}{\text{intercept}} = \frac{1}{4.00} = 0.250$$

and

$$K_M/(\text{mmol dm}^{-3}) = \frac{\text{slope}}{\text{intercept}} = \frac{40.0}{4.00} = 10.0$$

It follows that

$$k_{\text{cat}} = \frac{v_{\max}}{[\text{E}]_0} = \frac{2.5 \times 10^{-4} \text{ mol dm}^{-3} \text{ s}^{-1}}{2.3 \times 10^{-9} \text{ mol dm}^{-3}} = 1.1 \times 10^5 \text{ s}^{-1}$$

and

$$\varepsilon = \frac{k_{\text{cat}}}{K_M} = \frac{1.1 \times 10^5 \text{ s}^{-1}}{1.0 \times 10^{-2} \text{ mol dm}^{-3}} = 1.1 \times 10^7 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

A note on good practice The slope and the intercept are unit-less: we have remarked previously, that all graphs should be plotted as pure numbers.

Self-test 23.3 The enzyme α -chymotrypsin is secreted in the pancreas of mammals and cleaves peptide bonds made between certain amino acids. Several solutions containing the small peptide *N*-glutaryl-L-phenylalanine-*p*-nitroanilide at different concentrations were prepared and the same small amount of α -chymotrypsin was added to each one. The following data were obtained on the initial rates of the formation of product:

$[\text{S}]/(\text{mmol dm}^{-3})$	0.334	0.450	0.667	1.00	1.33	1.67
$v/(\text{mmol dm}^{-3} \text{ s}^{-1})$	0.152	0.201	0.269	0.417	0.505	0.667

Determine the maximum velocity and the Michaelis constant for the reaction.

$$[v_{\max} = 2.80 \text{ mmol dm}^{-3} \text{ s}^{-1}, K_M = 5.89 \text{ mmol dm}^{-3}]$$

Fig. 23.12 The Lineweaver–Burk plot of the data for Example 23.3.

(c) Mechanisms of enzyme inhibition

An inhibitor, I, decreases the rate of product formation from the substrate by binding to the enzyme, to the ES complex, or to the enzyme and ES complex simultaneously. The most general kinetic scheme for enzyme inhibition is then:

The lower the values of K_I and K'_I the more efficient are the inhibitors. The rate of product formation is always given by $v = k_b[\text{ES}]$, because only ES leads to product. As shown in the following *Justification*, the rate of reaction in the presence of an inhibitor is

$$v = \frac{v_{\max}}{\alpha' + \alpha K_M/[S]_0} \quad (23.26)$$

where $\alpha = 1 + [\text{I}]/K_I$ and $\alpha' = 1 + [\text{I}]/K'_I$. This equation is very similar to the Michaelis–Menten equation for the uninhibited enzyme (eqn 23.17) and is also amenable to analysis by a Lineweaver–Burk plot:

$$\frac{1}{v} = \frac{\alpha'}{v_{\max}} + \left(\frac{\alpha K_M}{v_{\max}} \right) \frac{1}{[S]_0} \quad (23.27)$$

Justification 23.3 Enzyme inhibition

By mass balance, the total concentration of enzyme is:

$$[\text{E}]_0 = [\text{E}] + [\text{EI}] + [\text{ES}] + [\text{ESI}]$$

By using eqns 23.25a and 23.25b and the definitions

$$\alpha = 1 + \frac{[\text{I}]}{K_I} \quad \text{and} \quad \alpha' = 1 + \frac{[\text{I}]}{K'_I}$$

it follows that

$$[\text{E}]_0 = [\text{E}]\alpha + [\text{ES}]\alpha'$$

By using $K_M = [\text{E}][\text{S}]/[\text{ES}]$, we can write

$$[\text{E}]_0 = \frac{K_M[\text{ES}]}{[\text{S}]_0} \alpha + [\text{ES}]\alpha' = [\text{ES}] \left(\frac{\alpha K_M}{[\text{S}]_0} + \alpha' \right)$$

The expression for the rate of product formation is then:

$$v = k_b[\text{ES}] = \frac{k_b[\text{E}]_0}{\alpha K_M/[S]_0 + \alpha'}$$

which, upon rearrangement, gives eqn 23.26.

Fig. 23.13 Lineweaver–Burk plots characteristic of the three major modes of enzyme inhibition: (a) competitive inhibition, (b) uncompetitive inhibition, and (c) non-competitive inhibition, showing the special case $\alpha = \alpha' > 1$.

Exploration Use eqn 23.26 to explore the effect of competitive, uncompetitive, and non-competitive inhibition on the shapes of the plots of v against $[\text{S}]$ for constant K_M and $v_{\max}$.

There are three major modes of inhibition that give rise to distinctly different kinetic behaviour (Fig. 23.13). In **competitive inhibition** the inhibitor binds only to the active site of the enzyme and thereby inhibits the attachment of the substrate. This condition corresponds to $\alpha > 1$ and $\alpha' = 1$ (because ESI does not form). The slope of

the Lineweaver–Burk plot increases by a factor of α relative to the slope for data on the uninhibited enzyme ($\alpha = \alpha' = 1$). The y -intercept does not change as a result of competitive inhibition (Fig. 23.13a). In **uncompetitive inhibition** the inhibitor binds to a site of the enzyme that is removed from the active site, but only if the substrate is already present. The inhibition occurs because ESI reduces the concentration of ES, the active type of complex. In this case $\alpha = 1$ (because EI does not form) and $\alpha' > 1$. The y -intercept of the Lineweaver–Burk plot increases by a factor of α' relative to the y -intercept for data on the uninhibited enzyme but the slope does not change (Fig. 23.13b). In **non-competitive inhibition** (also called **mixed inhibition**) the inhibitor binds to a site other than the active site, and its presence reduces the ability of the substrate to bind to the active site. Inhibition occurs at both the E and ES sites. This condition corresponds to $\alpha > 1$ and $\alpha' > 1$. Both the slope and y -intercept of the Lineweaver–Burk plot increase upon addition of the inhibitor. Figure 23.13c shows the special case of $K_I = K'_I$ and $\alpha = \alpha'$, which results in intersection of the lines at the x -axis.

In all cases, the efficiency of the inhibitor may be obtained by determining K_M and $v_{\max}$ from a control experiment with uninhibited enzyme and then repeating the experiment with a known concentration of inhibitor. From the slope and y -intercept of the Lineweaver–Burk plot for the inhibited enzyme (eqn 23.27), the mode of inhibition, the values of α or α' , and the values of K_I or K'_I may be obtained.

Photochemistry

Many reactions can be initiated by the absorption of electromagnetic radiation by one of the mechanisms described in Chapter 14. The most important of all are the photochemical processes that capture the radiant energy of the Sun. Some of these reactions lead to the heating of the atmosphere during the daytime by absorption of ultraviolet radiation (*Impact* I23.1). Others include the absorption of visible radiation during photosynthesis (*Impact* I7.2 and I23.2). Without photochemical processes, the Earth would be simply a warm, sterile, rock. Table 23.1 summarizes common photochemical reactions.

23.7 Kinetics of photophysical and photochemical processes

Photochemical processes are initiated by the absorption of radiation by at least one component of a reaction mixture. In a **primary process**, products are formed directly from the excited state of a reactant. Examples include fluorescence (Section 14.3) and the *cis*–*trans* photoisomerization of retinal (Table 23.1, see also *Impact* I14.1). Products of a **secondary process** originate from intermediates that are formed directly from the excited state of a reactant. Examples include photosynthesis and photochemical chain reactions (Section 23.8).

Competing with the formation of photochemical products is a host of primary photophysical processes that can deactivate the excited state (Table 23.2). Therefore, it is important to consider the timescales of excited state formation and decay before describing the mechanisms of photochemical reactions.

Comment 23.2

The web site contains links to databases on photochemical reactions.

(a) Timescales of photophysical processes

Electronic transitions caused by absorption of ultraviolet and visible radiation occur within 10^{-16} – 10^{-15} s. We expect, then, that the upper limit for the rate constant of a first-order photochemical reaction is about 10^{16} s⁻¹. Fluorescence is slower than

Table 23.1 Examples of photochemical processes

Process	General form	Example
Ionization	$A^* \rightarrow A^+ + e^-$	$\text{NO}^* \xrightarrow{134 \text{ nm}} \text{NO}^+ + e^-$
Electron transfer	$A^* + B \rightarrow A^+ + B^-$ or $A^- + B^+$	$[\text{Ru}(\text{bpy})_3]^{2+*} + \text{Fe}^{3+} \xrightarrow{452 \text{ nm}} \text{Ru}(\text{bpy})_3^{3+} + \text{Fe}^{2+}$
Dissociation	$A^* \rightarrow B + C$	$\text{O}_3^* \xrightarrow{1180 \text{ nm}} \text{O}_2 + \text{O}$
	$A^* + B-C \rightarrow A + B + C$	$\text{Hg}^* + \text{CH}_4 \xrightarrow{254 \text{ nm}} \text{Hg} + \text{CH}_3 + \text{H}$
Addition	$2 A^* \rightarrow B$	
Abstraction	$A^* + B \rightarrow AB$	$\text{Hg}^* + \text{H}_2 \xrightarrow{254 \text{ nm}} \text{HgH} + \text{H}$
Isomerization or rearrangement	$A^* \rightarrow A'$	

* Excited state.

Table 23.2 Common photophysical processes[†]

Primary absorption	$S + h\nu \rightarrow S^*$
Excited-state absorption	$S^* + h\nu \rightarrow S^{**}$
	$T^* + h\nu \rightarrow T^{**}$
Fluorescence	$S^* \rightarrow S + h\nu$
Stimulated emission	$S^* + h\nu \rightarrow S + 2h\nu$
Intersystem crossing (ISC)	$S^* \rightarrow T^*$
Phosphorescence	$T^* \rightarrow S + h\nu$
Internal conversion (IC)	$S^* \rightarrow S$
Collision-induced emission	$S^* + M \rightarrow S + M + h\nu$
Collisional deactivation	$S^* + M \rightarrow S + M$
	$T^* + M \rightarrow S + M$
Electronic energy transfer:	
Singlet-singlet	$S^* + S \rightarrow S + S^*$
Triplet-triplet	$T^* + T \rightarrow T + T^*$
Excimer formation	$S^* + S \rightarrow (SS)^*$
Energy pooling	
Singlet-singlet	$S^* + S^* \rightarrow S^{**} + S$
Triplet-triplet	$T^* + T^* \rightarrow S^* + S$

[†] S denotes a singlet state, T a triplet state, and M is a third body.

absorption, with typical lifetimes of 10^{-12} – 10^{-6} s. Therefore, the excited singlet state can initiate very fast photochemical reactions in the femtosecond (10^{-15} s) to picosecond (10^{-12} s) timescale. Examples of such ultrafast reactions are the initial events of vision (*Impact* I14.1) and of photosynthesis. Typical intersystem crossing (ISC) and phosphorescence times for large organic molecules are 10^{-12} – 10^{-4} s and 10^{-6} – 10^{-1} s, respectively. As a consequence, excited triplet states are photochemically important. Indeed, because phosphorescence decay is several orders of magnitude slower than most typical reactions, species in excited triplet states can undergo a very large number of collisions with other reactants before deactivation. The interplay between reaction rates and excited state lifetimes is a very important factor in the determination of the kinetic feasibility of a photochemical process.

Illustration 23.1 *Exploring the photochemical roles of excited singlet and triplet states*

To estimate whether the excited singlet or triplet state of the reactant is a suitable product precursor, we compare the emission lifetimes with the relaxation time, τ , of the reactant due to the chemical reaction. As an illustration, consider a unimolecular photochemical reaction with rate constant $k = 1.7 \times 10^4 \text{ s}^{-1}$ and relaxation time $\tau = 1/(1.7 \times 10^4 \text{ s}^{-1}) = 59 \text{ } \mu\text{s}$ that involves a reactant with an observed fluorescence lifetime of 1.0 ns and an observed phosphorescence lifetime of 1.0 ms. The excited singlet state is too short-lived and is not expected to be a major source of product in this reaction. On the other hand, the excited triplet state is a good candidate for a precursor.

(b) The primary quantum yield

We shall see that the rates of deactivation of the excited state by radiative, non-radiative, and chemical processes determine the yield of product in a photochemical reaction. The **primary quantum yield**, ϕ , is defined as the number of photophysical or photochemical events that lead to primary products divided by the number of photons absorbed by the molecule in the same interval. It follows that the primary quantum yield is also the rate of radiation-induced primary events divided by the rate of photon absorption. Because the rate of photon absorption is equal to the intensity of light absorbed by the molecule (Section 13.2), we write

$$\phi = \frac{\text{number of events}}{\text{number of photons absorbed}} = \frac{\text{rate of process}}{\text{intensity of light absorbed}} = \frac{\nu}{I_{\text{abs}}} \quad [23.28]$$

A molecule in an excited state must either decay to the ground state or form a photochemical product. Therefore, the total number of molecules deactivated by radiative processes, non-radiative processes, and photochemical reactions must be equal to the number of excited species produced by absorption of light. We conclude that the sum of primary quantum yields ϕ_i for *all* photophysical and photochemical events *i* must be equal to 1, regardless of the number of reactions involving the excited state. It follows that

$$\sum_i \phi_i = \sum_i \frac{\nu_i}{I_{\text{abs}}} = 1 \quad (23.29)$$

It follows that for an excited singlet state that decays to the ground state only via the photophysical processes described in Section 23.7(a), we write

$$\phi_f + \phi_{\text{IC}} + \phi_{\text{ISC}} + \phi_p = 1$$

where ϕ_f , ϕ_{IC} , ϕ_{ISC} , and ϕ_p are the quantum yields of fluorescence, internal conversion, intersystem crossing, and phosphorescence, respectively. The quantum yield of photon emission by fluorescence and phosphorescence is $\phi_{\text{emission}} = \phi_f + \phi_p$, which is less than 1. If the excited singlet state also participates in a primary photochemical reaction with quantum yield ϕ_R , we write

$$\phi_f + \phi_{IC} + \phi_{ISC} + \phi_p + \phi_R = 1$$

We can now strengthen the link between reaction rates and primary quantum yield already established by eqns 23.28 and 23.29. By taking the constant I_{abs} out of the summation in eqn 23.29 and rearranging, we obtain $I_{\text{abs}} = \sum_i v_i$. Substituting this result into eqn 23.29 gives the general result

$$\phi_i = \frac{v_i}{\sum_i v_i} \quad (23.30)$$

Therefore, the primary quantum yield may be determined directly from the experimental rates of *all* photophysical and photochemical processes that deactivate the excited state.

(c) Mechanism of decay of excited singlet states

Consider the formation and decay of an excited singlet state in the absence of a chemical reaction:

in which S is an absorbing species, S^* an excited singlet state, T^* an excited triplet state, and $h\nu_i$ and $h\nu_f$ are the energies of the incident and fluorescent photons, respectively. From the methods developed in Chapter 22 and the rates of the steps that form and destroy the excited singlet state S^* , we write the rate of formation and decay of S^* as:

$$\text{Rate of formation of } [S^*] = I_{\text{abs}}$$

$$\text{Rate of decay of } [S^*] = -k_f[S^*] - k_{ISC}[S^*] - k_{IC}[S^*] = -(k_f + k_{ISC} + k_{IC})[S^*]$$

It follows that the excited state decays by a first-order process so, when the light is turned off, the concentration of S^* varies with time t as:

$$[S^*]_t = [S^*]_0 e^{-t/\tau_0} \quad (23.31)$$

where the **observed fluorescence lifetime**, τ_0 , is defined as:

$$\tau_0 = \frac{1}{k_f + k_{ISC} + k_{IC}} \quad (23.32)$$

We show in the following *Justification* that the quantum yield of fluorescence is

$$\phi_f = \frac{k_f}{k_f + k_{ISC} + k_{IC}} \quad (23.33)$$

Justification 23.4 *The quantum yield of fluorescence*

Most fluorescence measurements are conducted by illuminating a relatively dilute sample with a continuous and intense beam of light. It follows that $[S^*]$ is small and constant, so we may invoke the steady-state approximation (Section 22.7) and write:

$$\frac{d[S^*]}{dt} = I_{\text{abs}} - k_f[S^*] - k_{\text{ISC}}[S^*] - k_{\text{IC}}[S^*] = I_{\text{abs}} - (k_f + k_{\text{ISC}} + k_{\text{IC}})[S^*] = 0$$

Consequently,

$$I_{\text{abs}} = (k_f + k_{\text{ISC}} + k_{\text{IC}})[S^*]$$

By using this expression and eqn 23.28, the quantum yield of fluorescence is written as:

$$\phi_f = \frac{v_f}{I_{\text{abs}}} = \frac{k_f[S^*]}{(k_f + k_{\text{ISC}} + k_{\text{IC}})[S^*]}$$

which, by cancelling the $[S^*]$, simplifies to eqn 23.33.

The observed fluorescence lifetime can be measured with a pulsed laser technique (Section 13.12b). First, the sample is excited with a short light pulse from a laser using a wavelength at which S absorbs strongly. Then, the exponential decay of the fluorescence intensity after the pulse is monitored. From eqn 13.28, it follows that

$$\tau_0 = \frac{1}{k_f + k_{\text{ISC}} + k_{\text{IC}}} = \left(\frac{k_f}{k_f + k_{\text{ISC}} + k_{\text{IC}}} \right) \times \frac{1}{k_f} = \frac{\phi_f}{k_f} \quad (23.34)$$

Illustration 23.2 *Calculating the fluorescence rate constant of tryptophan*

In water, the fluorescence quantum yield and observed fluorescence lifetime of tryptophan are $\phi_f = 0.20$ and $\tau_0 = 2.6$ ns, respectively. It follows from eqn 23.33 that the fluorescence rate constant k_f is

$$k_f = \frac{\phi_f}{\tau_0} = \frac{0.20}{2.6 \times 10^{-9} \text{ s}} = 7.7 \times 10^7 \text{ s}^{-1}$$

(d) Quenching

The shortening of the lifetime of the excited state is called **quenching**. Quenching may be either a desired process, such as in energy or electron transfer, or an undesired side reaction that can decrease the quantum yield of a desired photochemical process. Quenching effects may be studied by monitoring the emission from the excited state that is involved in the photochemical reaction.

The addition of a quencher, Q, opens an additional channel for deactivation of S^* :

The **Stern–Volmer equation**, which is derived in the *Justification* below, relates the fluorescence quantum yields $\phi_{f,0}$ and ϕ_f measured in the absence and presence, respectively, of a quencher Q at a molar concentration $[Q]$:

$$\frac{\phi_{f,0}}{\phi_f} = 1 + \tau_0 k_Q [Q] \quad (23.35)$$

Fig. 23.14 The format of a Stern–Volmer plot and the interpretation of the slope in terms of the rate constant for quenching and the observed fluorescence lifetime in the absence of quenching.

This equation tells us that a plot of $\phi_{f,0}/\phi_f$ against $[Q]$ should be a straight line with slope $\tau_0 k_Q$. Such a plot is called a **Stern–Volmer plot** (Fig. 23.14). The method may also be applied to the quenching of phosphorescence.

Justification 23.5 *The Stern–Volmer equation*

With the addition of quenching, the steady-state approximation for $[S^*]$ now gives:

$$\frac{d[S^*]}{dt} = I_{\text{abs}} - (k_f + k_{\text{IC}} + k_{\text{ISC}} + k_{\text{IC}} + k_Q[Q])[S^*] = 0$$

and the fluorescence quantum yield in the presence of the quencher is:

$$\phi_f = \frac{k_f}{k_f + k_{\text{ISC}} + k_{\text{IC}} + k_Q[Q]}$$

When $[Q] = 0$, the quantum yield is

$$\phi_{f,0} = \frac{k_f}{k_f + k_{\text{ISC}} + k_{\text{IC}}}$$

It follows that

$$\begin{aligned} \frac{\phi_{f,0}}{\phi_f} &= \left(\frac{k_f}{k_f + k_{\text{ISC}} + k_{\text{IC}}} \right) \times \left(\frac{k_f + k_{\text{ISC}} + k_{\text{IC}} + k_Q[Q]}{k_f} \right) \\ &= \frac{k_f + k_{\text{ISC}} + k_{\text{IC}} + k_Q[Q]}{k_f + k_{\text{ISC}} + k_{\text{IC}}} \\ &= 1 + \frac{k_Q}{k_f + k_{\text{ISC}} + k_{\text{IC}}}[Q] \end{aligned}$$

By using eqn 23.34, this expression simplifies to eqn 23.35.

Because the fluorescence intensity and lifetime are both proportional to the fluorescence quantum yield (specifically, from eqn 23.34, $\tau = \phi_f/k_f$), plots of $I_{f,0}/I_f$ and τ_0/τ (where the subscript 0 indicates a measurement in the absence of quencher) against $[Q]$ should also be linear with the same slope and intercept as those shown for eqn 23.35.

Example 23.4 *Determining the quenching rate constant*

The molecule 2,2'-bipyridine (**1**) forms a complex with the Ru^{2+} ion. Ruthenium(II) tris-(2,2'-bipyridyl), $\text{Ru}(\text{bipy})_3^{2+}$ (**2**), has a strong metal-to-ligand charge transfer (MLCT) transition (Section 14.2) at 450 nm. The quenching of the $^*\text{Ru}(\text{bipy})_3^{2+}$ excited state by $\text{Fe}(\text{H}_2\text{O})_6^{3+}$ in acidic solution was monitored by measuring emission lifetimes at 600 nm. Determine the quenching rate constant for this reaction from the following data:

$[\text{Fe}(\text{H}_2\text{O})_6^{3+}]/(10^{-4} \text{ mol dm}^{-3})$	0	1.6	4.7	7	9.4
$t/(10^{-7} \text{ s})$	6	4.05	3.37	2.96	2.17

Method Re-write the Stern–Volmer equation (eqn 23.35) for use with lifetime data then fit the data to a straight-line.

Answer Upon substitution of τ_0/τ for $\phi_{0,f}/\phi_f$ in eqn 23.35 and after rearrangement, we obtain:

$$\frac{1}{\tau} = \frac{1}{\tau_0} + k_Q[Q] \quad (23.36)$$

Figure 23.15 shows a plot of $1/\tau$ versus $[\text{Fe}^{3+}]$ and the results of a fit to eqn 23.36. The slope of the line is 2.8×10^9 , so $k_Q = 2.8 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$.

This example shows that measurements of emission lifetimes are preferred because they yield the value of k_Q directly. To determine the value of k_Q from intensity or quantum yield measurements, we need to make an independent measurement of τ_0 .

Self-test 23.4 The quenching of tryptophan fluorescence by dissolved O_2 gas was monitored by measuring emission lifetimes at 348 nm in aqueous solutions. Determine the quenching rate constant for this process from the following data:

$[\text{O}_2]/(10^{-2} \text{ mol dm}^{-3})$	0	2.3	5.5	8	10.8
$\tau/(10^{-9} \text{ s})$	2.6	1.5	0.92	0.71	0.57
					$[1.3 \times 10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}]$

Fig. 23.15 The Stern–Volmer plot of the data for Example 23.4.

Three common mechanisms for bimolecular quenching of an excited singlet (or triplet) state are:

Collisional quenching is particularly efficient when Q is a heavy species, such as iodide ion, which receives energy from S^* and then decays primarily by internal conversion to the ground state. This fact may be used to determine the accessibility of amino acid residues of a folded protein to solvent. For example, fluorescence from a tryptophan residue ($\lambda_{\text{abs}} \approx 290 \text{ nm}$, $\lambda_{\text{fluor}} \approx 350 \text{ nm}$) is quenched by iodide ion when the residue is on the surface of the protein and hence accessible to the solvent. Conversely, residues in the hydrophobic interior of the protein are not quenched effectively by I^- .

The quenching rate constant itself does not give much insight into the mechanism of quenching. For the system of Example 23.4, it is known that the quenching of the excited state of $\text{Ru}(\text{bipy})_3^{2+}$ is a result of light-induced electron transfer to Fe^{3+} , but the quenching data do not allow us to prove the mechanism. However, there are some criteria that govern the relative efficiencies of energy and electron transfer.

(e) Resonance energy transfer

We visualize the process $\text{S}^* + \text{Q} \rightarrow \text{S} + \text{Q}^*$ as follows. The oscillating electric field of the incoming electromagnetic radiation induces an oscillating electric dipole moment in S. Energy is absorbed by S if the frequency of the incident radiation, ν , is such that $\nu = \Delta E_S/h$, where ΔE_S is the energy separation between the ground and excited electronic states of S and h is Planck's constant. This is the 'resonance condition' for absorption of radiation. The oscillating dipole on S now can affect electrons bound to a nearby Q molecule by inducing an oscillating dipole moment in the latter. If the frequency of oscillation of the electric dipole moment in S is such that $\nu = \Delta E_Q/h$ then Q will absorb energy from S.

The efficiency, E_T , of resonance energy transfer is defined as

$$E_T = 1 - \frac{\phi_f}{\phi_{f,0}} \quad [23.37]$$

Table 23.3 Values of R_0 for some donor–acceptor pairs*

Donor†	Acceptor	R_0/nm
Naphthalene	Dansyl	2.2
Dansyl	ODR	4.3
Pyrene	Coumarin	3.9
IEDANS	FITC	4.9
Tryptophan	IEDANS	2.2
Tryptophan	Haem (heme)	2.9

* Additional values may be found in J.R. Lacowicz in *Principles of fluorescence spectroscopy*, Kluwer Academic/Plenum, New York (1999).

† Abbreviations: Dansyl, 5-dimethylamino-1-naphthalenesulfonic acid; FITC, fluorescein 5-isothiocyanate; IEDANS, 5-(((2-iodoacetyl)amino)ethyl)amino)naphthalene-1-sulfonic acid; ODR, octadecyl-rhodamine.

Fig. 23.16 According to the Förster theory, the rate of energy transfer from a molecule S^* in an excited state to a quencher molecule Q is optimized at radiation frequencies in which the emission spectrum of S^* overlaps with the absorption spectrum of Q , as shown in the shaded region.

According to the **Förster theory** of resonance energy transfer, which was proposed by T. Förster in 1959, energy transfer is efficient when:

- 1 The energy donor and acceptor are separated by a short distance (of the order of nanometres).
- 2 Photons emitted by the excited state of the donor can be absorbed directly by the acceptor.

We show in *Further information 23.1* that for donor–acceptor systems that are held rigidly either by covalent bonds or by a protein ‘scaffold’, E_T increases with decreasing distance, R , according to

$$E_T = \frac{R_0^6}{R_0^6 + R^6} \quad (23.38)$$

where R_0 is a parameter (with units of distance) that is characteristic of each donor–acceptor pair. Equation 23.38 has been verified experimentally and values of R_0 are available for a number of donor–acceptor pairs (Table 23.3).

The emission and absorption spectra of molecules span a range of wavelengths, so the second requirement of the Förster theory is met when the emission spectrum of the donor molecule overlaps significantly with the absorption spectrum of the acceptor. In the overlap region, photons emitted by the donor have the proper energy to be absorbed by the acceptor (Fig. 23.16).

In many cases, it is possible to prove that energy transfer is the predominant mechanism of quenching if the excited state of the acceptor fluoresces or phosphoresces at a characteristic wavelength. In a pulsed laser experiment, the rise in fluorescence intensity from Q^* with a characteristic time that is the same as that for the decay of the fluorescence of S^* is often taken as indication of energy transfer from S to Q .

Equation 23.38 forms the basis of **fluorescence resonance energy transfer** (FRET), in which the dependence of the energy transfer efficiency, E_T , on the distance, R , between energy donor and acceptor can be used to measure distances in biological systems. In a typical FRET experiment, a site on a biopolymer or membrane is labelled covalently with an energy donor and another site is labelled covalently with an energy acceptor. In certain cases, the donor or acceptor may be natural constituents of the system, such as amino acid groups, cofactors, or enzyme substrates. The distance between the labels is then calculated from the known value of R_0 and eqn 23.38. Several tests have shown that the FRET technique is useful for measuring distances ranging from 1 to 9 nm.

Illustration 23.3 Using FRET analysis

As an illustration of the FRET technique, consider a study of the protein rhodopsin (*Impact I14.1*). When an amino acid on the surface of rhodopsin was labelled covalently with the energy donor 1.5-I AEDANS (**3**), the fluorescence quantum yield of the label decreased from 0.75 to 0.68 due to quenching by the visual pigment 11-*cis*-retinal (**4**). From eqn 23.37, we calculate $E_T = 1 - (0.68/0.75) = 0.093$ and from eqn 23.38 and the known value of $R_0 = 5.4$ nm for the 1.5-I AEDANS/11-*cis*-retinal pair we calculate $R = 7.9$ nm. Therefore, we take 7.9 nm to be the distance between the surface of the protein and 11-*cis*-retinal.

If donor and acceptor molecules diffuse in solution or in the gas phase, Förster theory predicts that the efficiency of quenching by energy transfer increases as the

average distance travelled between collisions of donor and acceptor decreases. That is, the quenching efficiency increases with concentration of quencher, as predicted by the Stern–Volmer equation.

(f) Electron transfer reactions

According to the **Marcus theory** of electron transfer, which was proposed by R.A. Marcus in 1965 and is discussed fully in Section 24.11, the rates of electron transfer (from ground or excited states) depend on:

- 1 The distance between the donor and acceptor, with electron transfer becoming more efficient as the distance between donor and acceptor decreases.
- 2 The reaction Gibbs energy, $\Delta_r G$, with electron transfer becoming more efficient as the reaction becomes more exergonic. For example, efficient photooxidation of S requires that the reduction potential of S^* be lower than the reduction potential of Q.
- 3 The reorganization energy, the energy cost incurred by molecular rearrangements of donor, acceptor, and medium during electron transfer. The electron transfer rate is predicted to increase as this reorganization energy is matched closely by the reaction Gibbs energy.

Electron transfer can also be studied by time-resolved spectroscopy (Section 14.6). The oxidized and reduced products often have electronic absorption spectra distinct from those of their neutral parent compounds. Therefore, the rapid appearance of such known features in the absorption spectrum after excitation by a laser pulse may be taken as indication of quenching by electron transfer.

4 11-*cis*-retinal

IMPACT ON ENVIRONMENTAL SCIENCE

123.1 The chemistry of stratospheric ozone

The Earth's atmosphere contains primarily N_2 and O_2 gas, with low concentrations of a large number of other species of both natural and anthropogenic origins. Indeed, many of the natural trace constituents of our atmosphere participate in complex chemical reactions that have contributed to the proliferation of life on the planet. The development of industrial societies has added new components to the Earth's atmosphere and has led to significant changes in the concentrations of some natural trace species. The negative consequences of these changes for the environment are either already being felt or, more disturbingly, are yet to be felt in the next few decades (see, for example, the discussion of global warming in *Impact* I13.2). Careful kinetic analysis allows us to understand the origins of our complex atmosphere and point to ways in which environmental problems can be solved or avoided.

The Earth's atmosphere consists of layers, as shown in Fig. 23.17. The pressure decreases as altitude increases (see Problems 1.27 and 16.20), but the variation of temperature with altitude is complex, owing to processes that capture radiant energy from the Sun. We focus on the *stratosphere*, a region spanning from 15 km to 50 km above the surface of the Earth, and on the chemistry of the trace component ozone, O_3 .

In the *troposphere*, the region between the Earth's surface and the stratosphere, temperature decreases with increasing altitude. This behaviour may be understood in terms of a model in which the boundary between the troposphere and the stratosphere, also called the *tropopause*, is considered adiabatic. Then we know from Section 2.6 that, as atmospheric gases are allowed to expand from layers close to the surface to higher layers, the temperature varies with pressure, and hence height, as

$$\frac{T_{\text{low altitude}}}{T_{\text{high altitude}}} = \left(\frac{p_{\text{low altitude}}}{p_{\text{high altitude}}} \right)^c \quad c = \frac{C_{p,m}}{C_{V,m}} - 1$$

Fig. 23.17 The temperature profile through the atmosphere and some of the reactions that occur in each region.

The model predicts a decrease in temperature with increasing altitude because $C_{p,m}/C_{V,m} \approx \frac{7}{5}$ for air. In the stratosphere, a *temperature inversion* is observed because of photochemical chain reactions that produce ozone from O_2 . The *Chapman model* accounts for ozone formation and destruction in an atmosphere that contains only O_2 :

where M is an arbitrary third body, such as O_2 in an ‘oxygen-only’ atmosphere, which helps to remove excess energy from the products of combination and recombination reactions. The mechanism shows that absorption of radiation by O_2 and O_3 during the daytime leads to the production of reactive O atoms, which, in turn, participate in exothermic reactions that are responsible for the heating of the stratosphere.

Using values of the rate constants that are applicable to stratospheric conditions, the Chapman model predicts a net formation of trace amounts of ozone, as seen in Fig. 23.18 (see also Problem 23.33). However, the model overestimates the concentration of ozone in the stratosphere because other trace species X contribute to catalytic enhancement of the termination step $\text{O}_3 + \text{O} \rightarrow \text{O}_2 + \text{O}_2$ according to

Fig. 23.18 Net formation of ozone via the Chapman model in a stratospheric model containing only O_2 , O , and O_3 . The rate constants are consistent with reasonable stratospheric conditions. (a) Early reaction period after irradiation begins at $t = 0$. (b) Late reaction period, showing that the concentration of O atoms begins to level off after about 4 hours of continuous irradiation. (c) Late reaction period, showing that the ozone concentration also begins to level off similarly. For details of the calculation, see Problem 23.33 and M.P. Cady and C.A. Trapp, *A Mathcad primer for physical chemistry*. Oxford University Press (1999).

The catalyst X can be H , OH , NO , or Cl . Chlorine atoms are produced by photolysis of CH_3Cl which, in turn, is a by-product of reactions between Cl^- and decaying vegetation in oceans. Nitric oxide, NO , is produced in the stratosphere from reaction between excited oxygen atoms and N_2O , which is formed mainly by microbial denitrification processes in soil. The hydroxyl radical is a product, along with the methyl radical, of the reaction between excited oxygen atoms and methane gas, which is a by-product of a number of natural processes (such as digestion of cellulose in ruminant animals, anaerobic decomposition of organic waste matter) and industrial processes (such as food production and fossil fuel use). In spite of the presence of these catalysts, a natural stratosphere is still capable to maintain a low concentration of ozone.

The chemistry outlined above shows that the photochemical reactions of the Chapman model account for absorption of a significant portion of solar ultraviolet radiation in the stratosphere. Hence, the surface of the Earth is bathed by lower energy radiation, which does not damage biological tissue (see *Impact I23.3*). However, some pollutants can lower the concentration of stratospheric ozone. For example, chlorofluorocarbons (CFCs) have been used as propellants and refrigerants over many years. As CFC molecules diffuse slowly into the middle stratosphere, they are finally photolysed by ultraviolet radiation. For CF_2Cl_2 , also known as CFC-12, the reaction is:

We already know that the resulting Cl atoms can participate in the decomposition of ozone according to the catalytic cycle shown in Fig. 23.19. A number of experimental observations have linked this chemistry of CFCs to a dangerously rapid decline in the concentration of stratospheric ozone over the last three decades.

Ozone depletion has increased the amount of ultraviolet radiation at the Earth's surface, particularly radiation in the 'UVB range', 290–320 nm. The physiological consequences of prolonged exposure to UVB radiation include DNA damage, principally by photodimerization of adjacent thymine bases to yield either a cyclobutane

Fig. 23.19 A catalytic cycle showing the propagation of ozone decomposition by chlorine atoms.

thymine dimer (5) or a so-called 6–4 photoproduct (6). The former has been linked directly to cell death and the latter may lead to DNA mutations and, consequently, to the formation of tumours. There are several natural mechanisms for protection from and repair of photochemical damage. For example, the enzyme DNA photolyase, present in organisms from all kingdoms but not in humans, catalyses the destruction of cyclobutane thymine dimers. Also, ultraviolet radiation can induce the production of the pigment melanin (in a process more commonly known as ‘tanning’), which shields the skin from damage. However, repair and protective mechanisms become increasingly less effective with persistent and prolonged exposure to solar radiation. Consequently, there is concern that the depletion of stratospheric ozone may lead to an increase in mortality not only of animals but also the plants and lower organisms that form the base of the food chain.

Chlorofluorocarbons are being phased out according to international agreements and alternatives, such as the hydrofluorocarbon CH_2FCH_3 , are already being used. However, the temperature inversion shown in Fig. 23.17 leads to trapping of gases in the troposphere, so CFCs are likely to continue to cause ozone depletion over many decades as the molecules diffuse slowly into the middle stratosphere, where they are photolysed by intense solar UV radiation.

IMPACT ON BIOCHEMISTRY

I23.2 Harvesting of light during plant photosynthesis

A large proportion of solar radiation with wavelengths below 400 nm and above 1000 nm is absorbed by atmospheric gases such as ozone and O_2 , which absorb ultra-violet radiation (*Impact* I23.1), and CO_2 and H_2O , which absorb infrared radiation (*Impact* I13.2). As a result, plants, algae, and some species of bacteria evolved photosynthetic apparatus that capture visible and near-infrared radiation. Plants use radiation in the wavelength range of 400–700 nm to drive the endergonic reduction of CO_2 to glucose, with concomitant oxidation of water to O_2 ($\Delta_r G^\ominus = +2880 \text{ kJ mol}^{-1}$), in essence the reverse of glycolysis and the citric acid cycle (*Impact* I7.2):

7 Chlorophyll *a* and *b*

Electrons flow from reductant to oxidant via a series of electrochemical reactions that are coupled to the synthesis of ATP. The process takes place in the *chloroplast*, a special organelle of the plant cell, where chlorophylls *a* and *b* (7) and carotenoids (of which β -carotene, 8, is an example) bind to integral proteins called *light harvesting complexes*, which absorb solar energy and transfer it to protein complexes known as *reaction centres*, where light-induced electron transfer reactions occur. The combination of a light harvesting complex and a reaction centre complex is called a *photosystem*. Plants have two photosystems that drive the reduction of NADP^+ (9) by water:

It is clear that energy from light is required to drive this reaction because, in the dark, $E^\ominus = -1.135 \text{ V}$ and $\Delta_r G^\ominus = +438.0 \text{ kJ mol}^{-1}$.

Light harvesting complexes bind large numbers of pigments in order to provide a sufficiently large area for capture of radiation. In photosystems I and II, absorption of a photon raises a chlorophyll or carotenoid molecule to an excited singlet state and within 0.1–5 ps the energy hops to a nearby pigment via the Förster mechanism (Section 23.7e). About 100–200 ps later, which corresponds to thousands of hops within the light harvesting complex, more than 90 per cent of the absorbed energy reaches the reaction centre. There, a chlorophyll *a* dimer becomes electronically

excited and initiates ultrafast electron transfer reactions. For example, the transfer of an electron from the excited singlet state of P680, the chlorophyll dimer of the photosystem II reaction centre, to its immediate electron acceptor, a phaeophytin *a* molecule (a chlorophyll *a* molecule where the central Mg²⁺ ion is replaced by two protons, which are bound to two of the pyrrole nitrogens in the ring), occurs within 3 ps. Once the excited state of P680 has been quenched efficiently by this first reaction, subsequent steps that lead to the oxidation of water occur more slowly, with reaction times varying from 200 ps to 1 ms. The electrochemical reactions within the photosystem I reaction centre also occur in this time interval. We see that the initial energy and electron transfer events of photosynthesis are under tight kinetic control. Photosynthesis captures solar energy efficiently because the excited singlet state of chlorophyll is quenched rapidly by processes that occur with relaxation times that are much shorter than the fluorescence lifetime, which is typically about 1 ns in organic solvents at room temperature.

Working together, photosystem I and the enzyme ferredoxin:NADP⁺ oxidoreductase catalyse the light-induced oxidation of NADP⁺ to NADPH. The electrons required for this process come initially from P700 in its excited state. The resulting P700⁺ is then reduced by the mobile carrier plastocyanin (Pc), a protein in which the bound copper ion can exist in oxidation states +2 and +1. The net reaction is

Oxidized plastocyanin accepts electrons from reduced plastoquinone (PQ, **10**). The process is catalysed by the cytochrome *b₆f* complex, a membrane protein complex that resembles complex III of mitochondria (*Impact I7.2*):

$$E^\ominus = +0.370 \text{ V}, \Delta_r G^\ominus = -71.4 \text{ kJ mol}^{-1}$$

Fig. 23.20 In plant photosynthesis, light-induced electron transfer processes lead to the oxidation of water to O_2 and the reduction of $NADP^+$ to NADPH, with concomitant production of ATP. The energy stored in ATP and NADPH is used to reduce CO_2 to carbohydrate in a separate set of reactions. The scheme summarizes the general patterns of electron flow and does not show all the intermediate electron carriers in photosystems I and II, the cytochrome b_6f complex, and ferredoxin:NADP $^+$ oxidoreductase.

This reaction is sufficiently exergonic to drive the synthesis of ATP in the process known as **photophosphorylation**.

Plastoquinone is reduced by water in a process catalysed by light and photosystem II. The electrons required for the reduction of plastoquinone come initially from P680 in its excited state. The resulting $P680^+$ is then reduced ultimately by water. The net reaction is

In this way, plant photosynthesis uses an abundant source of electrons (water) and of energy (the Sun) to drive the endergonic reduction of $NADP^+$, with concomitant synthesis of ATP (Fig. 23.20). Experiments show that, for each molecule of NADPH formed in the chloroplast of green plants, one molecule of ATP is synthesized.

The ATP and NADPH molecules formed by the light-induced electron transfer reactions of plant photosynthesis participate directly in the reduction of CO_2 to glucose in the chloroplast:

In summary, plant photosynthesis uses solar energy to transfer electrons from a poor reductant (water) to carbon dioxide. In the process, high energy molecules (carbohydrates, such as glucose) are synthesized in the cell. Animals feed on the carbohydrates derived from photosynthesis. During aerobic metabolism, the O_2 released by photosynthesis as a waste product is used to oxidize carbohydrates to CO_2 , driving biological processes, such as biosynthesis, muscle contraction, cell division, and nerve conduction. Hence, the sustenance of life on Earth depends on a tightly regulated carbon–oxygen cycle that is driven by solar energy.

23.8 Complex photochemical processes

Many photochemical processes have complex mechanisms that may be examined by considering the concepts developed above. In this section, we consider two examples: photochemical chain reactions and photosensitization.

(a) The overall quantum yield of a photochemical reaction

For complex reactions involving secondary processes, such as chain reactions initiated by photolysis, many reactant molecules might be consumed as a result of absorption of a single photon. The **overall quantum yield**, Φ , for such reactions, the number of reactant molecules consumed per photon absorbed, might exceed 1. In the photolysis of HI, for example, the processes are

The overall quantum yield is 2 because the absorption of one photon leads to the destruction of two HI molecules. In a chain reaction, Φ may be very large, and values of about 10^4 are common. In such cases the chain acts as a chemical amplifier of the initial absorption step.

Example 23.5 *Determining the quantum yield of a photochemical reaction*

When a sample of 4-heptanone was irradiated for 100 s with 313 nm radiation with a power output of 50 W under conditions of total absorption, it was found that 2.8 mmol C_2H_4 was formed. What is the quantum yield for the formation of ethene?

Method First, calculate the amount of photons generated in an interval Δt : see Example 8.1. Then divide the amount of ethene molecules formed by the amount of photons absorbed.

Answer From Example 8.1, the amount (in moles) of photons absorbed is

$$n = \frac{P\Delta t}{(hc/\lambda)N_A}$$

If $n_{\text{C}_2\text{H}_4}$ is the amount of ethene formed, the quantum yield is

$$\begin{aligned}\Phi &= \frac{n_{\text{C}_2\text{H}_4}}{n} = \frac{n_{\text{C}_2\text{H}_4} N_A hc}{\lambda P \Delta t} \\ &= \frac{(2.8 \times 10^{-3} \text{ mol}) \times (6.022 \times 10^{23} \text{ mol}^{-1}) \times (6.626 \times 10^{-34} \text{ J s}) \times (2.997 \times 10^8 \text{ m s}^{-1})}{(3.13 \times 10^{-7} \text{ m}) \times (50 \text{ J s}^{-1}) \times (100 \text{ s})} \\ &= 0.21\end{aligned}$$

Self-test 23.5 The overall quantum yield for another reaction at 290 nm is 0.30. For what length of time must irradiation with a 100 W source continue in order to destroy 1.0 mol of molecules? [3.8 h]

(b) Rate laws of complex photochemical reactions

As an example of how to write a rate law for a complex photochemical process, consider the photochemical activation of the reaction

In place of the first step in the thermal reaction we have

where I_{abs} is the number of photons of the appropriate frequency absorbed divided by the volume in which absorption occurs and the time interval. We are assuming a

primary quantum yield of unity for the photodissociation of Br_2 . It follows that I_{abs} should take the place of $k_i[\text{Br}_2][\text{M}]$ in the thermal reaction scheme, so from Example 23.1 we can write

$$\frac{d[\text{HBr}]}{dt} = \frac{2k_p(1/k_t[\text{M}])^{1/2}[\text{H}_2][\text{Br}_2]I_{\text{abs}}^{1/2}}{[\text{Br}_2] + (k_t/k_p)[\text{HBr}]} \quad (23.39)$$

We predict that the reaction rate should depend on the square root of the absorbed light intensity, which is confirmed experimentally.

(c) Photosensitization

The reactions of a molecule that does not absorb directly can be made to occur if another absorbing molecule is present, because the latter may be able to transfer its energy to the former during a collision. An example of this **photosensitization** is the reaction used to generate excited state O_2 in a type of treatment known as *photodynamic therapy* (Impact I23.3). Another example is the reaction used to generate atomic hydrogen, the irradiation of hydrogen gas containing a trace of mercury vapour using radiation of wavelength 254 nm from a mercury discharge lamp. The Hg atoms are excited (to Hg^*) by resonant absorption of the radiation, and then collide with H_2 molecules. Two reactions then take place:

The latter reaction is the initiation step for other mercury photosensitized reactions, such as the synthesis of formaldehyde from carbon monoxide and hydrogen:

Note that the last step is termination by disproportionation rather than by combination.

IMPACT ON MEDICINE

I23.3 Photodynamic therapy

In photodynamic therapy (PDT), laser radiation, which is usually delivered to diseased tissue through a fibre optic cable, is absorbed by a drug which, in its first excited triplet state ^3P , photosensitizes the formation of an excited singlet state of O_2 , $^1\text{O}_2$. The $^1\text{O}_2$ molecules are very reactive and destroy cellular components and it is thought that cell membranes are the primary cellular targets. Hence, the photochemical cycle below leads to the shrinkage (and sometimes total destruction) of diseased tissue.

The photosensitizer is hence a 'photocatalyst' for the production of $^1\text{O}_2$. It is common practice to use a porphyrin photosensitizer, such as compounds derived from haematoporphyrin (**11**). However, much effort is being expended to develop better drugs with enhanced photochemical properties.

A potential PDT drug must meet many criteria. From the point of view of pharmacological effectiveness, the drug must be soluble in tissue fluids, so it can be transported to the diseased organ through blood and secreted from the body through

11 Haematoporphyrin

urine. The therapy should also result in very few side effects. The drug must also have unique photochemical properties. It must be activated photochemically at wavelengths that are not absorbed by blood and skin. In practice, this means that the drug should have a strong absorption band at $\lambda > 650$ nm. Drugs based on haematoporphyrin do not meet this criterion very well, so novel porphyrin and related macrocycles with more desirable electronic properties are being synthesized and tested. At the same time, the quantum yield of triplet formation and of $^1\text{O}_2$ formation must be high, so many drug molecules can be activated and many oxidation reactions can occur during a short period of laser irradiation. Photodynamic therapy has been used successfully in the treatment of macular degeneration, a disease of the retina that leads to blindness, and in a number of cancers, including those of the lung, bladder, skin, and oesophagus.

Checklist of key ideas

☐ 1. In a chain reaction, an intermediate (the chain carrier) produced in one step (the initiation step) attacks other reactant molecules (in the propagation steps), with each attack giving rise to a new carrier. The chain ends in the termination step. Examples of chain reactions include some explosions. ☐ 2. In stepwise polymerization any two monomers in the reaction mixture can link together at any time and growth of the polymer is not confined to chains that are already forming. The longer a stepwise polymerization proceeds, the higher the average molar mass of the product. ☐ 3. In chain polymerization an activated monomer attacks another monomer and links to it. That unit attacks another monomer, and so on. The slower the initiation of the chain, the higher the average molar mass of the polymer. ☐ 4. Catalysts are substances that accelerate reactions but undergo no net chemical change.	☐ 5. A homogeneous catalyst is a catalyst in the same phase as the reaction mixture. Enzymes are homogeneous, biological catalysts. ☐ 6. The Michaelis–Menten mechanism of enzyme kinetics accounts for the dependence of rate on the concentration of the substrate, $v = v_{\max}[\text{S}]_0/([\text{S}]_0 + K_{\text{M}})$. ☐ 7. A Lineweaver–Burk plot, based on $1/v = 1/v_{\max} + (K_{\text{M}}/v_{\max})(1/[\text{S}]_0)$, is used to determine the parameters that occur in the Michaelis–Menten mechanism. ☐ 8. In competitive inhibition of an enzyme, the inhibitor binds only to the active site of the enzyme and thereby inhibits the attachment of the substrate. ☐ 9. In uncompetitive inhibition the inhibitor binds to a site of the enzyme that is removed from the active site, but only if the substrate is already present.

- 10. In non-competitive inhibition, the inhibitor binds to a site other than the active site, and its presence reduces the ability of the substrate to bind to the active site.
- 11. The primary quantum yield of a photochemical reaction is the number of reactant molecules producing specified primary products for each photon absorbed; the overall quantum yield is the number of reactant molecules that react for each photon absorbed.
- 12. The observed fluorescence lifetime is related to the quantum yield, ϕ_f , and rate constant, k_f , of fluorescence by $\tau_0 = \phi_f/k_f$.
- 13. A Stern–Volmer plot is used to analyse the kinetics of fluorescence quenching in solution. It is based on the Stern–Volmer equation, $\phi_{f,0}/\phi_f = 1 + \tau_0 k_Q [Q]$.
- 14. Collisional deactivation, electron transfer, and resonance energy transfer are common fluorescence quenching processes. The rate constants of electron and resonance energy transfer decrease with increasing separation between donor and acceptor molecules.
- 15. In photosensitization, the reaction of a molecule that does not absorb radiation directly is made to occur by energy transfer during a collision with a molecule that does absorb radiation.

Further information

Further information 23.1 The Förster theory of resonance energy transfer

From the qualitative description given in Section 23.7e, we conclude that resonance energy transfer arises from the interaction between two oscillating dipoles with moments μ_S and μ_Q . From Section 18.4, the energy of the dipole–dipole interaction, $V_{\text{dipole–dipole}}$, is

$$V_{\text{dipole–dipole}} \propto \frac{\mu_S \mu_Q}{R^3}$$

where R is the distance between the dipoles. We saw in Section 9.10 that the rate of a transition from a state i to a state f at a radiation frequency ν is proportional to the square modulus of the matrix element of the perturbation between the two states:

$$w_{f \leftarrow i} \propto |H_{fi}^{(1)}|^2$$

For energy transfer, the wavefunctions of the initial and final states may be denoted as $\psi_S^* \psi_Q$ and $\psi_S \psi_Q^*$, respectively, and $H^{(1)}$ may be written from $V_{\text{dipole–dipole}}$. It follows that the rate of energy transfer, w_T , at a fixed distance R is given (using notation introduced in *Further information 9.1*) by

$$\begin{aligned} w_T &\propto \frac{1}{R^6} \left| \left\langle \psi_S \psi_Q^* \left| \mu_S \mu_Q \right| \psi_S^* \psi_Q \right\rangle \right|^2 \\ &= \frac{1}{R^6} \left| \left\langle \psi_S \left| \mu_S \right| \psi_S^* \right\rangle \right|^2 \left| \left\langle \psi_Q^* \left| \mu_Q \right| \psi_Q \right\rangle \right|^2 \end{aligned}$$

We have used the fact that the terms related to S are functions of coordinates that are independent of those for the functions related to Q. In the last expression, the integrals are squares of transition dipole moments at the radiation frequency ν , the first

corresponding to emission of S^* to S and the second to absorption of Q to Q^* .

We interpret the expression for w_T as follows. The rate of energy transfer is proportional to R^{-6} , so it decreases sharply with increasing separation between the energy donor and acceptor. Furthermore, the energy transfer rate is optimized when both emission of radiation by S^* and absorption of radiation by Q are efficient at the frequency ν . Because the absorption and emission spectra of large molecules in condensed phases are broad, it follows that the energy transfer rate is optimal at radiation frequencies in which the emission spectrum of the donor and the absorption spectrum of the acceptor overlap significantly.

In practice, it is more convenient to measure the efficiency of energy transfer and not the rate itself. In much the same way that we defined the quantum yield as a ratio of rates, we can also define the efficiency of energy transfer, E_T , as the ratio

$$E_T = \frac{w_T}{w_T + w_0} \quad w_0 = (k_f + k_{IC} + k_{ISC})[S^*] \quad (23.40)$$

where w_0 is the rate of deactivation of S^* in the absence of the quencher. The efficiency, E_T , may be expressed in terms of the experimental fluorescence quantum yields $\phi_{f,0}$ and ϕ_f of the donor in the absence and presence of the acceptor, respectively. To proceed, we use eqn 23.30 to write:

$$\phi_{f,0} = \frac{\nu_f}{w_0} \quad \text{and} \quad \phi_f = \frac{\nu_f}{w_0 + w_T}$$

where ν_f is the rate of fluorescence. Substituting these results into eqn 23.40 gives, after a little algebra, eqn 23.37.

Alternatively, we can express w_0 in terms of the parameter R_0 , the characteristic distance at which $w_T = w_0$ for a specified pair of S and Q (Table 23.3). By using $w_T \propto R^{-6}$ and $w_0 \propto R_0^{-6}$, we can rearrange the expression for E_T into eqn 23.38.

Discussion questions

23.1 Identify any initiation, propagation, retardation, inhibition, and termination steps in the following chain mechanisms:

- (a) (1) $AH \rightarrow A\cdot + H\cdot$
 (2) $A\cdot \rightarrow B\cdot + C$
 (3) $AH + B\cdot \rightarrow A\cdot + D$
 (4) $A\cdot + B\cdot \rightarrow P$
- (b) (1) $A_2 \rightarrow A\cdot + A\cdot$
 (2) $A\cdot \rightarrow B\cdot + C$
 (3) $A\cdot + P \rightarrow B\cdot$
 (4) $A\cdot + B\cdot \rightarrow P$

23.2 Bearing in mind distinctions between the mechanisms of stepwise and chain polymerization, describe ways in which it is possible to control the molar mass of a polymer by manipulating the kinetic parameters of polymerization.

23.3 Discuss the features, advantages, and limitations of the Michaelis–Menten mechanism of enzyme action.

23.4 Distinguish between competitive, non-competitive, and uncompetitive inhibition of enzymes. Discuss how these modes of inhibition may be detected experimentally.

23.5 Distinguish between the primary quantum yield and overall quantum yield of a chemical reaction. Describe an experimental procedure for the determination of the quantum yield.

23.6 Discuss experimental procedures that make it possible to differentiate between quenching by energy transfer, collisions, or electron transfer.

23.7 Summarize the main features of the Förster theory of resonance energy transfer. Then, discuss FRET in terms of Förster theory.

Exercises

In the following exercises and problems, it is recommended that rate constants are labelled with the number of the step in the proposed reaction mechanism, and any reverse steps are labelled similarly but with a prime.

23.1a Derive the rate law for the decomposition of ozone in the reaction $2 O_3(g) \rightarrow 3 O_2(g)$ on the basis of the following proposed mechanism:

- (1) $O_3 \rightleftharpoons O_2 + O \quad k_1, k'_1$
- (2) $O + O_3 \rightarrow O_2 + O_2 \quad k_2$

23.1b On the basis of the following proposed mechanism, account for the experimental fact that the rate law for the decomposition $2 N_2O_5(g) \rightarrow 4 NO_2(g) + O_2(g)$ is $v = k[N_2O_5]$.

- (1) $N_2O_5 \rightleftharpoons NO_2 + NO_3 \quad k_1, k'_1$
- (2) $NO_2 + NO_3 \rightarrow NO_2 + O_2 + NO \quad k_2$
- (3) $NO + N_2O_5 \rightarrow NO_2 + NO_2 + NO_2 \quad k_3$

23.2a A slightly different mechanism for the decomposition of N_2O_5 from that in Exercise 23.1b has also been proposed. It differs only in the last step, which is replaced by

Show that this mechanism leads to the same overall rate law.

23.2b Consider the following mechanism for the thermal decomposition of R_2 :

- (1) $R_2 \rightarrow R + R$
- (2) $R + R_2 \rightarrow P_B + R'$
- (3) $R' \rightarrow P_A + R$
- (4) $R + R \rightarrow P_A + P_B$

where R_2, P_A, P_B are stable hydrocarbons and R and R' are radicals. Find the dependence of the rate of decomposition of R_2 on the concentration of R_2 .

23.3a Refer to Fig. 23.3 and determine the pressure range for a branching chain explosion in the hydrogen–oxygen reaction at 800 K.

23.3b Refer to Fig. 23.3 and determine the pressure range for a branching chain explosion in the hydrogen–oxygen reaction at (a) 700 K, (b) 900 K.

23.4a The condensation reaction of propanone, $(\text{CH}_3)_2\text{CO}$, in aqueous solution is catalysed by bases, B, which react reversibly with propanone to form the carbanion $\text{C}_3\text{H}_5\text{O}^-$. The carbanion then reacts with a molecule of propanone to give the product. A simplified version of the mechanism is

- (1) $\text{AH} + \text{B} \rightarrow \text{BH}^+ + \text{A}^-$
- (2) $\text{A}^- + \text{BH}^+ \rightarrow \text{AH} + \text{B}$
- (3) $\text{A}^- + \text{AH} \rightarrow \text{product}$

where AH stands for propanone and A^- denotes its carbanion. Use the steady-state approximation to find the concentration of the carbanion and derive the rate equation for the formation of the product.

23.4b Consider the acid-catalysed reaction

- (1) $\text{HA} + \text{H}^+ \rightleftharpoons \text{HAH}^+ \quad k_1 k'_1, \text{ both fast}$
- (2) $\text{HAH}^+ + \text{B} \rightarrow \text{BH}^+ + \text{AH} \quad k_2, \text{ slow}$

Deduce the rate law and show that it can be made independent of the specific term $[\text{H}^+]$.

23.5a Consider the following chain mechanism:

- (1) $\text{AH} \rightarrow \text{A} \cdot + \text{H} \cdot$
- (2) $\text{A} \cdot \rightarrow \text{B} \cdot + \text{C}$
- (3) $\text{AH} + \text{B} \cdot \rightarrow \text{A} \cdot + \text{D}$
- (4) $\text{A} \cdot + \text{B} \cdot \rightarrow \text{P}$

Use the steady-state approximation to deduce that the decomposition of AH is first-order in AH.

23.5b Consider the following chain mechanism:

- (1) $\text{A}_2 \rightarrow \text{A} \cdot + \text{A} \cdot$
- (2) $\text{A} \cdot \rightarrow \text{B} \cdot + \text{C}$
- (3) $\text{A} \cdot + \text{P} \rightarrow \text{B} \cdot$
- (4) $\text{A} \cdot + \text{B} \cdot \rightarrow \text{P}$

Use the steady-state approximation to deduce that the rate law for the consumption of A_2 .

23.6a The enzyme-catalysed conversion of a substrate at 25°C has a Michaelis constant of $0.035 \text{ mol dm}^{-3}$. The rate of the reaction is $1.15 \times 10^{-3} \text{ mol dm}^{-3} \text{ s}^{-1}$ when the substrate concentration is $0.110 \text{ mol dm}^{-3}$. What is the maximum velocity of this enzymolysis?

23.6b The enzyme-catalysed conversion of a substrate at 25°C has a Michaelis constant of $0.042 \text{ mol dm}^{-3}$. The rate of the reaction is $2.45 \times 10^{-4} \text{ mol dm}^{-3} \text{ s}^{-1}$ when the substrate concentration is $0.890 \text{ mol dm}^{-3}$. What is the maximum velocity of this enzymolysis?

23.7a In a photochemical reaction $\text{A} \rightarrow 2 \text{B} + \text{C}$, the quantum efficiency with 500 nm light is $2.1 \times 10^2 \text{ mol einstein}^{-1}$ (1 einstein = 1 mol photons). After exposure of 300 mmol of A to the light, 2.28 mmol of B is formed. How many photons were absorbed by A?

23.7b In a photochemical reaction $\text{A} \rightarrow \text{B} + \text{C}$, the quantum efficiency with 500 nm light is $1.2 \times 10^2 \text{ mol einstein}^{-1}$. After exposure of 200 mmol A to the light, 1.77 mmol B is formed. How many photons were absorbed by A?

23.8a In an experiment to measure the quantum efficiency of a photochemical reaction, the absorbing substance was exposed to 490 nm light from a 100 W source for 45 min. The intensity of the transmitted light was 40 per cent of the intensity of the incident light. As a result of irradiation, 0.344 mol of the absorbing substance decomposed. Determine the quantum efficiency.

23.8b In an experiment to measure the quantum efficiency of a photochemical reaction, the absorbing substance was exposed to 320 nm radiation from a 87.5 W source for 28.0 min. The intensity of the transmitted light was 0.257 that of the incident light. As a result of irradiation, 0.324 mol of the absorbing substance decomposed. Determine the quantum efficiency.

Problems*

Numerical problems

23.1 Studies of combustion reactions depend on knowing the concentrations of H atoms and OH radicals. Measurements on a flow system using EPR for the detection of radicals gave information on the reactions

- (1) $\text{H} + \text{NO}_2 \rightarrow \text{OH} + \text{NO} \quad k_1 = 2.9 \times 10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$
- (2) $\text{OH} + \text{OH} \rightarrow \text{H}_2\text{O} + \text{O} \quad k_2 = 1.55 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$
- (3) $\text{O} + \text{OH} \rightarrow \text{O}_2 + \text{H} \quad k_3 = 1.1 \times 10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$

(J.N. Bradley, W. Hack, K. Hoyer mann, and H.G. Wagner, *J. Chem. Soc. Faraday Trans. I*, 1889 (1973)). Using initial H atom and NO_2 concentrations of $4.5 \times 10^{-10} \text{ mol cm}^{-3}$ and $5.6 \times 10^{-10} \text{ mol cm}^{-3}$, respectively, compute and plot curves showing the O, O_2 , and OH concentrations as a function of time in the range 0–10 ns.

23.2 In a flow study of the reaction between O atoms and Cl_2 (J.N. Bradley, D.A. Whytock, and T.A. Zaleski, *J. Chem. Soc. Faraday Trans. I*, 1251 (1973))

at high chlorine pressures, plots of $\ln [\text{O}]_0/[\text{O}]$ against distances l along the flow tube, where $[\text{O}]_0$ is the oxygen concentration at zero chlorine pressure, gave straight lines. Given the flow velocity as 6.66 m s^{-1} and the data below, find the rate coefficient for the reaction $\text{O} + \text{Cl}_2 \rightarrow \text{ClO} + \text{Cl}$.

l/cm	0	2	4	6	8	10	12	14	16	18
$\ln([\text{O}]_0/[\text{O}])$	0.27	0.31	0.34	0.38	0.45	0.46	0.50	0.55	0.56	0.60

with $[\text{O}]_0 = 3.3 \times 10^{-8} \text{ mol dm}^{-3}$, $[\text{Cl}_2] = 2.54 \times 10^{-7} \text{ mol dm}^{-3}$, $p = 1.70 \text{ Torr}$.

23.3‡ J.D. Chapple-Sokol, C.J. Giunta, and R.G. Gordon (*J. Electrochem. Soc.* **136**, 2993 (1989)) proposed the following radical chain mechanism for the initial stages of the gas-phase oxidation of silane by nitrous oxide:

- (1) $\text{N}_2\text{O} \rightarrow \text{N}_2 + \text{O}$
- (2) $\text{O} + \text{SiH}_4 \rightarrow \text{SiH}_3 + \text{OH}$
- (3) $\text{OH} + \text{SiH}_4 \rightarrow \text{SiH}_3 + \text{H}_2\text{O}$
- (4) $\text{SiH}_3 + \text{N}_2\text{O} \rightarrow \text{SiH}_3\text{O} + \text{N}_2$

* Problems denoted with the symbol ‡ were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

Label each step with its role in the chain. Use the steady-state approximation to show that this mechanism predicts the following rate law for SiH_4 consumption (provided k_1 and k_6 are in some sense small):

$$\frac{d[\text{SiH}_4]}{dt} = -k[\text{N}_2\text{O}][\text{SiH}_4]^{1/2}$$

23.4† The water formation reaction has been studied many times and continues to be of interest. Despite the many studies there is not uniform agreement on the mechanism. But as explosions are known to occur at certain critical values of the pressure, any proposed mechanism to be considered plausible must be consistent with the existence of these critical explosion limits. One such plausible mechanism is that of Example 23.2. Another is the following:

In a manner similar to that in Example 23.2, determine whether or not this mechanism can lead to explosions under appropriate conditions.

23.5† For many years the reaction $\text{H}_2(\text{g}) + \text{I}_2(\text{g}) \rightarrow 2\text{HI}(\text{g})$ and its reverse were assumed to be elementary bimolecular reactions. However, J.H. Sullivan (*J. Chem. Phys.* **46**, 73 (1967)) suggested that the following mechanism for the reaction, originally proposed by M. Bodenstein (*Z. Physik. Chem.* **29**, 56 (1898)), provides a better explanation of the experimental results:

Obtain the expression for the rate of formation of HI based on this mechanism. Under what conditions does this rate law reduce to the one for the originally accepted mechanism?

23.6 The number of photons falling on a sample can be determined by a variety of methods, of which the classical one is chemical actinometry. The decomposition of oxalic acid $(\text{COOH})_2$, in the presence of uranyl sulfate, $(\text{UO}_2)\text{SO}_4$, proceeds according to the sequence

with a quantum efficiency of 0.53 at the wavelength used. The amount of oxalic acid remaining after exposure can be determined by titration (with KMnO_4) and the extent of decomposition used to find the number of incident photons. In a particular experiment, the actinometry solution consisted of 5.232 g anhydrous oxalic acid, 25.0 cm^3 water (together with the uranyl salt). After exposure for 300 s the remaining solution was titrated with 0.212 M $\text{KMnO}_4(\text{aq})$, and 17.0 cm^3 were required for complete oxidation of the remaining oxalic acid. The titration reaction is

What is the rate of incidence of photons at the wavelength of the experiment? Express the answer in photons/second and einstein/second.

23.7 Dansyl chloride, which absorbs maximally at 330 nm and fluoresces maximally at 510 nm, can be used to label aminoacids in fluorescence microscopy and FRET studies. Tabulated below is the variation of the

fluorescence intensity of an aqueous solution of dansyl chloride with time after excitation by a short laser pulse (with I_0 the initial fluorescence intensity).

t/ns	5.0	10.0	15.0	20.0
I_t/I_0	0.45	0.21	0.11	0.05

- (a) Calculate the observed fluorescence lifetime of dansyl chloride in water.
(b) The fluorescence quantum yield of dansyl chloride in water is 0.70. What is the fluorescence rate constant?

23.8 When benzophenone is illuminated with ultraviolet light it is excited into a singlet state. This singlet changes rapidly into a triplet, which phosphoresces. Triethylamine acts as a quencher for the triplet. In an experiment in methanol as solvent, the phosphorescence intensity varied with amine concentration as shown below. A time-resolved laser spectroscopy experiment had also shown that the half-life of the fluorescence in the absence of quencher is 29 μs . What is the value of k_q ?

$[\text{Q}]/(\text{mol dm}^{-3})$	0.0010	0.0050	0.0100
$I_t/(\text{arbitrary units})$	0.41	0.25	0.16

23.9 An electronically excited state of Hg can be quenched by N_2 according to

in which energy transfer from Hg^* excites N_2 vibrationally. Fluorescence lifetime measurements of samples of Hg with and without N_2 present are summarized below ($T = 300\text{ K}$):

$p_{\text{N}_2} = 0.0\text{ atm}$					
Relative fluorescence intensity	1.000	0.606	0.360	0.22	0.135
$t/\mu\text{s}$	0.0	5.0	10.0	15.0	20.0
$p_{\text{N}_2} = 9.74 \times 10^{-4}\text{ atm}$					
Relative fluorescence intensity	1.000	0.585	0.342	0.200	0.117
$t/\mu\text{s}$	0.0	3.0	6.0	9.0	12.0

You may assume that all gases behave ideally. Determine the rate constant for the energy transfer process.

23.10 The Förster theory of resonance energy transfer and the basis for the FRET technique can be tested by performing fluorescence measurements on a series of compounds in which an energy donor and an energy acceptor are covalently linked by a rigid molecular linker of variable and known length. L. Stryer and R.P. Haugland (*Proc. Natl. Acad. Sci. USA* **58**, 719 (1967)) collected the following data on a family of compounds with the general composition dansyl-(L-prolyl) $_n$ -naphthyl, in which the distance R between the naphthyl donor and the dansyl acceptor was varied from 1.2 nm to 4.6 nm by increasing the number of prolyl units in the linker:

R/nm	1.2	1.5	1.8	2.8	3.1	3.4	3.7	4.0	4.3	4.6
$1 - E_T$	0.99	0.94	0.97	0.82	0.74	0.65	0.40	0.28	0.24	0.16

Are the data described adequately by eqn 23.38? If so, what is the value of R_0 for the naphthyl-dansyl pair?

Theoretical problems

23.11 The Rice–Herzfeld mechanism for the dehydrogenation of ethane is specified in Section 23.1, and it was noted there that it led to first-order kinetics. Confirm this remark, and find the approximations that lead to the rate law quoted there. How may the conditions be changed so that the reaction shows different orders?

23.12 The following mechanism has been proposed for the thermal decomposition of acetaldehyde (ethanal):

- $\text{CH}_3\text{CHO} \rightarrow \cdot\text{CH}_3 + \text{CHO}$
- $\cdot\text{CH}_3 + \text{CH}_3\text{CHO} \rightarrow \text{CH}_4 + \cdot\text{CH}_2\text{CHO}$
- $\cdot\text{CH}_2\text{CHO} \rightarrow \text{CO} + \cdot\text{CH}_3$
- $\cdot\text{CH}_3 + \cdot\text{CH}_3 \rightarrow \text{CH}_3\text{CH}_3$

Find an expression for the rate of formation of methane and the rate of disappearance of acetaldehyde.

23.13 Express the root mean square deviation $\{\langle M^2 \rangle - \langle \bar{M} \rangle^2\}^{1/2}$ of the molar mass of a condensation polymer in terms of p , and deduce its time dependence.

23.14 Calculate the ratio of the mean cube molar mass to the mean square molar mass in terms of (a) the fraction p , (b) the chain length.

23.15 Calculate the average polymer length in a polymer produced by a chain mechanism in which termination occurs by a disproportionation reaction of the form $M\cdot + M\cdot \rightarrow M + \cdot M$.

23.16 Derive an expression for the time dependence of the degree of polymerization for a stepwise polymerization in which the reaction is acid-catalysed by the $-\text{COOH}$ acid functional group. The rate law is $d[A]/dt = -k[A]^2[\text{OH}]$.

23.17 Autocatalysis is the catalysis of a reaction by the products. For example, for a reaction $A \rightarrow P$ it may be found that the rate law is $v = k[A][P]$ and the reaction rate is proportional to the concentration of P . The reaction gets started because there are usually other reaction routes for the formation of some P initially, which then takes part in the autocatalytic reaction proper. (a) Integrate the rate equation for an autocatalytic reaction of the form $A \rightarrow P$, with rate law $v = k[A][P]$, and show that

$$\frac{[P]}{[P]_0} = (b+1) \frac{e^{at}}{1 + be^{at}}$$

where $a = ([A]_0 + [P]_0)k$ and $b = [P]_0/[A]_0$. *Hint.* Starting with the expression $v = -d[A]/dt = k[A][P]$, write $[A] = [A]_0 - x$, $[P] = [P]_0 + x$ and then write the expression for the rate of change of either species in terms of x . To integrate the resulting expression, the following relation will be useful:

$$\frac{1}{([A]_0 - x)([P]_0 + x)} = \frac{1}{[A]_0 + [P]_0} \left(\frac{1}{[A]_0 - x} + \frac{1}{[P]_0 + x} \right)$$

(b) Plot $[P]/[P]_0$ against at for several values of b . Discuss the effect of autocatalysis on the shape of a plot of $[P]/[P]_0$ against t by comparing your results with those for a first-order process, in which $[P]/[P]_0 = 1 - e^{-kt}$. (c) Show that, for the autocatalytic process discussed in parts (a) and (b), the reaction rate reaches a maximum at $t_{\text{max}} = -(1/a) \ln b$. (d) An autocatalytic reaction $A \rightarrow P$ is observed to have the rate law $d[P]/dt = k[A]^2[P]$. Solve the rate law for initial concentrations $[A]_0$ and $[P]_0$. Calculate the time at which the rate reaches a maximum. (e) Another reaction with the stoichiometry $A \rightarrow P$ has the rate law $d[P]/dt = k[A][P]^2$; integrate the rate law for initial concentrations $[A]_0$ and $[P]_0$. Calculate the time at which the rate reaches a maximum.

23.18 Conventional equilibrium considerations do not apply when a reaction is being driven by light absorption. Thus the steady-state concentration of products and reactants might differ significantly from equilibrium values. For instance, suppose the reaction $A \rightarrow B$ is driven by light absorption and that its rate is I_a , but that the reverse reaction $B \rightarrow A$ is bimolecular and second-order with a rate $k[B]^2$. What is the stationary state concentration of B ? Why does this 'photostationary state' differ from the equilibrium state?

23.19 Derive an expression for the rate of disappearance of a species A in a photochemical reaction for which the mechanism is:

- (1) initiation with light of intensity I , $A \rightarrow R\cdot + R\cdot$
- (2) propagation, $A + R\cdot \rightarrow R\cdot + B$
- (3) termination, $R\cdot + R\cdot \rightarrow R_2$

Hence, show that rate measurements will give only a combination of k_2 and k_3 if a steady state is reached, but that both may be obtained if a steady state is not reached.

23.20 The photochemical chlorination of chloroform in the gas has been found to follow the rate law $d[\text{CCl}_4]/dt = k[\text{Cl}_2]^{1/2}I_a^{1/2}$. Devise a mechanism that leads to this rate law when the chlorine pressure is high.

23.21 Photolysis of $\text{Cr}(\text{CO})_6$ in the presence of certain molecules M , can give rise to the following reaction sequence:

- (1) $\text{Cr}(\text{CO})_6 + h\nu \rightarrow \text{Cr}(\text{CO})_5 + \text{CO}$
- (2) $\text{Cr}(\text{CO})_5 + \text{CO} \rightarrow \text{Cr}(\text{CO})_6$
- (3) $\text{Cr}(\text{CO})_5 + M \rightarrow \text{Cr}(\text{CO})_5M$
- (4) $\text{Cr}(\text{CO})_5M \rightarrow \text{Cr}(\text{CO})_5 + M$

Suppose that the absorbed light intensity is so weak that $I \ll k_4[\text{Cr}(\text{CO})_5M]$. Find the factor f in the equation $d[\text{Cr}(\text{CO})_5M]/dt = -f[\text{Cr}(\text{CO})_5M]$. Show that a graph of $1/f$ against $[M]$ should be a straight line.

Applications: to biochemistry and environmental science

23.22 Models of population growth are analogous to chemical reaction rate equations. In the model due to Malthus (1798) the rate of change of the population N of the planet is assumed to be given by $dN/dt = \text{births} - \text{deaths}$. The numbers of births and deaths are proportional to the population, with proportionality constants b and d . Obtain the integrated rate law. How well does it fit the (very approximate) data below on the population of the planet as a function of time?

Year	1750	1825	1922	1960	1974	1987	2000
$N/10^9$	0.5	1	2	3	4	5	6

23.23 Many enzyme-catalysed reactions are consistent with a modified version of the Michaelis–Menten mechanism in which the second step is also reversible. (a) For this mechanism show that the rate of formation of product is given by

$$v = \frac{(v_{\text{max}}/K_M)[S] - (v'_{\text{max}}/K'_M)[P]}{1 + [S]/K_M + [P]/K'_M}$$

where $v_{\text{max}} = k_b[E]_0$, $v'_{\text{max}} = k'_a[E]_0$, $K_M = (k'_a + k_b)/k_a$, and, and $K'_M = (k'_a + k_b)/k'_b$. (b) Find the limiting behaviour of this expression for large and small concentrations of substrate.

23.24 The following results were obtained for the action of an ATPase on ATP at 20°C, when the concentration of the ATPase was 20 nmol dm⁻³:

$[\text{ATP}]/(\mu\text{mol dm}^{-3})$	0.60	0.80	1.4	2.0	3.0
$v/(\mu\text{mol dm}^{-3} \text{ s}^{-1})$	0.81	0.97	1.30	1.47	1.69

Determine the Michaelis constant, the maximum velocity of the reaction, the turnover number, and the catalytic efficiency of the enzyme.

23.25 Enzyme-catalysed reactions are sometimes analysed by use of the *Eadie–Hofstee plot*, in which v is plotted against $v/[S]_0$. (a) Using the simple Michaelis–Menten mechanism, derive a relation between $v/[S]_0$ and v . (b) Discuss how the values of K_M and v_{max} are obtained from analysis of the Eadie–Hofstee plot. (c) Determine the Michaelis constant and the maximum velocity of the reaction of the reaction from Exercise 23.23 by using an Eadie–Hofstee plot to analyse the data.

23.26 In general, the catalytic efficiency of an enzyme depends on the pH of the medium in which it operates. One way to account for this behaviour is to propose that the enzyme and the enzyme–substrate complex are active only in specific protonation states. This situation can be summarized by the following mechanism:

in which only the EH and ESH forms are active. (a) For the mechanism above, show that

$$v = \frac{v'_{\max}}{1 + K'_M[\text{S}]_0}$$

with

$$\begin{aligned}
 v'_{\max} &= \frac{v_{\max}}{1 + \frac{[\text{H}^+]}{K_{\text{ES},b}} + \frac{K_{\text{ES},a}}{[\text{H}^+]}} \\
 K'_M &= K_M \frac{1 + \frac{[\text{H}^+]}{K_{\text{ES},b}} + \frac{K_{\text{ES},a}}{[\text{H}+]}}{1 + \frac{[\text{H}^+]}{K_{\text{ES},b}} + \frac{K_{\text{ES},a}}{[\text{H}+]}}
 \end{aligned}$$

where $v_{\max}$ and K_M correspond to the form EH of the enzyme. (b) For pH values ranging from 0 to 14, plot $v'_{\max}$ against pH for a hypothetical reaction for which $v_{\max} = 1.0 \times 10^{-6} \text{ mol dm}^{-3} \text{ s}^{-1}$, $K_{\text{ES},b} = 1.0 \times 10^{-6} \text{ mol dm}^{-3}$ and $K_{\text{ES},a} = 1.0 \times 10^{-8} \text{ mol dm}^{-3}$. Is there a pH at which $v'_{\max}$ reaches a maximum value? If so, determine the pH. (c) Redraw the plot in part (b) by using the same value of $v_{\max}$, but $K_{\text{ES},b} = 1.0 \times 10^{-4} \text{ mol dm}^{-3}$ and $K_{\text{ES},a} = 1.0 \times 10^{-10} \text{ mol dm}^{-3}$. Account for any differences between this plot and the plot from part (b).

23.27 The enzyme carboxypeptidase catalyses the hydrolysis of polypeptides and here we consider its inhibition. The following results were obtained when the rate of the enzymolysis of carbobenzoxy-glycyl-D-phenylalanine (CBGP) was monitored without inhibitor:

$[\text{CBGP}]_0 / (10^{-2} \text{ mol dm}^{-3})$	1.25	3.84	5.81	7.13
Relative reaction rate	0.398	0.669	0.859	1.000

(All rates in this problem were measured with the same concentration of enzyme and are relative to the rate measured when $[\text{CBGP}]_0 = 0.0713 \text{ mol dm}^{-3}$ in the absence of inhibitor.) When $2.0 \times 10^{-3} \text{ mol dm}^{-3}$ phenylbutyrate ion was added to a solution containing the enzyme and substrate, the following results were obtained:

$[\text{CBGP}]_0 / (10^{-2} \text{ mol dm}^{-3})$	1.25	2.50	4.00	5.50
Relative reaction rate	0.172	0.301	0.344	0.548

In a separate experiment, the effect of $5.0 \times 10^{-2} \text{ mol dm}^{-3}$ benzoate ion was monitored and the results were:

$[\text{CBGP}]_0 / (10^{-2} \text{ mol dm}^{-3})$	1.75	2.50	5.00	10.00
Relative reaction rate	0.183	0.201	0.231	0.246

Determine the mode of inhibition of carboxypeptidase by the phenylbutyrate ion and benzoate ion.

23.28 Many biological and biochemical processes involve autocatalytic steps (Problem 23.17). In the SIR model of the spread and decline of infectious diseases the population is divided into three classes; the susceptibles, S, who can catch the disease, the infectives, I, who have the disease and can transmit

it, and the removed class, R, who have either had the disease and recovered, are dead, or are immune or isolated. The model mechanism for this process implies the following rate laws:

$$\frac{dS}{dt} = -rSI \quad \frac{dI}{dt} = rSI - aI \quad \frac{dR}{dt} = aI$$

What are the autocatalytic steps of this mechanism? Find the conditions on the ratio a/r that decide whether the disease will spread (an epidemic) or die out. Show that a constant population is built into this system, namely, that $S + I + R = N$, meaning that the timescales of births, deaths by other causes, and migration are assumed large compared to that of the spread of the disease.

23.29 In light-harvesting complexes, the fluorescence of a chlorophyll molecule is quenched by nearby chlorophyll molecules. Given that for a pair of chlorophyll *a* molecules $R_0 = 5.6 \text{ nm}$, by what distance should two chlorophyll *a* molecules be separated to shorten the fluorescence lifetime from 1 ns (a typical value for monomeric chlorophyll *a* in organic solvents) to 10 ps?

23.30 The light-induced electron transfer reactions in photosynthesis occur because chlorophyll molecules (whether in monomeric or dimeric forms) are better reducing agents in their electronic excited states. Justify this observation with the help of molecular orbital theory.

23.31 The emission spectrum of a porphyrin dissolved in O_2 -saturated water shows a strong band at 650 nm and a weak band at 1270 nm. In separate experiments, it was observed that the electronic absorption spectrum of the porphyrin sample showed bands at 420 nm and 550 nm, and the electronic absorption spectrum of O_2 -saturated water showed no bands in the visible range of the spectrum (and therefore no emission spectrum when excited in the same range). Based on these data alone, make a preliminary assignment of the emission band at 1270 nm. Propose additional experiments that test your hypothesis.

23.32† Ultraviolet radiation photolyses O_3 to O_2 and O. Determine the rate at which ozone is consumed by 305 nm radiation in a layer of the stratosphere of thickness 1 km. The quantum efficiency is 0.94 at 220 K, the concentration about $8 \times 10^{-9} \text{ mol dm}^{-3}$, the molar absorption coefficient $260 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$, and the flux of 305 nm radiation about $1 \times 10^{14} \text{ photons cm}^{-2} \text{ s}^{-1}$. Data from W.B. DeMore, S.P. Sander, D.M. Golden, R.F. Hampson, M.J. Kurylo, C.J. Howard, A.R. Ravishankara, C.E. Kolb, and M.J. Molina, *Chemical kinetics and photochemical data for use in stratospheric modeling: Evaluation Number 11*, JPL Publication 94-26 (1994).

23.33† Use the Chapman model to explore the behaviour of a model atmosphere consisting of pure O_2 at 10 Torr and 298 K that is exposed to measurable frequencies and intensities of UV radiation. (a) Look up the values of k_2 , k_4 , and k_5 in a source such as the *CRC Handbook of chemistry and physics* or *Chemical kinetics and photochemical data for use in stratospheric modeling* (the URL is available at the text's web site). The rate constants k_1 and k_3 depend upon the radiation conditions; assume values of $1.0 \times 10^{-8} \text{ s}^{-1}$ and 0.016 s^{-1} , respectively. If you cannot find a value for k_5 , formulate chemically sound arguments for exclusion of the fifth step from the mechanism. (b) Write the rate expressions for the concentration of each chemical species. (c) Assume that the UV radiation is turned on at $t = 0$, and solve the rate expressions for the concentration of all species as a function of time over a period of 4 h. Examine relevant concentrations in the very early time period $t < 0.1 \text{ s}$. State all assumptions. Is there any ozone present initially? Why must the pressure be low and the UV radiation intensities high for the production of ozone? Draw graphs of the time variations of both atomic oxygen and ozone on both the very short and the long timescales. What is the percentage of ozone after 4.0 h of irradiation? *Hint.* You will need a software package for solving a 'stiff' system of differential equations. Stiff differential equations have at least two rate constants with very different values and result in different behaviours on different timescales, so the solution usually requires that the total time period be broken into two or more periods; one may be

very short and another very long. For help with using mathematical software to solve systems of differential equations, see M.P. Cady and C.A. Trapp, *A Mathcad primer for physical chemistry*. Oxford University Press (1999).

23.34† Chlorine atoms react rapidly with ozone in the gas-phase bimolecular reaction $\text{Cl} + \text{O}_3 \rightarrow \text{ClO} + \text{O}_2$ with $k = (1.7 \times 10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}) e^{-260/(T/\text{K})}$ (W.B. DeMore, S.P. Sander, D.M. Golden, R.F. Hampson, M.J. Kurylo, C.J. Howard, A.R. Ravishankara, C.E. Kolb, and M.J. Molina, Chemical kinetics and photochemical data for use in stratospheric modeling: Evaluation Number 11, JPL Publication 94-26 (1994)). Estimate the rate of this reaction at (a) 20 km, where $[\text{Cl}] = 5 \times 10^{-17} \text{ mol dm}^{-3}$, $[\text{O}_3] = 8 \times 10^{-9} \text{ mol dm}^{-3}$, and $T = 220 \text{ K}$; (b) 45 km, where $[\text{Cl}] = 3 \times 10^{-15} \text{ mol dm}^{-3}$, $[\text{O}_3] = 8 \times 10^{-11} \text{ mol dm}^{-3}$, and $T = 270 \text{ K}$.

23.35† Because of its importance in atmospheric chemistry, the thermal decomposition of nitric oxide, $2 \text{NO}(\text{g}) \rightarrow \text{N}_2(\text{g}) + \text{O}_2(\text{g})$, has been amongst the most thoroughly studied of gas-phase reactions. The commonly accepted mechanism has been that of H. Wise and M.F. Frech (*J. Chem. Phys.* **22**, 1724 (1952)):

(a) Label the steps of this mechanism as initiation, propagation, etc. (b) Write down the full expression for the rate of disappearance of NO. What does this expression for the rate become on the basis of the assumptions that $v_2 = v_3$ when $[\text{N}]$ reaches its steady state concentration, that the rate of the propagation step is more rapid than the rate of the initiation step, and that oxygen atoms are in equilibrium with oxygen molecules? (c) Find an expression for the effective activation energy, $E_{a,\text{eff}}$, for the overall reaction in terms of the activation energies of the individual steps of the reaction. (d) Estimate $E_{a,\text{eff}}$ from the bond energies of the species involved. (e) It has been pointed out by R.J. Wu and C.T. Yeh (*Int. J. Chem. Kinet.* **28**, 89 (1996)) that the reported experimental values of $E_{a,\text{eff}}$ obtained by different authors have varied from 253 to 357 kJ mol⁻¹. They suggest that the assumption of oxygen atoms and oxygen molecules being in equilibrium is unwarranted and that the steady-state approximation needs to be applied to the entire mechanism. Obtain the overall rate law based on the steady-state approximation and find the forms that it assumes for low NO conversion (low O₂ concentration). (f) When the reaction conversion becomes significant, Wu and Yeh suggest that two additional elementary steps,

start to compete with step (1) as the initiation step. Obtain the rate laws based on these alternative mechanisms and again estimate the apparent activation energies. Is the range of these different theoretically estimated values for $E_{a,\text{eff}}$ consistent with the range of values obtained experimentally?

Molecular reaction dynamics

24

The simplest quantitative account of reaction rates is in terms of collision theory, which can be used only for the discussion of reactions between simple species in the gas phase. Reactions in solution are classified into two types: diffusion-controlled and activation-controlled. The former can be expressed quantitatively in terms of the diffusion equation. In transition state theory, it is assumed that the reactant molecules form a complex that can be discussed in terms of the population of its energy levels. Transition state theory inspires a thermodynamic approach to reaction rates, in which the rate constant is expressed in terms of thermodynamic parameters. This approach is useful for parametrizing the rates of reactions in solution. The highest level of sophistication is in terms of potential energy surfaces and the motion of molecules through these surfaces. As we shall see, such an approach gives an intimate picture of the events that occur when reactions occur and is open to experimental study. We also use transition state theory to examine the transfer of electrons in homogeneous systems and see that the rate of the process depends on the distance between electron donor and acceptor, the standard Gibbs energy of reaction, and the energy associated with molecular rearrangements that accompany the transfer of charge.

Now we are at the heart of chemistry. Here we examine the details of what happens to molecules at the climax of reactions. Extensive changes of structure are taking place and energies the size of dissociation energies are being redistributed among bonds: old bonds are being ripped apart and new bonds are being formed.

As may be imagined, the calculation of the rates of such processes from first principles is very difficult. Nevertheless, like so many intricate problems, the broad features can be established quite simply. Only when we enquire more deeply do the complications emerge. In this chapter we look at several approaches to the calculation of a rate constant for elementary bimolecular processes, ranging from electron transfer to chemical reactions involving bond breakage and formation. Although a great deal of information can be obtained from gas-phase reactions, many reactions of interest take place in solution, and we shall also see to what extent their rates can be predicted.

Reactive encounters

In this section we consider two elementary approaches to the calculation of reaction rates, one relating to gas-phase reactions and the other to reactions in solution. Both approaches are based on the view that reactant molecules must meet, and that reaction takes place only if the molecules have a certain minimum energy. In the collision theory of bimolecular gas-phase reactions, which we mentioned briefly in Section 22.5,

Discussion questions

Exercises

Problems

products are formed only if the collision is sufficiently energetic; otherwise the colliding reactant molecules separate again. In solution, the reactant molecules may simply diffuse together and then acquire energy from their immediate surroundings while they are in contact.

24.1 Collision theory

We shall consider the bimolecular elementary reaction

where P denotes products, and aim to calculate the second-order rate constant k_2 .

We can anticipate the general form of the expression for k_2 by considering the physical requirements for reaction. We expect the rate v to be proportional to the rate of collisions, and therefore to the mean speed of the molecules, $\bar{c} \propto (T/M)^{1/2}$ where M is the molar mass of the molecules, their collision cross-section, σ , and the number densities $\mathcal{N}_A$ and $\mathcal{N}_B$ of A and B:

$$v \propto \sigma(T/M)^{1/2} \mathcal{N}_A \mathcal{N}_B \propto \sigma(T/M)^{1/2} [A][B]$$

However, a collision will be successful only if the kinetic energy exceeds a minimum value, the activation energy, E_a , of the reaction. This requirement suggests that the rate constant should also be proportional to a Boltzmann factor of the form $e^{-E_a/RT}$. So we can anticipate, by writing the reaction rate in the form given in eqn 24.1, that

$$k_2 \propto \sigma(T/M)^{1/2} e^{-E_a/RT}$$

Not every collision will lead to reaction even if the energy requirement is satisfied, because the reactants may need to collide in a certain relative orientation. This 'steric requirement' suggests that a further factor, P , should be introduced, and that

$$k_2 \propto P\sigma(T/M)^{1/2} e^{-E_a/RT} \quad (24.2)$$

As we shall see in detail below, this expression has the form predicted by collision theory. It reflects three aspects of a successful collision:

$$k_2 \propto \text{steric requirement} \times \text{encounter rate} \times \text{minimum energy requirement}$$

(a) Collision rates in gases

We have anticipated that the reaction rate, and hence k_2 , depends on the frequency with which molecules collide. The **collision density**, Z_{AB} , is the number of (A,B) collisions in a region of the sample in an interval of time divided by the volume of the region and the duration of the interval. The frequency of collisions of a single molecule in a gas was calculated in Section 21.1. As shown in the *Justification* below, that result can be adapted to deduce that

$$Z_{AB} = \sigma \left(\frac{8kT}{\pi\mu} \right)^{1/2} N_A^2 [A][B] \quad (24.3a)$$

where σ is the collision cross-section (Fig. 24.1)

$$\sigma = \pi d^2 \quad d = \frac{1}{2}(d_A + d_B) \quad (24.3b)$$

and μ is the reduced mass,

$$\mu = \frac{m_A m_B}{m_A + m_B} \quad (24.3c)$$

Fig. 24.1 The collision cross-section for two molecules can be regarded to be the area within which the projectile molecule (A) must enter around the target molecule (B) in order for a collision to occur. If the diameters of the two molecules are d_A and d_B , the radius of the target area is $d = \frac{1}{2}(d_A + d_B)$ and the cross-section is πd^2 .

Similarly, the collision density for like molecules at a molar concentration $[A]$ is

$$Z_{AA} = \sigma \left(\frac{4kT}{\pi m_A} \right)^{1/2} N_A^2 [A]^2 \quad (24.4)$$

Collision densities may be very large. For example, in nitrogen at room temperature and pressure, with $d = 280$ pm, $Z = 5 \times 10^{34} \text{ m}^{-3} \text{ s}^{-1}$.

Justification 24.1 The collision density

It follows from eqn 21.11 that the collision frequency, z , for a single A molecule of mass m_A in a gas of other A molecules is

$$z = \sigma \bar{c}_{\text{rel}} \mathcal{N}_A \quad (24.5)$$

where $\mathcal{N}_A$ is the number density of A molecules and $\bar{c}_{\text{rel}}$ is their relative mean speed. As indicated in Section 21.1a,

$$\bar{c}_{\text{rel}} = 2^{1/2} \bar{c} \quad \bar{c} = \left(\frac{8kT}{\pi m} \right)^{1/2} \quad (24.6)$$

For future convenience, it is sensible to introduce $\mu = \frac{1}{2}m$ (for like molecules of mass m), and then to write

$$\bar{c}_{\text{rel}} = \left(\frac{8kT}{\pi \mu} \right)^{1/2} \quad (24.7)$$

This expression also applies to the mean relative speed of dissimilar molecules, provided that μ is interpreted as the reduced mass in eqn 24.5.

The total collision density is the collision frequency multiplied by the number density of A molecules:

$$Z_{AA} = \frac{1}{2} z \mathcal{N}_A = \frac{1}{2} \sigma \bar{c}_{\text{rel}} \mathcal{N}_A^2 \quad (24.8)$$

The factor of $\frac{1}{2}$ has been introduced to avoid double counting of the collisions (so one A molecule colliding with another A molecule is counted as one collision regardless of their actual identities). For collisions of A and B molecules present at number densities $\mathcal{N}_A$ and $\mathcal{N}_B$, the collision density is

$$Z_{AB} = \sigma \bar{c}_{\text{rel}} \mathcal{N}_A \mathcal{N}_B \quad (24.9)$$

Note that we have discarded the factor of $\frac{1}{2}$ because now we are considering an A molecule colliding with any of the B molecules as a collision.

The number density of a species J is $\mathcal{N}_J = N_A [J]$, where $[J]$ is their molar concentration and N_A is Avogadro's constant. Equations 24.3 and 24.4 then follow.

(b) The energy requirement

According to collision theory, the rate of change in the molar concentration of A molecules is the product of the collision density and the probability that a collision occurs with sufficient energy. The latter condition can be incorporated by writing the collision cross-section as a function of the kinetic energy of approach of the two colliding species, and setting the cross-section, $\sigma(\epsilon)$, equal to zero if the kinetic energy of approach is below a certain threshold value, ϵ_a . Later, we shall identify $N_A \epsilon_a$ as E_a , the (molar) activation energy of the reaction. Then, for a collision with a specific relative speed of approach v_{rel} (not, at this stage, a mean value),

$$\frac{d[A]}{dt} = -\sigma(\epsilon) v_{\text{rel}} N_A [A][B] \quad (24.10)$$

Comment 24.1

See Further information 10.1. The kinetic energy associated with the relative motion of two particles takes the form $\epsilon = \frac{1}{2} \mu v_{\text{rel}}^2$ when the centre-of-mass coordinates are separated from the internal coordinates of each particle.

Comment 24.2

To go from eqn 24.10 to eqn 24.11, we need to review concepts of probability theory summarized in *Appendix 2*. Namely, the mean value of a continuous variable X is given by

$$\langle X \rangle = \int x f(x) dx$$

where the integral is over all values x that X can assume and the probability of finding a value of X between x and $x + dx$ is $f(x)dx$, with $f(x)$ a measure of the distribution of the probability values over x . The mean value of a function $g(X)$ is given by

$$\langle g(X) \rangle = \int g(x) f(x) dx$$

Fig. 24.2 The variation of the reactive cross-section with energy as expressed by eqn 24.13. The data points are from experiments on the reaction $\text{H} + \text{D}_2 \rightarrow \text{HD} + \text{D}$ (K. Tsukiyama, B. Katz, and R. Bersohn, *J. Chem. Phys.* **84**, 1934 (1986)).

Fig. 24.3 The parameters used in the calculation of the dependence of the collision cross-section on the relative kinetic energy of two molecules A and B.

The relative kinetic energy, ϵ , and the relative speed are related by $\epsilon = \frac{1}{2}\mu v_{\text{rel}}^2$, so $v_{\text{rel}} = (2\epsilon\mu)^{1/2}$. At this point we recognize that a wide range of approach energies is present in a sample, so we should average the expression just derived over a Boltzmann distribution of energies $f(\epsilon)$, and write (see *Comment 24.2*)

$$\frac{d[A]}{dt} = - \left\{ \int_0^\infty \sigma(\epsilon) v_{\text{rel}} f(\epsilon) d\epsilon \right\} N_A [A] [B] \quad (24.11)$$

and hence recognize the rate constant as

$$k_2 = N_A \int_0^\infty \sigma(\epsilon) v_{\text{rel}} f(\epsilon) d\epsilon \quad (24.12)$$

Now suppose that the reactive collision cross-section is zero below ϵ_a . We show in the *Justification* below that, above ϵ_a , $\sigma(\epsilon)$ varies as

$$\sigma(\epsilon) = \left(1 - \frac{\epsilon_a}{\epsilon} \right) \sigma \quad (24.13)$$

This form of the energy dependence is broadly consistent with experimental determinations of the reaction between H and D_2 as determined by molecular beam measurements of the kind described later (Fig. 24.2). Then, in the *Justification* below, we show that

$$k_2 = N_A \sigma \tilde{c}_{\text{rel}} e^{-E_a/RT} \quad (24.14)$$

Justification 24.2 *The rate constant*

Consider two colliding molecules A and B with relative speed v_{rel} and relative kinetic energy $\epsilon = \frac{1}{2}\mu v_{\text{rel}}^2$ (Fig. 24.3). Intuitively we expect that a head-on collision between A and B will be most effective in bringing about a chemical reaction. Therefore, $v_{\text{rel},A-B}$, the magnitude of the relative velocity component parallel to an axis that contains the vector connecting the centres of A and B, must be large. From trigonometry and the definitions of the distances a and d , and the angle θ given in Fig. 24.3, it follows that

$$v_{\text{rel},A-B} = v_{\text{rel}} \cos \theta = v_{\text{rel}} \left(\frac{d^2 - a^2}{d^2} \right)^{1/2} \quad (24.15)$$

We assume that only the kinetic energy associated with the head-on component of the collision, ϵ_{A-B} , can lead to a chemical reaction. After squaring both sides of the equation above and multiplying by $\frac{1}{2}\mu$, it follows that

$$\epsilon_{A-B} = \epsilon \frac{d^2 - a^2}{d^2} \quad (24.16)$$

The existence of an energy threshold, ϵ_a , for the formation of products implies that there is a maximum value of a , a_{max} , above which reactions do not occur. Setting $a = a_{\text{max}}$ and $\epsilon_{A-B} = \epsilon_a$ in the equation above gives

$$a_{\text{max}}^2 = \left(1 - \frac{\epsilon_a}{\epsilon} \right) d^2 \quad (24.17)$$

Substitution of $\sigma(\epsilon)$ for πa_{max}^2 and σ for πd^2 in the equation above gives eqn 24.13. Note that the equation can be used only when $\epsilon > \epsilon_a$.

We proceed with the calculation of the rate constant by considering the Maxwell-Boltzmann distribution of molecular speeds given in Section 21.1. It may be expressed

in terms of the kinetic energy, ε , by writing $\varepsilon = \frac{1}{2}\mu v^2$, then $dv = d\varepsilon/(2\mu\varepsilon)^{1/2}$ and eqn 21.4 becomes

$$\begin{aligned} f(v)dv &= 4\pi \left(\frac{\mu}{2\pi kT} \right)^{3/2} \left(\frac{2\varepsilon}{\mu} \right) e^{-\varepsilon/kT} \frac{d\varepsilon}{(2\mu\varepsilon)^{1/2}} \\ &= 2\pi \left(\frac{1}{\pi kT} \right)^{3/2} \varepsilon^{1/2} e^{-\varepsilon/kT} d\varepsilon = f(\varepsilon)d\varepsilon \end{aligned} \quad (24.18)$$

The integral we need to evaluate is therefore

$$\begin{aligned} \int_0^\infty \sigma(\varepsilon) v_{\text{rel}} f(\varepsilon) d\varepsilon &= 2\pi \left(\frac{1}{\pi kT} \right)^{3/2} \int_0^\infty \sigma(\varepsilon) \left(\frac{2\varepsilon}{\mu} \right)^{1/2} \varepsilon^{1/2} e^{-\varepsilon/kT} d\varepsilon \\ &= \left(\frac{8}{\pi \mu kT} \right)^{1/2} \left(\frac{1}{kT} \right) \int_0^\infty \varepsilon \sigma(\varepsilon) e^{-\varepsilon/kT} d\varepsilon \end{aligned}$$

To proceed, we introduce the approximation for $\sigma(\varepsilon)$ in eqn 24.13, and evaluate

$$\int_0^\infty \varepsilon \sigma(\varepsilon) e^{-\varepsilon/kT} d\varepsilon = \sigma \int_{\varepsilon_a}^\infty \varepsilon \left(1 - \frac{\varepsilon_a}{\varepsilon} \right) e^{-\varepsilon/kT} d\varepsilon = (kT)^2 \sigma e^{-\varepsilon_a/kT}$$

We have made use of the fact that $\sigma = 0$ for $\varepsilon < \varepsilon_a$. It follows that

$$\int_0^\infty \sigma(\varepsilon) v_{\text{rel}} f(\varepsilon) d\varepsilon = \sigma \left(\frac{8kT}{\pi \mu} \right)^{1/2} e^{-\varepsilon_a/kT}$$

as in eqn 24.14 (with $\varepsilon_a/kT = E_a/RT$).

Equation 24.14 has the Arrhenius form $k_2 = Ae^{-E_a/RT}$ provided the exponential temperature dependence dominates the weak square-root temperature dependence of the pre-exponential factor. It follows that we can identify the activation energy, E_a , with the minimum kinetic energy along the line of approach that is needed for reaction, and that the pre-exponential factor is a measure of the rate at which collisions occur in the gas.

(c) The steric requirement

The simplest procedure for calculating k_2 is to use for σ the values obtained for non-reactive collisions (for example, typically those obtained from viscosity measurements) or from tables of molecular radii. Table 24.1 compares some values of the pre-exponential factor calculated in this way with values obtained from Arrhenius plots (Section 22.5a). One of the reactions shows fair agreement between theory and

Fig. 24.4 The collision cross-section is the target area that results in simple deflection of the projectile molecule; the reaction cross-section is the corresponding area for chemical change to occur on collision.

experiment, but for others there are major discrepancies. In some cases the experimental values are orders of magnitude smaller than those calculated, which suggests that the collision energy is not the only criterion for reaction and that some other feature, such as the relative orientation of the colliding species, is important. Moreover, one reaction in the table has a pre-exponential factor larger than theory, which seems to indicate that the reaction occurs more quickly than the particles collide!

We can accommodate the disagreement between experiment and theory by introducing a **steric factor**, P , and expressing the **reactive cross-section**, σ^* , as a multiple of the collision cross-section, $\sigma^* = P\sigma$ (Fig. 24.4). Then the rate constant becomes

$$k_2 = P\sigma \left(\frac{8kT}{\pi\mu} \right)^{1/2} N_A e^{-E_a/RT} \quad (24.19)$$

This expression has the form we anticipated in eqn 24.2. The steric factor is normally found to be several orders of magnitude smaller than 1.

Example 24.1 Estimating a steric factor (1)

Estimate the steric factor for the reaction $\text{H}_2 + \text{C}_2\text{H}_4 \rightarrow \text{C}_2\text{H}_6$ at 628 K given that the pre-exponential factor is $1.24 \times 10^6 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$.

Method To calculate P , we need to calculate the pre-exponential factor, A , by using eqn 24.19 and then compare the answer with experiment: the ratio is P . Table 21.1 lists collision cross-sections for non-reactive encounters. The best way to estimate the collision cross-section for dissimilar spherical species is to calculate the collision diameter for each one (from $\sigma = \pi d^2$), to calculate the mean of the two diameters, and then to calculate the cross-section for that mean diameter. However, as neither species is spherical, a simpler but more approximate procedure is just to take the average of the two collision cross-sections.

Answer The reduced mass of the colliding pair is

$$\mu = \frac{m_1 m_2}{m_1 + m_2} = 3.12 \times 10^{-27} \text{ kg}$$

because $m_1 = 2.016 \text{ u}$ for H_2 and $m_2 = 28.05 \text{ u}$ for C_2H_4 (the atomic mass unit, 1 u, is defined inside the front cover). Hence

$$\left(\frac{8kT}{\pi\mu} \right)^{1/2} = 2.66 \times 10^3 \text{ m s}^{-1}$$

From Table 21.1, $\sigma(\text{H}_2) = 0.27 \text{ nm}^2$ and $\sigma(\text{C}_2\text{H}_4) = 0.64 \text{ nm}^2$, giving a mean collision cross-section of $\sigma = 0.46 \text{ nm}^2$. Therefore,

$$A = \sigma \left(\frac{8kT}{\pi\mu} \right)^{1/2} N_A = 7.37 \times 10^{11} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

Experimentally $A = 1.24 \times 10^6 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$, so it follows that $P = 1.7 \times 10^{-6}$. The very small value of P is one reason why catalysts are needed to bring this reaction about at a reasonable rate. As a general guide, the more complex the molecules, the smaller the value of P .

Self-test 24.1 It is found for the reaction $\text{NO} + \text{Cl}_2 \rightarrow \text{NOCl} + \text{Cl}$ that $A = 4.0 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ at 298 K. Use $\sigma(\text{NO}) = 0.42 \text{ nm}^2$ and $\sigma(\text{Cl}_2) = 0.93 \text{ nm}^2$ to estimate the P factor for the reaction. [0.018]

An example of a reaction for which it is possible to estimate the steric factor is $\text{K} + \text{Br}_2 \rightarrow \text{KBr} + \text{Br}$, with the experimental value $P = 4.8$. In this reaction, the distance of approach at which reaction occurs appears to be considerably larger than the distance needed for deflection of the path of the approaching molecules in a non-reactive collision. It has been proposed that the reaction proceeds by a **harpoon mechanism**. This brilliant name is based on a model of the reaction that pictures the K atom as approaching a Br_2 molecule, and when the two are close enough an electron (the harpoon) flips across from K to Br_2 . In place of two neutral particles there are now two ions, so there is a Coulombic attraction between them: this attraction is the line on the harpoon. Under its influence the ions move together (the line is wound in), the reaction takes place, and $\text{KBr} + \text{Br}$ emerge. The harpoon extends the cross-section for the reactive encounter, and the reaction rate is greatly underestimated by taking for the collision cross-section the value for simple mechanical contact between $\text{K} + \text{Br}_2$.

Example 24.2 Estimating a steric factor (2)

Estimate the value of P for the harpoon mechanism by calculating the distance at which it becomes energetically favourable for the electron to leap from K to Br_2 .

Method We should begin by identifying all the contributions to the energy of interaction between the colliding species. There are three contributions to the energy of the process $\text{K} + \text{Br}_2 \rightarrow \text{K}^+ + \text{Br}_2^-$. The first is the ionization energy, I , of K. The second is the electron affinity, E_{ea} , of Br_2 . The third is the Coulombic interaction energy between the ions when they have been formed: when their separation is R , this energy is $-e^2/4\pi\epsilon_0 R$. The electron flips across when the sum of these three contributions changes from positive to negative (that is, when the sum is zero).

Answer The net change in energy when the transfer occurs at a separation R is

$$E = I - E_{\text{ea}} - \frac{e^2}{4\pi\epsilon_0 R}$$

The ionization energy I is larger than E_{ea} , so E becomes negative only when R has decreased to less than some critical value R^* given by

$$\frac{e^2}{4\pi\epsilon_0 R^*} = I - E_{\text{ea}}$$

When the particles are at this separation, the harpoon shoots across from K to Br_2 , so we can identify the reactive cross-section as $\sigma^* = \pi R^{*2}$. This value of σ^* implies that the steric factor is

$$P = \frac{\sigma^*}{\sigma} = \frac{R^{*2}}{d^2} = \left\{ \frac{e^2}{4\pi\epsilon_0 d(I - E_{\text{ea}})} \right\}^2$$

where $d = R(\text{K}) + R(\text{Br}_2)$. With $I = 420 \text{ kJ mol}^{-1}$ (corresponding to $7.0 \times 10^{-19} \text{ J}$), $E_{\text{ea}} \approx 250 \text{ kJ mol}^{-1}$ (corresponding to $4.2 \times 10^{-19} \text{ J}$), and $d = 400 \text{ pm}$, we find $P = 4.2$, in good agreement with the experimental value (4.8).

Self-test 24.2 Estimate the value of P for the harpoon reaction between Na and Cl_2 for which $d \approx 350 \text{ pm}$; take $E_{\text{ea}} \approx 230 \text{ kJ mol}^{-1}$. [2.2]

Example 24.2 illustrates two points about steric factors. First, the concept of a steric factor is not wholly useless because in some cases its numerical value can be estimated.

Second (and more pessimistically) most reactions are much more complex than $K + Br_2$, and we cannot expect to obtain P so easily. What we need is a more powerful theory that lets us calculate, and not merely guess, its value. We go some way to setting up that theory in Section 24.4.

24.2 Diffusion-controlled reactions

Encounters between reactants in solution occur in a very different manner from encounters in gases. Reactant molecules have to jostle their way through the solvent, so their encounter frequency is considerably less than in a gas. However, because a molecule also migrates only slowly away from a location, two reactant molecules that encounter each other stay near each other for much longer than in a gas. This lingering of one molecule near another on account of the hindering presence of solvent molecules is called the **cage effect**. Such an encounter pair may accumulate enough energy to react even though it does not have enough energy to do so when it first forms. The activation energy of a reaction is a much more complicated quantity in solution than in a gas because the encounter pair is surrounded by solvent and we need to consider the energy of the entire local assembly of reactant and solvent molecules.

(a) Classes of reaction

The complicated overall process can be divided into simpler parts by setting up a simple kinetic scheme. We suppose that the rate of formation of an encounter pair AB is first-order in each of the reactants A and B :

As we shall see, k_d (where the d signifies diffusion) is determined by the diffusional characteristics of A and B . The encounter pair can break up without reaction or it can go on to form products P . If we suppose that both processes are pseudofirst-order reactions (with the solvent perhaps playing a role), then we can write

and

The concentration of AB can now be found from the equation for the net rate of change of concentration of AB :

$$\frac{d[AB]}{dt} = k_d[A][B] - k'_d[AB] - k_a[AB] \approx 0 \quad (24.21)$$

where we have applied the steady-state approximation. This expression solves to

$$[AB] = \frac{k_d[A][B]}{k_a + k'_d} \quad (24.22)$$

The rate of formation of products is therefore

$$\frac{d[P]}{dt} \approx k_a[AB] = k_2[A][B] \quad k_2 = \frac{k_a k_d}{k_a + k'_d} \quad (24.23)$$

Two limits can now be distinguished. If the rate of separation of the unreacted encounter pair is much slower than the rate at which it forms products, then $k'_d \ll k_a$ and the effective rate constant is

Synoptic table 24.2* Arrhenius parameters for reactions in solution

	Solvent	$A/(\text{dm}^3 \text{ mol}^{-1} \text{ s}^{-1})$	$E_a/(\text{kJ mol}^{-1})$
$(\text{CH}_3)_3\text{CCl}$ solvolysis	Water	7.1×10^{16}	100
	Ethanol	3.0×10^{13}	112
	Chloroform	1.4×10^4	45
$\text{CH}_3\text{CH}_2\text{Br}$	Ethanol	4.3×10^{11}	90

* More values are given in the *Data section*.

$$k_2 \approx \frac{k_a k_d}{k_a} = k_d \quad (24.24)$$

In this **diffusion-controlled limit**, the rate of reaction is governed by the rate at which the reactant molecules diffuse through the solvent. An indication that a reaction is diffusion-controlled is that its rate constant is of the order of $10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ or greater. Because the combination of radicals involves very little activation energy, radical and atom recombination reactions are often diffusion-controlled.

An **activation-controlled reaction** arises when a substantial activation energy is involved in the reaction $\text{AB} \rightarrow \text{P}$. Then $k_a \ll k'_d$ and

$$k_2 \approx \frac{k_a k_d}{k'_d} = k_a K \quad (24.25)$$

where K is the equilibrium constant for $\text{A} + \text{B} \rightleftharpoons \text{AB}$. In this limit, the reaction proceeds at the rate at which energy accumulates in the encounter pair from the surrounding solvent. Some experimental data are given in Table 24.2.

(b) Diffusion and reaction

The rate of a diffusion-controlled reaction is calculated by considering the rate at which the reactants diffuse together. As shown in the *Justification* below, the rate constant for a reaction in which the two reactant molecules react if they come within a distance R^* of one another is

$$k_d = 4\pi R^* D N_A \quad (24.26)$$

where D is the sum of the diffusion coefficients the two reactant species in the solution.

Justification 24.3 Solution of the radial diffusion equation

From the form of the diffusion equation (Section 21.10) corresponding to motion in three dimensions, $D_B \nabla^2 [\text{B}] = \partial [\text{B}] / \partial t$, the concentration of B when the system has reached a steady state ($\partial [\text{B}] / \partial t = 0$) satisfies $\nabla^2 [\text{B}]_r = 0$, where the subscript r signifies a quantity that varies with the distance r . For a spherically symmetrical system, ∇^2 can be replaced by radial derivatives alone (see Table 8.1), so the equation satisfied by $[\text{B}]_r$ is

$$\frac{d^2 [\text{B}]_r}{dr^2} + \frac{2}{r} \frac{d [\text{B}]_r}{dr} = 0 \quad (24.27)$$

The general solution of this equation is

$$[\text{B}]_r = a + \frac{b}{r} \quad (24.28)$$

Fig. 24.5 The concentration profile for reaction in solution when a molecule B diffuses towards another reactant molecule and reacts if it reaches R^* .

as may be verified by substitution. We need two boundary conditions to pin down the values of the two constants. One condition is that $[B]_r$ has its bulk value $[B]$ as $r \rightarrow \infty$. The second condition is that the concentration of B is zero at $r = R^*$, the distance at which reaction occurs. It follows that $a = [B]$ and $b = -R^*[B]$, and hence that (for $r \geq R^*$)

$$[B]_r = \left(1 + \frac{R^*}{r}\right)[B] \quad (24.29)$$

Figure 24.5 illustrates the variation of concentration expressed by this equation.

The rate of reaction is the (molar) flux, J , of the reactant B towards A multiplied by the area of the spherical surface of radius R^* :

$$\text{Rate of reaction} = 4\pi R^{*2} J \quad (24.30)$$

From Fick's first law (eqn 21.17), the flux towards A is proportional to the concentration gradient, so at a radius R^* :

$$J = D_B \left(\frac{d[B]_r}{dr} \right)_{r=R^*} = \frac{D_B [B]}{R^*} \quad (24.31)$$

(A sign change has been introduced because we are interested in the flux towards decreasing values of r .) When this condition is substituted into the previous equation we obtain

$$\text{Rate of reaction} = 4\pi R^* D_B [B] \quad (24.32)$$

The rate of the diffusion-controlled reaction is equal to the average flow of B molecules to all the A molecules in the sample. If the bulk concentration of A is $[A]$, the number of A molecules in the sample of volume V is $N_A [A] V$; the global flow of all B to all A is therefore $4\pi R^* D_B N_A [A] [B] V$. Because it is unrealistic to suppose that all A are stationary; we replace D_B by the sum of the diffusion coefficients of the two species and write $D = D_A + D_B$. Then the rate of change of concentration of AB is

$$\frac{d[AB]}{dt} = 4\pi R^* D N_A [A] [B] \quad (24.33)$$

Hence, the diffusion-controlled rate constant is as given in eqn 24.26.

We can take eqn 24.26 further by incorporating the Stokes–Einstein equation (eqn 21.66) relating the diffusion constant and the hydrodynamic radius R_A and R_B of each molecule in a medium of viscosity η :

$$D_A = \frac{kT}{6\pi\eta R_A} \quad D_B = \frac{kT}{6\pi\eta R_B} \quad (24.34)$$

As these relations are approximate, little extra error is introduced if we write $R_A = R_B = \frac{1}{2}R^*$, which leads to

$$k_d = \frac{8RT}{3\eta} \quad (24.35)$$

(The R in this equation is the gas constant.) The radii have cancelled because, although the diffusion constants are smaller when the radii are large, the reactive collision radius is larger and the particles need travel a shorter distance to meet. In this approximation, the rate constant is independent of the identities of the reactants, and depends only on the temperature and the viscosity of the solvent.

Illustration 24.1 Estimating a diffusional rate constant

The rate constant for the recombination of I atoms in hexane at 298 K, when the viscosity of the solvent is 0.326 cP (with $1 \text{ P} = 10^{-1} \text{ kg m}^{-1} \text{ s}^{-1}$) is

$$k_d = \frac{8 \times (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})}{3 \times (3.26 \times 10^{-4} \text{ kg m}^{-1} \text{ s}^{-1})} = 2.0 \times 10^7 \text{ m}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

where we have used $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$. Because $1 \text{ m}^3 = 10^3 \text{ dm}^3$, this result corresponds to $2.0 \times 10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$. The experimental value is $1.3 \times 10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$, so the agreement is very good considering the approximations involved.

24.3 The material balance equation

The diffusion of reactants plays an important role in many chemical processes, such as the diffusion of O_2 molecules into red blood corpuscles and the diffusion of a gas towards a catalyst. We can have a glimpse of the kinds of calculations involved by considering the diffusion equation (Section 21.10) generalized to take into account the possibility that the diffusing, convecting molecules are also reacting.

(a) The formulation of the equation

Consider a small volume element in a chemical reactor (or a biological cell). The net rate at which J molecules enter the region by diffusion and convection is given by eqn 21.71:

$$\frac{\partial[J]}{\partial t} = D \frac{\partial^2[J]}{\partial x^2} - v \frac{\partial[J]}{\partial x} \quad (24.36)$$

The net rate of change of molar concentration due to chemical reaction is

$$\frac{\partial[J]}{\partial t} = -k[J] \quad (24.37)$$

if we suppose that J disappears by a pseudofirst-order reaction. Therefore, the overall rate of change of the concentration of J is

$$\frac{\partial[J]}{\partial t} = \underbrace{D \frac{\partial^2[J]}{\partial x^2}}_{\substack{\text{Spread due to} \\ \text{non-uniform} \\ \text{concentration}}} - \underbrace{v \frac{\partial[J]}{\partial x}}_{\substack{\text{Change} \\ \text{due to} \\ \text{convection}}} - \underbrace{k[J]}_{\substack{\text{Loss} \\ \text{due to} \\ \text{reaction}}} \quad (24.38)$$

Equation 24.38 is called the **material balance equation**. If the rate constant is large, then $[J]$ will decline rapidly. However, if the diffusion constant is large, then the decline can be replenished as J diffuses rapidly into the region. The convection term, which may represent the effects of stirring, can sweep material either into or out of the region according to the signs of v and the concentration gradient $\partial[J]/\partial x$.

(b) Solutions of the equation

The material balance equation is a second-order partial differential equation and is far from easy to solve in general. Some idea of how it is solved can be obtained by considering the special case in which there is no convective motion (as in an unstirred reaction vessel):

$$\frac{\partial[J]}{\partial t} = D \frac{\partial^2[J]}{\partial x^2} - k[J] \quad (24.39)$$

Fig. 24.6 The concentration profiles for a diffusing, reacting system (for example, a column of solution) in which one reactant is initially in a layer at $x = 0$. In the absence of reaction (grey lines) the concentration profiles are the same as in Fig. 21.26.

 **Exploration** Use the interactive applet found in the *Living graphs* section of the text's web site to explore the effect of varying the value of the rate constant k on the spatial variation of $[J]$ for a constant value of the diffusion constant D .

Comment 24.3

This chapter inevitably puts heavy demands on the letter K; the various meanings are summarized in Table 24.3 at the end of the chapter.

As may be verified by substitution, if the solution of this equation in the absence of reaction (that is, for $k = 0$) is $[J]$, then the solution in the presence of reaction ($k > 0$) is

$$[J]^* = k \int_0^t [J] e^{-kt} dt + [J] e^{-kt} \quad (24.40)$$

We have already met one solution of the diffusion equation in the absence of reaction: eqn 21.71 is the solution for a system in which initially a layer of $n_0 N_A$ molecules is spread over a plane of area A :

$$[J] = \frac{n_0 e^{-x^2/4Dt}}{A(\pi Dt)^{1/2}} \quad (24.41)$$

When this expression is substituted into eqn 24.40 and the integral is evaluated numerically, we obtain the concentration of J as it diffuses away from its initial surface layer and undergoes reaction in the solution above (Fig. 24.6).

Even this relatively simple example has led to an equation that is difficult to solve, and only in some special cases can the full material balance equation be solved analytically. Most modern work on reactor design and cell kinetics uses numerical methods to solve the equation, and detailed solutions for realistic environments, such as vessels of different shapes (which influence the boundary conditions on the solutions) and with a variety of inhomogeneously distributed reactants can be obtained reasonably easily.

Transition state theory

We saw in Section 22.5b that an activated complex forms between reactants as they collide and begin to assume the nuclear and electronic configurations characteristic of products. We also saw that the change in potential energy associated with formation of the activated complex accounts for the activation energy of the reaction. We now consider a more detailed calculation of rate constants which uses the concepts of statistical thermodynamics developed in Chapter 17. The approach we describe, which is called **transition state theory** (also widely referred to as *activated complex theory*), has the advantage that a quantity corresponding to the steric factor appears automatically, and P does not need to be grafted on to an equation as an afterthought. Transition state theory is an attempt to identify the principal features governing the size of a rate constant in terms of a model of the events that take place during the reaction. There are several approaches to the calculation, all of which lead to the same final expression (see *Further reading*); here we present the simplest approach.

24.4 The Eyring equation

Transition state theory pictures a reaction between A and B as proceeding through the formation of an activated complex, $C^\ddagger$, in a rapid pre-equilibrium (Fig. 24.7):

When we express the partial pressures, p_j , in terms of the molar concentrations, $[J]$, by using $p_j = RT[J]$, the concentration of activated complex is related to the (dimensionless) equilibrium constant by

$$[C^\ddagger] = \frac{RT}{p^\ominus} K^\ddagger [A][B] \quad (24.43)$$

The activated complex falls apart by unimolecular decay into products, P , with a rate constant $k^\ddagger$:

It follows that

$$v = k_2[A][B] \quad k_2 = \frac{RT}{p^\ominus} k^\ddagger K^\ddagger \quad (24.45)$$

Our task is to calculate the unimolecular rate constant $k^\ddagger$ and the equilibrium constant $K^\ddagger$.

(a) The rate of decay of the activated complex

An activated complex can form products if it passes through the **transition state**, the arrangement the atoms must achieve in order to convert to products (Section 22.5b). If its vibration-like motion along the reaction coordinate occurs with a frequency ν , then the frequency with which the cluster of atoms forming the complex approaches the transition state is also ν . However, it is possible that not every oscillation along the reaction coordinate takes the complex through the transition state. For instance, the centrifugal effect of rotations might also be an important contribution to the break-up of the complex, and in some cases the complex might be rotating too slowly, or rotating rapidly but about the wrong axis. Therefore, we suppose that the rate of passage of the complex through the transition state is proportional to the vibrational frequency along the reaction coordinate, and write

$$k^\ddagger = \kappa \nu \quad (24.46)$$

where κ is the **transmission coefficient**. In the absence of information to the contrary, κ is assumed to be about 1.

(b) The concentration of the activated complex

We saw in Section 17.8 how to calculate equilibrium constants from structural data. Equation 17.54 of that section can be used directly, which in this case gives

$$K^\ddagger = \frac{N_A q_{C^\ddagger}^\ominus}{q_A^\ominus q_B^\ominus} e^{-\Delta E_0/RT} \quad (24.47)$$

where $p^\ominus = 1$ bar and

$$\Delta E_0 = E_0(C^\ddagger) - E_0(A) - E_0(B) \quad (24.48)$$

The $q_j^\ominus$ are the standard molar partition functions, as defined in Section 17.1. Note that the units of N_A and the q_j are mol^{-1} , so $K^\ddagger$ is dimensionless (as is appropriate for an equilibrium constant).

In the final step of this part of the calculation, we focus attention on the partition function of the activated complex. We have already assumed that a vibration of the activated complex $C^\ddagger$ tips it through the transition state. The partition function for this vibration is

$$q = \frac{1}{1 - e^{-h\nu/kT}} \quad (24.49a)$$

where ν is its frequency (the same frequency that determines $k^\ddagger$). This frequency is much lower than for an ordinary molecular vibration because the oscillation corresponds to the complex falling apart (Fig. 24.8), so the force constant is very low.

Fig. 24.7 A reaction profile. The horizontal axis is the reaction coordinate, and the vertical axis is potential energy. The activated complex is the region near the potential maximum, and the transition state corresponds to the maximum itself.

Fig. 24.8 In an elementary depiction of the activated complex close to the transition state, there is a broad, shallow dip in the potential energy surface along the reaction coordinate. The complex vibrates harmonically and almost classically in this well. However, this depiction is an oversimplification, for in many cases there is no dip at the top of the barrier, and the curvature of the potential energy, and therefore the force constant, is negative. Formally, the vibrational frequency is then imaginary. We ignore this problem here, but see *Further reading*.

Therefore, provided that $h\nu/kT \ll 1$, the exponential may be expanded and the partition function reduces to

$$q = \frac{1}{1 - \left(1 - \frac{h\nu}{kT} + \dots\right)} \approx \frac{kT}{h\nu} \quad (24.49b)$$

We can therefore write

$$q_{C^\ddagger} \approx \frac{kT}{h\nu} \bar{q}_{C^\ddagger} \quad (24.50)$$

where $\bar{q}$ denotes the partition function for all the other modes of the complex. The constant $K^\ddagger$ is therefore

$$K^\ddagger = \frac{kT}{h\nu} \bar{K}^\ddagger \quad \bar{K}^\ddagger = \frac{N_A \bar{q}_{C^\ddagger}}{q_A^\ominus q_B^\ominus} e^{-\Delta E_0/RT} \quad (24.51)$$

with $\bar{K}^\ddagger$ a kind of equilibrium constant, but with one vibrational mode of $C^\ddagger$ discarded.

(c) The rate constant

We can now combine all the parts of the calculation into

$$k_2 = k^\ddagger \frac{RT}{p^\ominus} K^\ddagger = \kappa \nu \frac{kT}{h\nu} \frac{RT}{p^\ominus} \bar{K}^\ddagger \quad (24.52)$$

At this stage the unknown frequencies ν cancel and, after writing $\bar{K}_c^\ddagger = (RT/p^\ominus) \bar{K}^\ddagger$, we obtain the **Eyring equation**:

$$k_2 = \kappa \frac{kT}{h} \bar{K}_c^\ddagger \quad (24.53)$$

The factor $\bar{K}_c^\ddagger$ is given by eqn 24.51 and the definition $\bar{K}_c^\ddagger = (RT/p^\ominus) \bar{K}^\ddagger$ in terms of the partition functions of A, B, and $C^\ddagger$, so in principle we now have an explicit expression for calculating the second-order rate constant for a bimolecular reaction in terms of the molecular parameters for the reactants and the activated complex and the quantity κ .

The partition functions for the reactants can normally be calculated quite readily, using either spectroscopic information about their energy levels or the approximate expressions set out in Table 17.3. The difficulty with the Eyring equation, however, lies in the calculation of the partition function of the activated complex: $C^\ddagger$ is difficult to investigate spectroscopically (but see Section 24.9), and in general we need to make assumptions about its size, shape, and structure. We shall illustrate what is involved in one simple but significant case.

(d) The collision of structureless particles

Consider the case of two structureless particles A and B colliding to give an activated complex that resembles a diatomic molecule. Because the reactants $J = A, B$ are structureless ‘atoms’, the only contributions to their partition functions are the translational terms:

$$q_J^\ominus = \frac{V_m^\ominus}{\Lambda_J^3} \quad \Lambda_J = \frac{h}{(2\pi m_J kT)^{1/2}} \quad V_m^\ominus = \frac{RT}{p^\ominus} \quad (24.54)$$

The activated complex is a diatomic cluster of mass $m_C = m_A + m_B$ and moment of inertia I . It has one vibrational mode, but that mode corresponds to motion along the

reaction coordinate and therefore does not appear in $\bar{q}_{C^\ddagger}$. It follows that the standard molar partition function of the activated complex is

$$q_{C^\ddagger}^\ominus = \left(\frac{2IkT}{\hbar^2} \right) \frac{V_m^\ominus}{\Lambda_{C^\ddagger}^3} \quad (24.55)$$

The moment of inertia of a diatomic molecule of bond length r is μr^2 , where $\mu = m_A m_B / (m_A + m_B)$ is the effective mass, so the expression for the rate constant is

$$\begin{aligned} k_2 &= \kappa \frac{kT}{h} \frac{RT}{p^\ominus} \left(\frac{N_A \Lambda_A^3 \Lambda_B^3}{\Lambda_{C^\ddagger}^3 V_m^\ominus} \right) \left(\frac{2IkT}{\hbar^2} \right) e^{-\Delta E_0/RT} \\ &= \kappa \frac{kT}{h} N_A \left(\frac{\Lambda_A \Lambda_B}{\Lambda_{C^\ddagger}} \right) \left(\frac{2IkT}{\hbar^2} \right) e^{-\Delta E_0/RT} \\ &= \kappa N_A \left(\frac{8kT}{\pi\mu} \right)^{1/2} \pi r^2 e^{-\Delta E_0/RT} \end{aligned} \quad (24.56)$$

Finally, by identifying $\kappa \pi r^2$ as the reactive cross-section σ^* , we arrive at precisely the same expression as that obtained from simple collision theory (eqn 24.14).

24.5 Thermodynamic aspects

The statistical thermodynamic version of transition state theory rapidly runs into difficulties because only in some cases is anything known about the structure of the activated complex. However, the concepts that it introduces, principally that of an equilibrium between the reactants and the activated complex, have motivated a more general, empirical approach in which the activation process is expressed in terms of thermodynamic functions.

(a) Activation parameters

If we accept that $\bar{K}^\ddagger$ is an equilibrium constant (despite one mode of $C^\ddagger$ having been discarded), we can express it in terms of a **Gibbs energy of activation**, $\Delta^\ddagger G$, through the definition

$$\Delta^\ddagger G = -RT \ln \bar{K}^\ddagger \quad [24.57]$$

(All the $\Delta^\ddagger X$ in this section are *standard* thermodynamic quantities, $\Delta^\ddagger X^\ominus$, but we shall omit the standard state sign to avoid overburdening the notation). Then the rate constant becomes

$$k_2 = \kappa \frac{kT}{h} \frac{RT}{p^\ominus} e^{-\Delta^\ddagger G/RT} \quad (24.58)$$

Because $G = H - TS$, the Gibbs energy of activation can be divided into an **entropy of activation**, $\Delta^\ddagger S$, and an **enthalpy of activation**, $\Delta^\ddagger H$, by writing

$$\Delta^\ddagger G = \Delta^\ddagger H - T\Delta^\ddagger S \quad [24.59]$$

When eqn 24.59 is used in eqn 24.58 and κ is absorbed into the entropy term, we obtain

$$k_2 = B e^{\Delta^\ddagger S/R} e^{-\Delta^\ddagger H/RT} \quad B = \frac{kT}{h} \frac{RT}{p^\ominus} \quad (24.60)$$

The formal definition of activation energy, $E_a = RT^2(\partial \ln k / \partial T)$, then gives $E_a = \Delta^\ddagger H + 2RT$, so

$$k_2 = e^2 B e^{\Delta^\ddagger S/R} e^{-E_a/RT} \quad (24.61)$$

Comment 24.4

For reactions of the type $A + B \rightleftharpoons P$ in the gas phase, $E_a = \Delta^\ddagger H + 2RT$. For these reactions in solution, $E_a = \Delta^\ddagger H + RT$.

Fig. 24.9 For a related series of reactions, as the magnitude of the standard reaction Gibbs energy increases, so the activation barrier decreases. The approximate linear correlation between $\Delta^\ddagger G$ and $\Delta_r G^\circ$ is the origin of linear free energy relations.

from which it follows that the Arrhenius factor A can be identified as

$$A = e^2 B e^{\Delta^\ddagger S/R} \quad (24.62)$$

The entropy of activation is negative because two reactant species come together to form one species. However, if there is a reduction in entropy below what would be expected for the simple encounter of A and B, then A will be smaller than that expected on the basis of simple collision theory. Indeed, we can identify that additional reduction in entropy, $\Delta^\ddagger S_{\text{steric}}$, as the origin of the steric factor of collision theory, and write

$$P = e^{\Delta^\ddagger S_{\text{steric}}/R} \quad (24.63)$$

Thus, the more complex the steric requirements of the encounter, the more negative the value of $\Delta^\ddagger S_{\text{steric}}$, and the smaller the value of P .

Gibbs energies, enthalpies, entropies, volumes, and heat capacities of activation are widely used to report experimental reaction rates, especially for organic reactions in solution. They are encountered when relationships between equilibrium constants and rates of reaction are explored using **correlation analysis**, in which $\ln K$ (which is equal to $-\Delta_r G^\circ/RT$) is plotted against $\ln k$ (which is proportional to $-\Delta^\ddagger G/RT$). In many cases the correlation is linear, signifying that, as the reaction becomes thermodynamically more favourable, its rate constant increases (Fig. 24.9). This linear correlation is the origin of the alternative name **linear free energy relation** (LFER; see *Further reading*).

(b) Reactions between ions

The thermodynamic version of transition state theory simplifies the discussion of reactions in solution. The statistical thermodynamic theory is very complicated to apply because the solvent plays a role in the activated complex. In the thermodynamic approach we combine the rate law

$$\frac{d[P]}{dt} = k^\ddagger [C^\ddagger] \quad (24.64)$$

with the thermodynamic equilibrium constant

$$K = \frac{a_{C^\ddagger}}{a_A a_B} = K_\gamma \frac{[C^\ddagger]}{[A][B]} \quad K_\gamma = \frac{\gamma_{C^\ddagger}}{\gamma_A \gamma_B} \quad (24.65)$$

Then

$$\frac{d[P]}{dt} = k_2 [A][B] \quad k_2 = \frac{k^\ddagger K}{K_\gamma} \quad (24.66)$$

If k_2° is the rate constant when the activity coefficients are 1 (that is, $k_2^\circ = k^\ddagger K$), we can write

$$k_2 = \frac{k_2^\circ}{K_\gamma} \quad (24.67)$$

At low concentrations the activity coefficients can be expressed in terms of the ionic strength, I , of the solution by using the Debye–Hückel limiting law (Section 5.9, particularly eqn 5.69) in the form

$$\log \gamma_i = -A z_i^2 I^{1/2} \quad (24.68)$$

with $A = 0.509$ in aqueous solution at 298 K. Then

$$\log k_2 = \log k_2^\circ - A \{z_A^2 + z_B^2 - (z_A + z_B)^2\} I^{1/2} = \log k_2^\circ + 2A z_A z_B I^{1/2} \quad (24.69)$$

The charge numbers of A and B are z_A and z_B , so the charge number of the activated complex is $z_A + z_B$; the z_i are positive for cations and negative for anions.

Equation 24.69 expresses the **kinetic salt effect**, the variation of the rate constant of a reaction between ions with the ionic strength of the solution (Fig. 24.10). If the reactant ions have the same sign (as in a reaction between cations or between anions), then increasing the ionic strength by the addition of inert ions increases the rate constant. The formation of a single, highly charged ionic complex from two less highly charged ions is favoured by a high ionic strength because the new ion has a denser ionic atmosphere and interacts with that atmosphere more strongly. Conversely, ions of opposite charge react more slowly in solutions of high ionic strength. Now the charges cancel and the complex has a less favourable interaction with its atmosphere than the separated ions.

Fig. 24.10 Experimental tests of the kinetic salt effect for reactions in water at 298 K. The ion types are shown as spheres, and the slopes of the lines are those given by the Debye–Hückel limiting law and eqn 24.69.

Fig. 24.11 The experimental ionic strength dependence of the rate constant of a hydrolysis reaction: the slope gives information about the charge types involved in the activated complex of the rate-determining step. See Example 24.3.

Example 24.3 Analysing the kinetic salt effect

The rate constant for the base hydrolysis of $[\text{CoBr}(\text{NH}_3)_5]^{2+}$ varies with ionic strength as tabulated below. What can be deduced about the charge of the activated complex in the rate-determining stage?

I	0.0050	0.0100	0.0150	0.0200	0.0250	0.0300
k/k°	0.718	0.631	0.562	0.515	0.475	0.447

Method According to eqn 24.69, plot $\log(k/k^\circ)$ against $I^{1/2}$, when the slope will give $1.02z_A z_B$, from which we can infer the charges of the ions involved in the formation of the activated complex.

Answer Form the following table:

I	0.0050	0.0100	0.0150	0.0200	0.0250	0.0300
$I^{1/2}$	0.071	0.100	0.122	0.141	0.158	0.173
$\log(k/k^\circ)$	-0.14	-0.20	-0.25	-0.29	-0.32	-0.35

These points are plotted in Fig. 24.11. The slope of the (least squares) straight line is -2.04 , indicating that $z_A z_B = -2$. Because $z_A = -1$ for the OH^- ion, if that ion is involved in the formation of the activated complex, then the charge number of the second ion is $+2$. This analysis suggests that the pentaamminebromocobalt(III) cation participates in the formation of the activated complex. The rate constant is also influenced by the relative permittivity of the medium.

Self-test 24.3 An ion of charge number $+1$ is known to be involved in the activated complex of a reaction. Deduce the charge number of the other ion from the following data:

I	0.0050	0.010	0.015	0.020	0.025	0.030
k/k°	0.930	0.902	0.884	0.867	0.853	0.841

$[-1]$

The dynamics of molecular collisions

We now come to the third and most detailed level of our examination of the factors that govern the rates of reactions.

Fig. 24.12 In a crossed-beam experiment, state-selected molecules are generated in two separate sources, and are directed perpendicular to one another. The detector responds to molecules (which may be product molecules if chemical reaction occurs) scattered into a chosen direction.

Fig. 24.13 Infrared chemiluminescence from CO produced in the reaction $\text{O} + \text{CS} \rightarrow \text{CO} + \text{S}$ arises from the non-equilibrium populations of the vibrational states of CO and the radiative relaxation to equilibrium.

24.6 Reactive collisions

Molecular beams allow us to study collisions between molecules in preselected energy states, and can be used to determine the states of the products of a reactive collision. Information of this kind is essential if a full picture of the reaction is to be built, because the rate constant is an average over events in which reactants in different initial states evolve into products in their final states.

(a) Experimental probes of reactive collisions

Detailed experimental information about the intimate processes that occur during reactive encounters comes from molecular beams, especially crossed molecular beams (Fig. 24.12). The detector for the products of the collision of two beams can be moved to different angles, so the angular distribution of the products can be determined. Because the molecules in the incoming beams can be prepared with different energies (for example, with different translational energies by using rotating sectors and supersonic nozzles, with different vibrational energies by using selective excitation with lasers, as shown in Section 24.9b, and with different orientations (by using electric fields), it is possible to study the dependence of the success of collisions on these variables and to study how they affect the properties of the outcoming product molecules.

One method for examining the energy distribution in the products is **infrared chemiluminescence**, in which vibrationally excited molecules emit infrared radiation as they return to their ground states. By studying the intensities of the infrared emission spectrum, the populations of the vibrational states may be determined (Fig. 24.13). Another method makes use of **laser-induced fluorescence**. In this technique, a laser is used to excite a product molecule from a specific vibration-rotation level; the intensity of the fluorescence from the upper state is monitored and interpreted in terms of the population of the initial vibration-rotation state. When the molecules being studied do not fluoresce efficiently, coherent anti-Stokes Raman spectroscopy (CARS, Section 13.16) can be used to monitor the progress of reaction. **Multiphoton ionization** (MPI) techniques are also good alternatives for the study of weakly fluorescing molecules. In MPI, the absorption of several photons by a molecule results in ionization if the total photon energy is greater than the ionization energy of the molecule. One or more pulsed lasers are used to generate the molecular ions, which are commonly detected by time-of-flight mass spectrometry (TOF-MS, Section 19.2). The angular distribution of products can also be determined by **reaction product imaging**. In this technique, product ions are accelerated by an electric field towards a phosphorescent screen and the light emitted from specific spots where the ions struck the screen is imaged by a charge-coupled device (CCD, *Further information* 13.1). An important variant of MPI is **resonant multiphoton ionization** (REMPI), in which one or more photons promote a molecule to an electronically excited state and then additional photons are used to generate ions from the excited state. The power of REMPI lies in the fact that the experimenter can choose which reactant or product to study by tuning the laser frequency to the electronic absorption band of a specific molecule.

(b) State-to-state dynamics

The concept of collision cross-section was introduced in connection with collision theory in Section 24.1, where we saw that the second-order rate constant, k_2 , can be expressed as a Boltzmann-weighted average of the reactive collision cross-section and the relative speed of approach. We shall write eqn 24.12 as

$$k_2 = \langle \sigma v_{\text{rel}} \rangle N_A \quad (24.70)$$

where the angle brackets denote a Boltzmann average. Molecular beam studies provide a more sophisticated version of this quantity, for they provide the **state-to-state cross-section**, $\sigma_{nn'}$, and hence the **state-to-state rate constant**, $k_{nn'}$:

$$k_{nn'} = \langle \sigma_{nn'} v_{\text{rel}} \rangle N_A \quad (24.71)$$

The rate constant k_2 is the sum of the state-to-state rate constant over all final states (because a reaction is successful whatever the final state of the products) and over a Boltzmann-weighted sum of initial states (because the reactants are initially present with a characteristic distribution of populations at a temperature T):

$$k_2 = \sum_{n,n'} k_{nn'}(T) f_n(T) \quad (24.72)$$

where $f_n(T)$ is the Boltzmann factor at a temperature T . It follows that, if we can determine or calculate the state-to-state cross-sections for a wide range of approach speeds and initial and final states, then we have a route to the calculation of the rate constant for the reaction.

24.7 Potential energy surfaces

One of the most important concepts for discussing beam results and calculating the state-to-state collision cross-section is the **potential energy surface** of a reaction, the potential energy as a function of the relative positions of all the atoms taking part in the reaction. Potential energy surfaces may be constructed from experimental data, with the techniques described in Section 24.6, and from results of quantum chemical calculations (Section 11.7). The theoretical method requires the systematic calculation of the energies of the system in a large number of geometrical arrangements. Special computational techniques are used to take into account electron correlation, which arises from instantaneous interactions between electrons as they move closer to and farther from each other in molecule or molecular cluster. Techniques that incorporate electron correlation are very time-consuming and, consequently, only reactions between relatively small particles, such as the reactions $\text{H} + \text{H}_2 \rightarrow \text{H}_2 + \text{H}$ and $\text{H} + \text{H}_2\text{O} \rightarrow \text{OH} + \text{H}_2$, are amenable to this type of theoretical treatment. An alternative is to use semi-empirical methods, in which results of calculations and experimental parameters are used to construct the potential energy surface.

To illustrate the features of a potential energy surface we consider the collision between an H atom and an H_2 molecule. Detailed calculations show that the approach of an atom along the H—H axis requires less energy for reaction than any other approach, so initially we confine our attention to a collinear approach. Two parameters are required to define the nuclear separations: one is the H_A — H_B separation R_{AB} , and the other is the H_B — H_C separation R_{BC} .

At the start of the encounter R_{AB} is infinite and R_{BC} is the H_2 equilibrium bond length. At the end of a successful reactive encounter R_{AB} is equal to the equilibrium bond length and R_{BC} is infinite. The total energy of the three-atom system depends on their relative separations, and can be found by doing a molecular orbital calculation. The plot of the total energy of the system against R_{AB} and R_{BC} gives the potential energy surface of this collinear reaction (Fig. 24.14). This surface is normally depicted as a contour diagram (Fig. 24.15).

When R_{AB} is very large, the variations in potential energy represented by the surface as R_{BC} changes are those of an isolated H_2 molecule as its bond length is altered. A section through the surface at $R_{\text{AB}} = \infty$, for example, is the same as the H_2 bonding potential energy curve drawn in Fig. 11.16. At the edge of the diagram where R_{BC} is very large, a section through the surface is the molecular potential energy curve of an isolated $\text{H}_\text{A}\text{H}_\text{B}$ molecule.

Fig. 24.14 The potential energy surface for the $\text{H} + \text{H}_2 \rightarrow \text{H}_2 + \text{H}$ reaction when the atoms are constrained to be collinear.

Fig. 24.15 The contour diagram (with contours of equal potential energy) corresponding to the surface in Fig. 24.14. R_e marks the equilibrium bond length of an H_2 molecule (strictly, it relates to the arrangement when the third atom is at infinity).

Fig. 24.16 Various trajectories through the potential energy surface shown in Fig. 24.15. Path A corresponds to a route in which R_{BC} is held constant as H_A approaches; path B corresponds to a route in which R_{BC} lengthens at an early stage during the approach of H_A ; path C is the route along the floor of the potential valley.

Fig. 24.17 The transition state is a set of configurations (here, marked by the line across the saddle point) through which successful reactive trajectories must pass.

The actual path of the atoms in the course of the encounter depends on their total energy, the sum of their kinetic and potential energies. However, we can obtain an initial idea of the paths available to the system for paths that correspond to least potential energy. For example, consider the changes in potential energy as H_A approaches H_BH_C . If the H_B-H_C bond length is constant during the initial approach of H_A , then the potential energy of the H_3 cluster rises along the path marked A in Fig. 24.16. We see that the potential energy reaches a high value as H_A is pushed into the molecule and then decreases sharply as H_C breaks off and separates to a great distance. An alternative reaction path can be imagined (B) in which the H_B-H_C bond length increases while H_A is still far away. Both paths, although feasible if the molecules have sufficient initial kinetic energy, take the three atoms to regions of high potential energy in the course of the encounter.

The path of least potential energy is the one marked C, corresponding to R_{BC} lengthening as H_A approaches and begins to form a bond with H_B . The H_B-H_C bond relaxes at the demand of the incoming atom, and the potential energy climbs only as far as the saddle-shaped region of the surface, to the **saddle point** marked $C^\ddagger$. The encounter of least potential energy is one in which the atoms take route C up the floor of the valley, through the saddle point, and down the floor of the other valley as H_C recedes and the new H_A-H_B bond achieves its equilibrium length. This path is the reaction coordinate we met in Section 24.4.

We can now make contact with the transition state theory of reaction rates. In terms of trajectories on potential surfaces, the transition state can be identified with a critical geometry such that every trajectory that goes through this geometry goes on to react (Fig. 24.17).

24.8 Some results from experiments and calculations

To travel successfully from reactants to products the incoming molecules must possess enough kinetic energy to be able to climb to the saddle point of the potential surface. Therefore, the shape of the surface can be explored experimentally by changing the relative speed of approach (by selecting the beam velocity) and the degree of vibrational excitation and observing whether reaction occurs and whether the products emerge in a vibrationally excited state (Fig. 24.18). For example, one question that can be answered is whether it is better to smash the reactants together with a lot of translational kinetic energy or to ensure instead that they approach in highly excited vibrational states. Thus, is trajectory $C_2^\ddagger$, where the H_BH_C molecule is initially vibrationally excited, more efficient at leading to reaction than the trajectory $C_1^\ddagger$, in which the total energy is the same but has a high translational kinetic energy?

(a) The direction of attack and separation

Figure 24.19 shows the results of a calculation of the potential energy as an H atom approaches an H_2 molecule from different angles, the H_2 bond being allowed to relax to the optimum length in each case. The potential barrier is least for collinear attack, as we assumed earlier. (But we must be aware that other lines of attack are feasible and contribute to the overall rate.) In contrast, Fig. 24.20 shows the potential energy changes that occur as a Cl atom approaches an HI molecule. The lowest barrier occurs for approaches within a cone of half-angle 30° surrounding the H atom. The relevance of this result to the calculation of the steric factor of collision theory should be noted: not every collision is successful, because not every one lies within the reactive cone.

If the collision is sticky, so that when the reactants collide they orbit around each other, the products can be expected to emerge in random directions because all

Fig. 24.18 Some successful (*) and unsuccessful encounters. (a) C_1^* corresponds to the path along the foot of the valley. (b) C_2^* corresponds to an approach of A to a vibrating BC molecule, and the formation of a vibrating AB molecule as C departs. (c) C_3 corresponds to A approaching a non-vibrating BC molecule, but with insufficient translational kinetic energy. (d) C_4 corresponds to A approaching a vibrating BC molecule, but still the energy, and the phase of the vibration, is insufficient for reaction.

memory of the approach direction has been lost. A rotation takes about 1 ps, so if the collision is over in less than that time the complex will not have had time to rotate and the products will be thrown off in a specific direction. In the collision of K and I_2 , for example, most of the products are thrown off in the forward direction. This product distribution is consistent with the harpoon mechanism (Section 24.1c) because the transition takes place at long range. In contrast, the collision of K with CH_3I leads to reaction only if the molecules approach each other very closely. In this mechanism, K effectively bumps into a brick wall, and the KI product bounces out in the backward direction. The detection of this anisotropy in the angular distribution of products gives an indication of the distance and orientation of approach needed for reaction, as well as showing that the event is complete in less than 1 ps.

(b) Attractive and repulsive surfaces

Some reactions are very sensitive to whether the energy has been predigested into a vibrational mode or left as the relative translational kinetic energy of the colliding molecules. For example, if two HI molecules are hurled together with more than twice the activation energy of the reaction, then no reaction occurs if all the energy is translational. For $F + HCl \rightarrow Cl + HF$, for example, the reaction is about five times as efficient when the HCl is in its first vibrational excited state than when, although HCl has the same total energy, it is in its vibrational ground state.

Fig. 24.19 An indication of the anisotropy of the potential energy changes as H_2 with different angles of attack. The collinear attack has the lowest potential barrier to reaction. The surface indicates the potential energy profile along the reaction coordinate for each configuration.

Fig. 24.20 The potential energy barrier for the approach of Cl to HI. In this case, successful encounters occur only when Cl approaches within a cone surrounding the H atom.

Comment 24.5

In molecular beam work the remarks we make in our discussion normally refer to directions in a centre-of-mass coordinate system. The origin of the coordinates is the centre of mass of the colliding reactants, and the collision takes place when the molecules are at the origin. The way in which centre-of-mass coordinates are constructed and the events in them interpreted involves too much detail for our present purposes, but we should bear in mind that ‘forward’ and ‘backward’ have unconventional meanings. The details are explained in the books in *Further reading*.

Fig. 24.21 An attractive potential energy surface. A successful encounter (C^*) involves high translational kinetic energy and results in a vibrationally excited product.

Fig. 24.22 A repulsive potential energy surface. A successful encounter (C^*) involves initial vibrational excitation and the products have high translational kinetic energy. A reaction that is attractive in one direction is repulsive in the reverse direction.

The origin of these requirements can be found by examining the potential energy surface. Figure 24.21 shows an **attractive surface** in which the saddle point occurs early in the reaction coordinate. Figure 24.22 shows a **repulsive surface** in which the saddle point occurs late. A surface that is attractive in one direction is repulsive in the reverse direction.

Consider first the attractive surface. If the original molecule is vibrationally excited, then a collision with an incoming molecule takes the system along C . This path is bottled up in the region of the reactants, and does not take the system to the saddle point. If, however, the same amount of energy is present solely as translational kinetic energy, then the system moves along C^* and travels smoothly over the saddle point into products. We can therefore conclude that reactions with attractive potential energy surfaces proceed more efficiently if the energy is in relative translational motion. Moreover, the potential surface shows that once past the saddle point the trajectory runs up the steep wall of the product valley, and then rolls from side to side as it falls to the foot of the valley as the products separate. In other words, the products emerge in a vibrationally excited state.

Now consider the repulsive surface (Fig. 24.22). On trajectory C the collisional energy is largely in translation. As the reactants approach, the potential energy rises. Their path takes them up the opposing face of the valley, and they are reflected back into the reactant region. This path corresponds to an unsuccessful encounter, even though the energy is sufficient for reaction. On C^* some of the energy is in the vibration of the reactant molecule and the motion causes the trajectory to weave from side to side up the valley as it approaches the saddle point. This motion may be sufficient to tip the system round the corner to the saddle point and then on to products. In this case, the product molecule is expected to be in an unexcited vibrational state. Reactions with repulsive potential surfaces can therefore be expected to proceed more efficiently if the excess energy is present as vibrations. This is the case with the $\text{H} + \text{Cl}_2 \rightarrow \text{HCl} + \text{Cl}$ reaction, for instance.

(c) Classical trajectories

A clear picture of the reaction event can be obtained by using classical mechanics to calculate the trajectories of the atoms taking place in a reaction from a set of initial conditions, such as velocities, relative orientations, and internal energies of the reacting

particles. The initial values used for the internal energy reflect the quantization of electronic, vibrational, and rotational energies in molecules but the features of quantum mechanics are not used explicitly in the calculation of the trajectory.

Figure 24.23 shows the result of such a calculation of the positions of the three atoms in the reaction $\text{H} + \text{H}_2 \rightarrow \text{H}_2 + \text{H}$, the horizontal coordinate now being time and the vertical coordinate the separations. This illustration shows clearly the vibration of the original molecule and the approach of the attacking atom. The reaction itself, the switch of partners, takes place very rapidly and is an example of a **direct mode process**. The newly formed molecule shakes, but quickly settles down to steady, harmonic vibration as the expelled atom departs. In contrast, Fig. 24.24 shows an example of a **complex mode process**, in which the activated complex survives for an extended period. The reaction in the illustration is the exchange reaction $\text{KCl} + \text{NaBr} \rightarrow \text{KBr} + \text{NaCl}$. The tetratomic activated complex survives for about 5 ps, during which time the atoms make about 15 oscillations before dissociating into products.

(d) Quantum mechanical scattering theory

Classical trajectory calculations do not recognize the fact that the motion of atoms, electrons, and nuclei is governed by quantum mechanics. The concept of trajectory then fades and is replaced by the unfolding of a wavefunction that represents initially the reactants and finally products.

Complete quantum mechanical calculations of trajectories and rate constants are very onerous because it is necessary to take into account all the allowed electronic, vibrational, and rotational states populated by each atom and molecule in the system at a given temperature. It is common to define a 'channel' as a group of molecules in well-defined quantum mechanically allowed states. Then, at a given temperature, there are many channels that represent the reactants and many channels that represent possible products, with some transitions between channels being allowed but others not allowed. Furthermore, not every transition leads to a chemical reaction. For example, the process $\text{H}_2^* + \text{OH} \rightarrow \text{H}_2 + (\text{OH})^*$, where the asterisk denotes an excited state, amounts to energy transfer between H_2 and OH , whereas the process $\text{H}_2^* + \text{OH} \rightarrow \text{H}_2\text{O} + \text{H}$ represents a chemical reaction. What complicates a quantum mechanical calculation of trajectories and rate constants even in this simple four-atom system is that many reacting channels present at a given temperature can lead to the desired products $\text{H}_2\text{O} + \text{H}$, which themselves may be formed as many distinct channels. The **cumulative reaction probability**, $N(E)$, at a fixed total energy E is then written as

$$N(E) = \sum_{i,j} P_{ij}(E) \quad (24.73)$$

Fig. 24.23 The calculated trajectories for a reactive encounter between A and a vibrating BC molecule leading to the formation of a vibrating AB molecule. This direct-mode reaction is between H and H_2 . (M. Karplus, R.N. Porter, and R.D. Sharma, *J. Chem. Phys.*, **43**, 3258 (1965).)

Fig. 24.24 An example of the trajectories calculated for a complex-mode reaction, $\text{KCl} + \text{NaBr} \rightarrow \text{KBr} + \text{NaCl}$, in which the collision cluster has a long lifetime. (P. Brumer and M. Karplus, *Faraday Disc. Chem. Soc.*, **55**, 80 (1973).)

where $P_{ij}(E)$ is the probability for a transition between a reacting channel i and a product channel j and the summation is over all possible transitions that lead to product. It is then possible to show that the rate constant is given by

$$k(T) = \frac{\int_0^\infty N(E) e^{-E/kT} dE}{hQ_r(T)} \quad (24.74)$$

where $Q_r(T)$ is the partition function density (the partition function divided by the volume) of the reactants at the temperature T . The significance of eqn 24.74 is that it provides a direct connection between an experimental quantity, the rate constant, and a theoretical quantity, $N(E)$.

24.9 The investigation of reaction dynamics with ultrafast laser techniques

The development of femtosecond pulsed lasers (Section 14.6) has made it possible to make observations on species that have such short lifetimes that in a number of respects they resemble an activated complex. Pulsed-laser techniques can also be used to control the outcome of chemical reactions.

(a) Spectroscopic observation of the activated complex

Until very recently there were no direct spectroscopic observations on activated complexes, for they have a very fleeting existence and often survive for only a few picoseconds. In a typical experiment designed to detect an activated complex, a femtosecond laser pulse is used to excite a molecule to a dissociative state, and then a second femtosecond pulse is fired at an interval after the dissociating pulse. The frequency of the second pulse is set at an absorption of one of the free fragmentation products, so its absorption is a measure of the abundance of the dissociation product. For example, when ICN is dissociated by the first pulse, the emergence of CN from the photoactivated state can be monitored by watching the growth of the free CN absorption (or, more commonly, its laser-induced fluorescence). In this way it has been found that the CN signal remains zero until the fragments have separated by about 600 pm, which takes about 205 fs.

Some sense of the progress that has been made in the study of the intimate mechanism of chemical reactions can be obtained by considering the decay of the ion pair Na^+I^- . As shown in Fig. 24.25, excitation of the ionic species with a femtosecond laser pulse forms an excited state that corresponds to a covalently bonded NaI molecule. The system can be described with two potential energy surfaces, one largely ‘ionic’ and another ‘covalent’, which cross at an internuclear separation of 693 pm. A short laser pulse is composed of a wide range of frequencies, which excite many vibrational states of NaI simultaneously. Consequently, the electronically excited complex exists as a superposition of states, or a localized wavepacket (Section 8.6), which oscillates between the ‘covalent’ and ‘ionic’ potential energy surfaces, as shown in Fig. 24.25. The complex can also dissociate, shown as movement of the wavepacket toward very long internuclear separation along the dissociative surface. However, not every outward-going swing leads to dissociation because there is a chance that the I atom can be harpooned again, in which case it fails to make good its escape. The dynamics of the system is probed by a second laser pulse with a frequency that corresponds to the absorption frequency of the free Na product or to the frequency at which Na absorbs when it is a part of the complex. The latter frequency depends on the $\text{Na}\cdots\text{I}$ distance, so an absorption (in practice, a laser-induced fluorescence) is obtained each time the wavepacket returns to that separation.

Fig. 24.25 Excitation of the ion pair Na^+I^- forms an excited state with covalent character. Also shown is movement between a ‘covalent’ surface (in green) and an ‘ionic’ surface (in purple) of the wavepacket formed by laser excitation.

A typical set of results is shown in Fig. 24.26. The bound Na absorption intensity shows up as a series of pulses that recur in about 1 ps, showing that the wavepacket oscillates with about that period. The decline in intensity shows the rate at which the complex can dissociate as the two atoms swing away from each other. The free Na absorption also grows in an oscillating manner, showing the periodicity of wavepacket oscillation, each swing of which gives it a chance to dissociate. The precise period of the oscillation in NaI is 1.25 ps, corresponding to a vibrational wavenumber of 27 cm^{-1} (recall that the activated complex theory assumes that such a vibration has a very low frequency). The complex survives for about ten oscillations. In contrast, although the oscillation frequency of NaBr is similar, it barely survives one oscillation.

Femtosecond spectroscopy has also been used to examine analogues of the activated complex involved in bimolecular reactions. Thus, a molecular beam can be used to produce a van der Waals molecule (Section 18.6), such as $\text{IH}\cdots\text{OCO}$. The HI bond can be dissociated by a femtosecond pulse, and the H atom is ejected towards the O atom of the neighbouring CO_2 molecule to form HOCO. Hence, the van der Waals molecule is a source of a species that resembles the activated complex of the reaction

The probe pulse is tuned to the OH radical, which enables the evolution of $[\text{HOCO}]^\ddagger$ to be studied in real time. Femtosecond transition state spectroscopy has also been used to study more complex reactions, such as the Diels–Alder reaction, nucleophilic substitution reactions, and pericyclic addition and cleavage reactions. Biological processes that are open to study by femtosecond spectroscopy include the energy-converting processes of photosynthesis and the photostimulated processes of vision. In other experiments, the photoejection of carbon monoxide from myoglobin and the attachment of O_2 to the exposed site have been studied to obtain rate constants for the two processes.

(b) Controlling chemical reactions with lasers

A long-standing goal of chemistry is to control the rate and distribution of products in chemical reactions, with an eye toward minimizing undesirable side reactions and improving the efficiency of industrial processes. We already have at our disposal a number of successful strategies for achieving this goal. For example, it is possible to synthesize a catalyst that accelerates a specific type of reaction but not others, so a desired product may be formed more quickly than an undesired product. However, this strategy is not very general, as a new catalyst needs to be developed for every reaction type of interest. A more ambitious and potentially more powerful strategy consists of using lasers to prepare specific states of reactant molecules that lead to a specific activated complex and hence a specific product, perhaps not even the major product isolated under ordinary laboratory conditions. Here we examine two ways in which the outcome of a chemical reaction can be affected by laser irradiation.

Some reactions may be controlled by exciting the reactants to different vibrational states. Consider the gas-phase reaction between H and HOD. It has been observed that H_2 and OD are the preferred products when thermally equilibrated H atoms react with vibrationally excited HOD molecules prepared by laser irradiation at a wavelength that excites the H–OD stretching mode from the $v=0$ to the $v=4$ energy level. On the other hand, when the same stretching mode is excited to the $v=5$ energy level, HD and OH are the preferred products. This control strategy is commonly referred to as *mode-selective chemistry* and has been used to alter product distributions in a number of bimolecular reactions. However, the technique is limited to those cases in which energy can be deposited and remains localized in the desired vibrational mode of the reactant for a time that is much longer than the reaction time. This is difficult to

Fig. 24.26 Femtosecond spectroscopic results for the reaction in which sodium iodide separates into Na and I. The lower curve is the absorption of the electronically excited complex and the upper curve is the absorption of free Na atoms (Adapted from A.H. Zewail, *Science* **242**, 1645 (1988)).

achieve in large molecules, in which intramolecular vibrational relaxation redistributes energy among the many vibrational modes within a few picoseconds.

A strategy that seeks to avoid the problem of vibrational relaxation uses ultrafast lasers and is related closely to the techniques used for the spectroscopic detection of transition states. Consider the reaction $\text{I}_2 + \text{Xe} \rightarrow \text{XeI}^* + \text{I}$, which occurs via a harpoon mechanism with a transition state denoted as $[\text{Xe}^+ \cdots \text{I}^- \cdots \text{I}]$. The reaction can be initiated by exciting I_2 to an electronic state at least $52\,460\text{ cm}^{-1}$ above the ground state and then followed by measuring the time dependence of the chemiluminescence of XeI^* . To exert control over the yield of the product, a pair of femtosecond pulses can be used to induce the reaction. The first pulse excites the I_2 molecule to a low energy and unreactive electronic state. We already know that excitation by a femtosecond pulse generates a wavepacket that can be treated as a particle travelling across the potential energy surface. In this case, the wavepacket does not have enough energy to react, but excitation by another laser pulse with the proper wavelength can provide the necessary additional energy. It follows that activated complexes with different geometries can be prepared by varying the time delay between the two pulses, as the partially localized wave packet will be at different locations along the potential energy surface as it evolves after being formed by the first pulse. Because the reaction occurs via the harpoon mechanism, the product yield is expected to be optimal if the second pulse is applied when the wave packet is at a point where the $\text{Xe} \cdots \text{I}_2$ distance is just right for electron transfer from Xe to I_2 to occur (see Example 24.2). This type of control of the $\text{I}_2 + \text{Xe}$ reaction has been demonstrated.

So far, the control techniques we have discussed have only been applied to reactions between relatively small molecules, with simple and well-understood potential energy surfaces. Extension of these techniques to the controlled synthesis of materials in routine laboratory work will require much more sophisticated knowledge of how laser pulses may be combined to stimulate a specific molecular response in a complex system.

Electron transfer in homogeneous systems

We end the chapter by applying the concepts of transition state theory and quantum theory to the study of a deceptively simple process, electron transfer between molecules in homogeneous systems. We begin by examining the features of a theory that describes the factors governing the rates of electron transfer. Then, we discuss the theory in the light of experimental results on a variety of systems, including protein complexes. We shall see that relatively simple expressions may be used to predict the rates of electron transfer with reasonable accuracy.

24.10 The rates of electron transfer processes

Consider electron transfer from a donor species D to an acceptor species A in solution. The net reaction is

In the first step of the mechanism, D and A must diffuse through the solution and collide to form a complex DA, in which the donor and acceptor are separated by a distance comparable to r , the distance between the edges of each species. We assume that D, A, and DA are in equilibrium:

$$D + A \rightleftharpoons DA \quad K_{DA} = \frac{k_a}{k'_a} = \frac{[DA]}{[D][A]} \quad (24.76a)$$

where k_a and k'_a are, respectively, the rate constants for the association and dissociation of the DA complex. Next, electron transfer occurs within the DA complex to yield D^+A^- :

where k_{et} is the first-order rate constant for the forward electron transfer step. The D^+A^- complex has two possible fates. First, reverse electron transfer with a rate constant k_r can regenerate DA:

Second, D^+A^- can break apart and the ions diffuse through the solution:

We show in the following *Justification* that

$$\frac{1}{k_{obs}} = \frac{1}{k_a} + \frac{k'_a}{k_a k_{et}} \left(1 + \frac{k_r}{k_d} \right) \quad (24.77)$$

Justification 24.4 *The rate constant for electron transfer in solution*

To find an expression for the second-order rate constant k_{obs} for electron transfer between D and A in solution, we begin by equating the rate of the net reaction (eqn 24.75) to the rate of formation of separated ions, the reaction products (eqn 24.76d):

$$v = k_{obs}[D][A] = k_d[D^+A^-]$$

Now we apply the steady-state approximation to the intermediate D^+A^- :

$$\frac{d[D^+A^-]}{dt} = k_{et}[DA] - k_r[D^+A^-] - k_d[D^+A^-] = 0$$

It follows that

$$[D^+A^-] = \frac{k_{et}}{k_r + k_d} [DA]$$

However, DA is also an intermediate so we apply the steady-state approximation again

$$\frac{d[DA]}{dt} = k_a[D][A] - k'_a[DA] - k_{et}[DA] + k_r[D^+A^-] = 0$$

Substitution of the initial expression for the steady-state concentration of D^+A^- into this expression for $[DA]$ gives, after some algebra, a new expression for $[D^+A^-]$:

$$[D^+A^-] = \frac{k_a k_{et}}{k'_a k_r + k'_a k_d + k_d k_{et}} [D][A]$$

When we multiply this expression by k_d , we see that the resulting equation has the form of the rate of electron transfer, $v = k_{obs}[D][A]$, with k_{obs} given by

$$k_{obs} = \frac{k_d k_a k_{et}}{k'_a k_r + k'_a k_d + k_d k_{et}}$$

To obtain eqn 24.77, we divide the numerator and denominator on the right-hand side of this expression by $k_d k_{et}$ and solve for the reciprocal of k_{obs} .

To gain insight into eqn 24.77 and the factors that determine the rate of electron transfer reactions in solution, we assume that the main decay route for D^+A^- is dissociation of the complex into separated ions, or $k_d \gg k_t$. It follows that

$$\frac{1}{k_{\text{obs}}} \approx \frac{1}{k_a} \left(1 + \frac{k'_a}{k_{\text{et}}} \right)$$

When $k_{\text{et}} \gg k'_a$, we see that $k_{\text{obs}} \approx k_a$ and the rate of product formation is controlled by diffusion of D and A in solution, which fosters formation of the DA complex. When $k_{\text{et}} \ll k'_a$, we see that $k_{\text{obs}} \approx (k_a/k'_a)k_{\text{et}}$ or, after using eqn 24.76a,

$$k_{\text{obs}} \approx K_{\text{DA}}k_{\text{et}} \quad (24.78)$$

and the process is controlled by the activation energy of electron transfer in the DA complex. Using transition state theory (Section 24.4), we write

$$k_{\text{et}} = \kappa \nu e^{-\Delta^\ddagger G/RT} \quad (24.79)$$

where κ is the transmission coefficient, ν is the vibrational frequency with which the activated complex approaches the transition state, and $\Delta^\ddagger G$ is the Gibbs energy of activation. Our first task is to write theoretical expressions for $\kappa \nu$ and $\Delta^\ddagger G$ by describing the motions of electrons and nuclei mathematically.

24.11 Theory of electron transfer processes

Our discussion concentrates on the following two key aspects of the theory, which was developed independently by R.A. Marcus, N.S. Hush, V.G. Levich, and R.R. Dogonadze:

- 1 Electrons are transferred by tunnelling through a potential energy barrier, the height of which is partly determined by the ionization energies of the DA and D^+A^- complexes. Electron tunnelling influences the magnitude of $\kappa \nu$.
- 2 The complex DA and the solvent molecules surrounding it undergo structural rearrangements prior to electron transfer. The energy associated with these rearrangements and the standard reaction Gibbs energy determine $\Delta^\ddagger G$.

(a) Electron tunnelling

We saw in Section 14.2 that, according to the Franck–Condon principle, electronic transitions are so fast that they can be regarded as taking place in a stationary nuclear framework. This principle also applies to an electron transfer process in which an electron migrates from one energy surface, representing the dependence of the energy of DA on its geometry, to another representing the energy of D^+A^- . We can represent the potential energy (and the Gibbs energy) surfaces of the two complexes (the reactant complex, DA, and the product complex, D^+A^-) by the parabolas characteristic of harmonic oscillators, with the displacement coordinate corresponding to the changing geometries (Fig. 24.27). This coordinate represents a collective mode of the donor, acceptor, and solvent.

According to the Franck–Condon principle, the nuclei do not have time to move when the system passes from the reactant to the product surface as a result of the transfer of an electron. Therefore, electron transfer can occur only after thermal fluctuations bring the geometry of DA to q^* in Fig. 24.27, the value of the nuclear coordinate at which the two parabolas intersect.

The factor $\kappa \nu$ is a measure of the probability that the system will convert from reactants (DA) to products (D^+A^-) at q^* by electron transfer within the thermally excited DA complex. To understand the process, we must turn our attention to the

Fig. 24.27 The Gibbs energy surfaces of the complexes DA and D^+A^- involved in an electron transfer process are represented by parabolas characteristic of harmonic oscillators, with the displacement coordinate q corresponding to the changing geometries of the system. In the plot, q_0^R and q_0^P are the values of q at which the minima of the reactant and product parabolas occur, respectively. The parabolas intersect at $q = q^*$. The plots also portray the Gibbs energy of activation, $\Delta^\ddagger G$, the standard reaction Gibbs energy, $\Delta_r G^\circ$, and the reorganization energy, λ (discussed in Section 24.11b).

effect that the rearrangement of nuclear coordinates has on electronic energy levels of DA and D^+A^- for a given distance r between D and A (Fig. 24.28). Initially, the electron to be transferred occupies the HOMO of D, and the overall energy of DA is lower than that of D^+A^- (Fig. 24.28a). As the nuclei rearrange to a configuration represented by q^* in Fig. 24.28b, the highest occupied electronic level of DA and the lowest unoccupied electronic level of D^+A^- become degenerate and electron transfer becomes energetically feasible. Over reasonably short distances r , the main mechanism of electron transfer is tunnelling through the potential energy barrier depicted in Fig. 24.28b. The height of the barrier increases with the ionization energies of the DA and D^+A^- complexes. After an electron moves from the HOMO of D to the LUMO of A, the system relaxes to the configuration represented by q_0^P in Fig. 24.28c. As shown in the illustration, now the energy of D^+A^- is lower than that of DA, reflecting the thermodynamic tendency for A to remain reduced and for D to remain oxidized.

The tunnelling event responsible for electron transfer is similar to that described in Section 9.3, except that in this case the electron tunnels from an electronic level of D, with wavefunction ψ_D , to an electronic level of A, with wavefunction ψ_A . We saw in Section 9.3 that the rate of an electronic transition from a level described by the wavefunction ψ_D to a level described by ψ_A is proportional to the square of the integral

$$\langle H_{DA} \rangle = \int \psi_A \hat{H}_{DA} \psi_D d\tau$$

where H_{DA} is a hamiltonian that describes the coupling of the electronic wavefunctions. It turns out that in cases where the coupling is relatively weak we may write:

$$\langle H_{DA} \rangle^2 = \langle H_{DA}^0 \rangle^2 e^{-\beta r} \quad (24.80)$$

where r is the edge-to-edge distance between D and A, β is a parameter that measures the sensitivity of the electronic coupling matrix element to distance, and $\langle H_{DA}^0 \rangle^2$ is the value of the electronic coupling matrix element when D and A are in contact ($r = 0$). The exponential dependence on distance in eqn 24.80 is essentially the same as the exponential decrease in transmission probability through a potential energy barrier described in Section 9.3.

(b) The expression for the rate of electron transfer

The full expression for k_{et} turns out to be (see *Further reading* for a derivation)

$$k_{et} = \frac{2\langle H_{DA} \rangle^2}{h} \left(\frac{\pi^3}{4\lambda RT} \right)^{1/2} e^{-\Delta^\ddagger G/RT} \quad (24.81)$$

where $\langle H_{DA} \rangle^2$ can be approximated by eqn 24.80. We show in *Further information* 24.1 that the Gibbs energy of activation $\Delta^\ddagger G$ is

$$\Delta^\ddagger G = \frac{(\Delta_r G^\circ + \lambda)^2}{4\lambda} \quad (24.82)$$

where $\Delta_r G^\circ$ is the standard reaction Gibbs energy for the electron transfer process $DA \rightarrow D^+A^-$, and λ is the **reorganization energy**, the energy change associated with molecular rearrangements that must take place so that DA can take on the equilibrium geometry of D^+A^- . These molecular rearrangements include the relative reorientation of the D and A molecules in DA and the relative reorientation of the solvent molecules surrounding DA. Equation 24.82 shows that $\Delta^\ddagger G = 0$, with the implication that the reaction is not slowed down by an activation barrier, when $\Delta_r G^\circ = -\lambda$, corresponding to the cancellation of the reorganization energy term by the standard reaction Gibbs energy.

Fig. 24.28 Correspondence between the electronic energy levels (shown on the left) and the nuclear energy levels (shown on the right) for the DA and D^+A^- complexes involved in an electron transfer process. (a) At the nuclear configuration denoted by q_0^R , the electron to be transferred in DA is in an occupied electronic energy level (denoted by a blue circle) and the lowest unoccupied energy level of D^+A^- (denoted by an unfilled circle) is of too high an energy to be a good electron acceptor. (b) As the nuclei rearrange to a configuration represented by q^* , DA and D^+A^- become degenerate and electron transfer occurs by tunnelling through the barrier of height V and width r , the edge-to-edge distance between donor and acceptor. (c) The system relaxes to the equilibrium nuclear configuration of D^+A^- denoted by q_0^P , in which the lowest unoccupied electronic level of DA is higher in energy than the highest occupied electronic level of D^+A^- . (Adapted from R.A. Marcus and N. Sutin, *Biochim. Biophys. Acta* **811**, 265 (1985).)

Equation 24.81 has some limitations. First, it describes only those processes with weak electronic coupling between donor and acceptor. Weak coupling is observed when the electroactive species are sufficiently far apart that the wavefunctions ψ_A and ψ_D do not overlap extensively. An example of a weakly coupled system is the cytochrome *c*–cytochrome *b*₅ complex, in which the electroactive haem-bound iron ions shuttle between oxidation states +2 and +3 during electron transfer and are about 1.7 nm apart. Strong coupling is observed when the wavefunctions ψ_A and ψ_D overlap very extensively. Examples of strongly coupled systems are mixed-valence, binuclear *d*-metal complexes with the general structure $L_m M^{n+} - B - M^{p+} L_m$, in which the electroactive metal ions are separated by a bridging ligand B. In these systems, $r < 1.0$ nm. The weak coupling limit applies to a large number of electron transfer reactions, including those between proteins during metabolism (*Impact* I7.2). Second, the term $(\pi^3/4\lambda RT)^{1/2} e^{-\Delta^\ddagger G/RT}$ should be used only at high temperatures. At low temperatures, thermal fluctuations alone cannot bring the reactants to the transition state and transition state theory, which is at the heart of the theory presented in this section, fails to account for any observed electron transfer. Electron transfer can still occur, but by *nuclear* tunnelling from the reactant to the product surfaces. We saw in Section 9.5 that the wavefunctions for the lower levels of the quantum mechanical harmonic oscillator extend significantly beyond classically allowed regions, so an oscillator can tunnel into a region of space in which another oscillator may be found. Full quantum mechanical treatments of electron transfer reactions replace the $(\pi^3/4\lambda RT)^{1/2} e^{-\Delta^\ddagger G/RT}$ term with Franck–Condon factors similar to those discussed in Section 14.2, which couple the *nuclear* wavefunctions and provide a measure of the contribution of nuclear tunnelling to the rate of electron transfer.

24.12 Experimental results

It is difficult to measure the distance dependence of k_{et} when the reactants are ions or molecules that are free to move in solution. In such cases, electron transfer occurs after a donor–acceptor complex forms and it is not possible to exert control over r , the edge-to-edge distance. The most meaningful experimental tests of the dependence of k_{et} on r are those in which the same donor and acceptor are positioned at a variety of distances, perhaps by covalent attachment to molecular linkers (see **1** for an example). Under these conditions, the term $e^{-\Delta^\ddagger G/RT}$ becomes a constant and, after taking the natural logarithm of eqn 24.81 and using eqn 24.80, we obtain

$$\ln k_{et} = -\beta r + \text{constant} \quad (24.83)$$

which implies that a plot of $\ln k_{et}$ against r should be a straight line with slope $-\beta$. The value of β depends on the medium through which the electron must travel from donor to acceptor. In a vacuum, $28 \text{ nm}^{-1} < \beta < 35 \text{ nm}^{-1}$, whereas $\beta \approx 9 \text{ nm}^{-1}$ when the intervening medium is a molecular link between donor and acceptor.

The dependence of k_{et} on the standard reaction Gibbs energy has been investigated in systems where the edge-to-edge distance, the reorganization energy, and $\kappa\nu$ are constant for a series of reactions. Then eqn 24.81 becomes

$$\ln k_{et} = -\frac{1}{4\lambda} \left(\frac{\Delta_r G^\circ}{RT} \right)^2 - \frac{1}{2} \left(\frac{\Delta_r G^\circ}{RT} \right) + \text{constant} \quad (24.84)$$

and a plot of $\ln k_{et}$ (or $\log k_{et}$) against $\Delta_r G^\circ$ (or $-\Delta_r G^\circ$) is predicted to be shaped like a downward parabola. Equation 24.84 implies that the rate constant increases as $\Delta_r G^\circ$ decreases but only up to $-\Delta_r G^\circ = \lambda$. Beyond that, the reaction enters the **inverted region**, in which the rate constant decreases as the reaction becomes more exergonic ($\Delta_r G^\circ$ becomes more negative). The inverted region has been observed in a series of

1 An electron donor-acceptor complex

special compounds in which the electron donor and acceptor are linked covalently to a molecular spacer of known and fixed size (Fig. 24.29).

The behaviour predicted by eqn 24.84 and observed experimentally in Fig. 24.29 can be explained by considering the dependence of the activation Gibbs energy on the standard Gibbs energy of electron transfer. We suppose that the energies of the reactant and product complexes can be characterized by parabolas with identical curvatures and fixed but distinct q_0^R and q_0^P . Now we let the minimum energy of the product complex change while keeping q_0^P constant, which corresponds to changing the magnitude of $\Delta_r G^\circ$. Figure 24.30 shows the effect of increasing the exergonicity of the process. In Fig. 24.30a we see that, for a range of values of $\Delta_r G^\circ$, $\Delta^\ddagger G > 0$ and the transition state is at $q_a^* > q_0^R$. As the process becomes more exergonic, the activation Gibbs energy decreases and the rate constant increases. (This behaviour is another example of a 'linear free-energy relation', first discussed in Section 24.5.) Figure 24.30b shows that, when $\Delta^\ddagger G = 0$ and $q_b^* = q_0^R$, the rate constant for the process reaches a maximum as there is no activation barrier to overcome. According to eqn 24.81, this condition occurs when $-\Delta_r G^\circ = \lambda$. Finally, Fig. 24.30c shows that, as the process becomes even more exergonic, $\Delta^\ddagger G$ becomes positive again but now the transition state is at $q_c^* < q_0^R$. The rate constant for the process decreases steadily as the activation barrier for the process increases with decreasing $\Delta_r G^\circ$. This is the explanation for the 'inverted region' observed in Fig. 24.29.

Fig. 24.29 Variation of $\log k_{et}$ with $-\Delta_r G^\circ$ for a series of compounds with the structures given in (1). Kinetic measurements were conducted in 2-methyltetrahydrofuran and at 296 K. The distance between donor (the reduced biphenyl group) and the acceptor is constant for all compounds in the series because the molecular linker remains the same. Each acceptor has a characteristic standard reduction potential, so it follows that the standard Gibbs energy for the electron transfer process is different for each compound in the series. The line is a fit to a version of eqn 24.84 and the maximum of the parabola occurs at $-\Delta_r G^\circ = \lambda = 1.2 \text{ eV} = 1.2 \times 10^2 \text{ kJ mol}^{-1}$. (Reproduced with permission from J.R. Miller, L.T. Calcaterra, and G.L. Closs, *J. Amer. Chem. Soc.* **106**, 3047 (1984).)

Fig. 24.30 (a) $\Delta^\ddagger G > 0$ and the transition state is at $q_a^* > q_0^R$. As the process becomes more exergonic, the activation Gibbs energy decreases and the rate constant increases. (b) When $\Delta^\ddagger G = 0$ and $q_b^* = q_0^R$ the rate constant for the process reaches a maximum as there is no activation barrier to overcome. (c) As the process becomes even more exergonic, $\Delta^\ddagger G$ becomes positive again but now the transition state is at $q_c^* < q_0^R$. The rate constant for the process decreases steadily as the activation barrier for the process increases with decreasing $\Delta_r G^\ominus$.

Some of the key features of electron transfer theory have been tested by experiments, showing in particular the predicted dependence of k_{et} on the standard reaction Gibbs energy and the edge-to-edge distance between electron donor and acceptor. The basic theory presented in Section 24.11 has been extended to transfer of other light particles, such as protons.

IMPACT ON BIOCHEMISTRY

I24.1 Electron transfer in and between proteins

We saw in *Impact* I7.2 and I21.2 that exergonic electron transfer processes drive the synthesis of ATP in the mitochondrion during oxidative phosphorylation. Electron transfer between protein-bound cofactors or between proteins also plays a role in other biological processes, such as photosynthesis (*Impact* I23.2), nitrogen fixation, the reduction of atmospheric N_2 to NH_3 by certain microorganisms, and the mechanisms of action of oxidoreductases, which are enzymes that catalyse redox reactions.

Equation 24.78 applies to a large number of biological systems, such as cytochrome *c* and cytochrome *c* oxidase (*Impact* I7.2), which must form an encounter complex before electron transfer can take place. Electron transfer between protein-bound cofactors can occur at distances of up to about 2.0 nm, a relatively long distance on a molecular scale, with the protein providing an intervening medium between donor and acceptor.

When the electron donor and acceptor are anchored at fixed distances within a single protein, only k_{et} needs to be considered when calculating the rate of electron transfer by using eqn 24.81. Cytochrome *c* oxidase is an example of a system where such intraprotein electron transfer is important. In that enzyme, bound copper ions and haem groups work together to reduce O_2 to water in the final step of respiration. However, there is a great deal of controversy surrounding the interpretation of protein electron transfer data in the light of the theory that leads to eqn 24.81. Much of the available data may be interpreted with $\beta \approx 14 \text{ nm}^{-1}$, a value that appears to be insensitive to the primary and secondary structures of the protein but does depend slightly on the density of atoms in the section of protein that separates donor from acceptor. More detailed work on the specific effect of secondary structure suggests that $12.5 \text{ nm}^{-1} < \beta < 16.0 \text{ nm}^{-1}$ when the intervening medium consists primarily of α helices and $9.0 \text{ nm}^{-1} < \beta < 11.5 \text{ nm}^{-1}$ when the medium is primarily β sheet. Yet another view suggests that the electron takes specific paths through covalent bonds and hydrogen bonds that exist in the protein for the purpose of optimizing the rate of electron transfer.

A value of β is not necessary for the prediction of the rate constants for electron transfer processes between proteins if we take a different approach. It follows from eqns 24.78 and 24.79 that the rate constant k_{obs} may be written as

$$k_{\text{obs}} = Z e^{-\Delta^\ddagger G/RT} \quad (24.85)$$

where $Z = K_{\text{DA}} \kappa v$. It is difficult to estimate k_{obs} because we often lack knowledge of β , λ , and κv . However, when $\lambda \gg |\Delta_r G^\ominus|$, k_{obs} may be estimated by a special case of the **Marcus cross-relation**, which we derive in *Further information* 24.1:

$$k_{\text{obs}} = (k_{\text{DD}} k_{\text{AA}} K)^{1/2} \quad (24.86)$$

where K is the equilibrium constant for the net electron transfer reaction (eqn 24.75) and k_{DD} and k_{AA} are the experimental rate constants for the electron self-exchange processes (with the asterisks distinguishing one molecule from another)

The rate constants estimated by eqn 24.86 agree fairly well with experimental rate constants for electron transfer between proteins, as we see in the following *Example*.

Example 24.4 Using the Marcus cross-relation

The following kinetic and thermodynamic data were obtained for cytochrome *c* and cytochrome *c*₅₅₁, two proteins in which haem-bound iron ions shuttle between the oxidation states Fe(II) and Fe(III):

	$k_{ii}/(\text{dm}^3 \text{ mol}^{-1} \text{ s}^{-1})$	$E^\ominus/\text{V}$
cytochrome <i>c</i>	1.5×10^2	0.260
cytochrome <i>c</i> ₅₅₁	4.6×10^7	0.286

Estimate the rate constant k_{obs} for the process

Then, compare the estimated value with the observed value of $6.7 \times 10^4 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$.

Method We use the standard potentials and eqns 7.30 ($\ln K = vFE^\ominus/RT$) and 7.37 ($E^\ominus = E_{\text{R}}^\ominus - E_{\text{L}}^\ominus$) to calculate the equilibrium constant K . Then, we use eqn 24.86, the calculated value of K , and the self-exchange rate constants k_{ii} to calculate the rate constant k_{obs} .

Answer The two reduction half-reactions are

The difference is

$$E^\ominus = (0.260 \text{ V}) - (0.286 \text{ V}) = -0.026 \text{ V}$$

It then follows from eqn 7.30 with $v = 1$ and $RT/F = 25.69 \text{ mV}$ that

$$\ln K = -\frac{0.026 \text{ V}}{25.69 \times 10^{-3} \text{ V}} = -\frac{2.6}{2.569}$$

Therefore, $K = 0.36$. From eqn 24.76 and the self-exchange rate constants, we calculate

$$\begin{aligned} k_{\text{obs}} &= \{(1.5 \times 10^2 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}) \times (4.6 \times 10^7 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}) \times 0.36\}^{1/2} \\ &= 5.0 \times 10^4 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1} \end{aligned}$$

The calculated and observed values differ by only 25 per cent, indicating that the Marcus relation can lead to reasonable estimates of rate constants for electron transfer.

Self-test 24.4 Estimate k_{obs} for the reduction by cytochrome *c* of plastocyanin, a protein containing a copper ion that shuttles between the +2 and +1 oxidation states and for which $k_{\text{AA}} = 6.6 \times 10^2 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ and $E^\ominus = 0.350 \text{ V}$.

$$[1.8 \times 10^3 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}]$$

Table 24.3 Summary of uses of k

Symbol	Significance
k	Boltzmann's constant
k_2	Second-order rate constant
k_2^o	Rate constant at zero ionic strength
$k_a, k_b, \dots$	Rate constants for individual steps
$k'_a, k'_b, \dots$	Rate constants for individual reverse steps
$k^\ddagger$	Rate constant for unimolecular decay of activated complex
K	Equilibrium constant (dimensionless)
K_γ	Ratio of activity coefficients
$K^\ddagger$	Proportionality constant in transition state theory
κ	Transmission coefficient
$\tilde{K}$	Equilibrium constant with one mode discarded
k_f	Force constant

Checklist of key ideas

- ☐ 1. In collision theory, it is supposed that the rate is proportional to the collision frequency, a steric factor, and the fraction of collisions that occur with at least the kinetic energy E_a along their lines of centres.
- ☐ 2. A reaction in solution may be diffusion-controlled if its rate is controlled by the rate at which reactant molecules encounter each other in solution. The rate of an activation-controlled reaction is controlled by the rate of accumulating sufficient energy.
- ☐ 3. In transition state theory, it is supposed that an activated complex is in equilibrium with the reactants, and that the rate at which that complex forms products depends on the rate at which it passes through a transition state. The result is the Eyring equation, $k_2 = \kappa(kT/h)\tilde{K}_c^\ddagger$.
- ☐ 4. The rate constant may be parametrized in terms of the Gibbs energy, entropy, and enthalpy of activation, $k_2 = (kT/h)e^{\Delta^\ddagger S/R}e^{-\Delta^\ddagger H/RT}$.
- ☐ 5. The kinetic salt effect is the effect of an added inert salt on the rate of a reaction between ions, $\log k_2 = \log k_2^o + 2Az_Az_BI^{1/2}$.
- ☐ 6. Techniques for the study of reactive collisions include infrared chemiluminescence, laser-induced fluorescence, multiphoton ionization (MPI), reaction product imaging, and resonant multiphoton ionization (REMPI).
- ☐ 7. A potential energy surface maps the potential energy as a function of the relative positions of all the atoms taking part in a reaction. In an attractive surface, the saddle point (the highest point) occurs early on the reaction coordinate. In a repulsive surface, the saddle point occurs late on the reaction coordinate.
- ☐ 8. Ultrafast laser techniques can be used to probe directly the activated complex and to control the outcome of some chemical reactions.
- ☐ 9. The rate constant of electron transfer in a donor–acceptor complex depends on the distance between electron donor and acceptor, the standard reaction Gibbs energy, and the reorganization energy, λ : $k_{et} \propto e^{-\beta r}e^{-\Delta^\ddagger G/RT}$ (constant T), with $\Delta^\ddagger G = (\Delta_r G^\circ + \lambda)^2/4\lambda$.
- ☐ 10. The Marcus cross-relation predicts the rate constant for electron transfer in solution from the reaction's equilibrium constant K and the self-exchange rate constants k_{ii} : $k_{obs} = (k_{DD}k_{AA}K)^{1/2}$.

Further information

Further information 24.1 The Gibbs energy of activation of electron transfer and the Marcus cross-relation

The simplest way to derive an expression for the Gibbs energy of activation of electron transfer processes is to construct a model in which the surfaces for DA (the 'reactant complex', denoted R) and for D^+A^- (the 'product complex', denoted P) are described by classical harmonic oscillators with identical reduced masses μ and angular frequencies ω , but displaced minima, as shown in Fig. 24.27. The molar Gibbs energies $G_{m,R}(q)$ and $G_{m,P}(q)$ of the reactant and product complexes, respectively, may be written as

$$G_{m,R}(q) = \frac{1}{2}N_A\mu\omega^2(q - q_0^R)^2 + G_{m,R}(q_0^R) \quad (24.88a)$$

$$G_{m,P}(q) = \frac{1}{2}N_A\mu\omega^2(q - q_0^P)^2 + G_{m,P}(q_0^P) \quad (24.88b)$$

where q_0^R and q_0^P are the values of q at which the minima of the reactant and product parabolas occur, respectively. The standard reaction Gibbs energy for the electron transfer process $DA \rightarrow D^+A^-$ is $\Delta_r G^\ominus = G_{m,P}(q_0^P) - G_{m,R}(q_0^R)$, the difference in standard molar Gibbs energy between the minima of the parabolas. In Fig. 24.27, $\Delta_r G^\ominus < 0$.

We also note that q^* , the value of q corresponding to the transition state of the complex, may be written in terms of the parameter α , the fractional change in q :

$$q^* = q_0^R + \alpha(q_0^P - q_0^R) \quad (24.89)$$

We see from Fig. 24.27 that $\Delta^\ddagger G = G_{m,R}(q^*) - G_{m,R}(q_0^R)$. It then follows from eqns 24.88a, 24.88b, and 24.89 that

$$\Delta^\ddagger G = \frac{1}{2}N_A\mu\omega^2(q^* - q_0^R)^2 = \frac{1}{2}N_A\mu\omega^2\{\alpha(q_0^P - q_0^R)\}^2 \quad (24.90)$$

We now define the reorganization energy, λ , as

$$\lambda = \frac{1}{2}N_A\mu\omega^2(q_0^P - q_0^R)^2 \quad (24.91)$$

which can be interpreted as $G_{m,R}(q_0^P) - G_{m,R}(q_0^R)$ and, consequently, as the (Gibbs) energy required to deform the equilibrium configuration of DA to the equilibrium configuration of D^+A^- (as shown in Fig. 24.27). It follows from eqns 24.90 and 24.91 that

$$\Delta^\ddagger G = \alpha^2\lambda \quad (24.92)$$

Because $G_{m,R}(q^*) = G_{m,P}(q^*)$, it follows from eqns 24.88b, 24.91, and 24.92 that

$$\alpha^2\lambda = \frac{1}{2}N_A\mu\omega^2\{(\alpha - 1)(q_0^P - q_0^R)\}^2 + \Delta_r G^\ominus \\ = (\alpha - 1)\lambda + \Delta_r G^\ominus \quad (24.93)$$

which implies that

$$\alpha = \frac{1}{2} \left(\frac{\Delta_r G^\ominus}{\lambda} + 1 \right) \quad (24.94)$$

By combining eqns 24.92 and 24.94, we obtain eqn 24.82. We can obtain an identical relation if we allow the harmonic oscillators to have different angular frequencies and hence different curvatures (see *Further reading*).

Equation 24.82 can be used to derive the form of the Marcus cross-relation (eqn 24.86) used in *Impact I24.1*. We begin by using eqn 24.85 to write the rate constants for the self-exchange reactions as

$$k_{DD} = Z_{DD}e^{-\Delta^\ddagger G_{DD}/RT} \quad k_{AA} = Z_{AA}e^{-\Delta^\ddagger G_{AA}/RT}$$

For the net reaction (also called the 'cross-reaction') and the self-exchange reactions, the Gibbs energy of activation may be written from eqn 24.82 as

$$\Delta^\ddagger G = \frac{\Delta_r G^{\ominus 2}}{4\lambda} + \frac{\Delta_r G^\ominus}{2} + \frac{\lambda}{4}$$

When $\lambda \gg |\Delta_r G^\ominus|$, we obtain

$$\Delta^\ddagger G = \frac{\Delta_r G^\ominus}{2} + \frac{\lambda}{4}$$

This expression can be used without further elaboration to denote the Gibbs energy of activation of the net reaction. For the self-exchange reactions, we set $\Delta_r G_{DD}^\ominus = \Delta_r G_{AA}^\ominus = 0$ and write

$$\Delta^\ddagger G_{DD} = \frac{\lambda_{DD}}{4} \quad \Delta^\ddagger G_{AA} = \frac{\lambda_{AA}}{4}$$

It follows that

$$k_{\text{DD}} = Z_{\text{DD}} e^{-\lambda_{\text{DD}}/4RT} \quad k_{\text{AA}} = Z_{\text{AA}} e^{-\lambda_{\text{AA}}/4RT}$$

To make further progress, we assume that the reorganization energy of the net reaction is the arithmetic mean of the reorganization energies of the self-exchange reactions:

$$\lambda_{\text{DA}} = \frac{\lambda_{\text{DD}} + \lambda_{\text{AA}}}{2}$$

It follows that the Gibbs energy of activation of the net reaction is

$$\Delta^\ddagger G = \frac{\Delta_{\text{r}} G^\ominus}{2} + \frac{\lambda_{\text{DD}}}{8} + \frac{\lambda_{\text{AA}}}{8}$$

Therefore, the rate constant for the net reaction is

$$k_{\text{obs}} = Z e^{-\Delta_{\text{r}} G^\ominus/2RT} e^{-\lambda_{\text{DD}}/8RT} e^{-\lambda_{\text{AA}}/8RT}$$

We can use eqn 7.17 ($\ln K = -\Delta_{\text{r}} G^\ominus/RT$) to write

$$K = e^{-\Delta_{\text{r}} G^\ominus/RT}$$

Then, by combining this expression with the expressions for k_{DD} and k_{AA} , and using the relations $e^{x+y} = e^x e^y$ and $e^{x/2} = (e^x)^{1/2}$, we obtain the most general case of the Marcus cross-relation:

$$k_{\text{obs}} = (k_{\text{DD}} k_{\text{AA}} K)^{1/2} f$$

where

$$f = \frac{Z}{(Z_{\text{AA}} Z_{\text{DD}})^{1/2}}$$

In practice, the factor f is usually set to 1 and we obtain eqn 24.86.

Discussion questions

24.1 Describe the essential features of the harpoon mechanism.

24.2 Distinguish between a diffusion-controlled reaction and an activation-controlled reaction.

24.3 Describe the formulation of the Eyring equation.

24.4 Discuss the physical origin of the kinetic salt effect.

24.5 Describe how the following techniques are used in the study of chemical dynamics: infrared chemiluminescence, laser-induced fluorescence, multiphoton ionization, resonant multiphoton ionization, reaction product imaging, and femtosecond spectroscopy.

24.6 Justify the following statements: (a) Reactions with attractive potential energy surfaces proceed more efficiently if the energy is in relative translational motion. (b) Reactions with repulsive potential surfaces proceed more efficiently if the excess energy is present as vibrations.

24.7 A method for directing the outcome of a chemical reaction consists of using molecular beams to control the relative orientations of reactants during a collision. Consider the reaction $\text{Rb} + \text{CH}_3\text{I} \rightarrow \text{RbI} + \text{CH}_3$. How should CH_3I molecules and Rb atoms be oriented to maximize the production of RbI?

24.8 Discuss how the following factors determine the rate of electron transfer in homogeneous systems: the distance between electron donor and acceptor, and the reorganization energy of redox active species and the surrounding medium.

Exercises

24.1a Calculate the collision frequency, z , and the collision density, Z , in ammonia, $R = 190$ pm, at 25°C and 100 kPa. What is the percentage increase when the temperature is raised by 10 K at constant volume?

24.1b Calculate the collision frequency, z , and the collision density, Z , in carbon monoxide, $R = 180$ pm at 25°C and 100 kPa. What is the percentage increase when the temperature is raised by 10 K at constant volume?

24.2a Collision theory demands knowing the fraction of molecular collisions having at least the kinetic energy E_{a} along the line of flight. What is this fraction when (a) $E_{\text{a}} = 10$ kJ mol $^{-1}$, (b) $E_{\text{a}} = 100$ kJ mol $^{-1}$ at (i) 300 K and (ii) 1000 K?

24.2b Collision theory demands knowing the fraction of molecular collisions having at least the kinetic energy E_{a} along the line of flight. What is this fraction when (a) $E_{\text{a}} = 15$ kJ mol $^{-1}$, (b) $E_{\text{a}} = 150$ kJ mol $^{-1}$ at (i) 300 K and (ii) 800 K?

24.3a Calculate the percentage increase in the fractions in Exercise 24.2a when the temperature is raised by 10 K.

24.3b Calculate the percentage increase in the fractions in Exercise 24.2b when the temperature is raised by 10 K.

24.4a Use the collision theory of gas-phase reactions to calculate the theoretical value of the second-order rate constant for the reaction $\text{H}_2(\text{g}) + \text{I}_2(\text{g}) \rightarrow 2 \text{HI}(\text{g})$ at 650 K, assuming that it is elementary bimolecular. The collision cross-section is 0.36 nm ^{2} , the reduced mass is 3.32×10^{-27} kg, and the activation energy is 171 kJ mol $^{-1}$.

24.4b Use the collision theory of gas-phase reactions to calculate the theoretical value of the second-order rate constant for the reaction $\text{D}_2(\text{g}) + \text{Br}_2(\text{g}) \rightarrow 2 \text{DBr}(\text{g})$ at 450 K, assuming that it is elementary bimolecular. Take the collision cross-section as 0.30 nm ^{2} , the reduced mass as 3.930 u, and the activation energy as 200 kJ mol $^{-1}$.

24.5a A typical diffusion coefficient for small molecules in aqueous solution at 25°C is 5×10^{-9} m ^{2} s $^{-1}$. If the critical reaction distance is 0.4 nm, what value is expected for the second-order rate constant for a diffusion-controlled reaction?

24.5b Suppose that the typical diffusion coefficient for a reactant in aqueous solution at 25°C is 4.2×10^{-9} m ^{2} s $^{-1}$. If the critical reaction distance is 0.50 nm, what value is expected for the second-order rate constant for the diffusion-controlled reaction?

24.6a Calculate the magnitude of the diffusion-controlled rate constant at 298 K for a species in (a) water, (b) pentane. The viscosities are $1.00 \times 10^{-3} \text{ kg m}^{-1} \text{ s}^{-1}$, and $2.2 \times 10^{-4} \text{ kg m}^{-1} \text{ s}^{-1}$, respectively.

24.6b Calculate the magnitude of the diffusion-controlled rate constant at 298 K for a species in (a) decylbenzene, (b) concentrated sulfuric acid. The viscosities are 3.36 cP and 27 cP, respectively.

24.7a Calculate the magnitude of the diffusion-controlled rate constant at 298 K for the recombination of two atoms in water, for which $\eta = 0.89 \text{ cP}$. Assuming the concentration of the reacting species is 1.0 mmol dm^{-3} initially, how long does it take for the concentration of the atoms to fall to half that value? Assume the reaction is elementary.

24.7b Calculate the magnitude of the diffusion-controlled rate constant at 298 K for the recombination of two atoms in benzene, for which $\eta = 0.601 \text{ cP}$. Assuming the concentration of the reacting species is 1.8 mmol dm^{-3} initially, how long does it take for the concentration of the atoms to fall to half that value? Assume the reaction is elementary.

24.8a For the gaseous reaction $A + B \rightarrow P$, the reactive cross-section obtained from the experimental value of the pre-exponential factor is $9.2 \times 10^{-22} \text{ m}^2$. The collision cross-sections of A and B estimated from the transport properties are 0.95 and 0.65 nm^2 , respectively. Calculate the P-factor for the reaction.

24.8b For the gaseous reaction $A + B \rightarrow P$, the reactive cross-section obtained from the experimental value of the pre-exponential factor is $8.7 \times 10^{-22} \text{ m}^2$. The collision cross-sections of A and B estimated from the transport properties are 0.88 and 0.40 nm^2 , respectively. Calculate the P factor for the reaction.

24.9a Two neutral species, A and B, with diameters 588 pm and 1650 pm, respectively, undergo the diffusion-controlled reaction $A + B \rightarrow P$ in a solvent of viscosity $2.37 \times 10^{-3} \text{ kg m}^{-1} \text{ s}^{-1}$ at 40°C . Calculate the initial rate $d[P]/dt$ if the initial concentrations of A and B are $0.150 \text{ mol dm}^{-3}$ and $0.330 \text{ mol dm}^{-3}$, respectively.

24.9b Two neutral species, A and B, with diameters 442 pm and 885 pm, respectively, undergo the diffusion-controlled reaction $A + B \rightarrow P$ in a solvent of viscosity 1.27 cP at 20°C . Calculate the initial rate $d[P]/dt$ if the initial concentrations of A and B are $0.200 \text{ mol dm}^{-3}$ and $0.150 \text{ mol dm}^{-3}$, respectively.

24.10a The reaction of propylxanthate ion in acetic acid buffer solutions has the mechanism $A^- + H^+ \rightarrow P$. Near 30°C the rate constant is given by the empirical expression $k_2 = (2.05 \times 10^{13})e^{-(8681 \text{ K})/T} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$. Evaluate the energy and entropy of activation at 30°C .

24.10b The reaction $A^- + H^+ \rightarrow P$ has a rate constant given by the empirical expression $k_2 = (8.72 \times 10^{12})e^{-(6134 \text{ K})/T} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$. Evaluate the energy and entropy of activation at 25°C .

24.11a When the reaction in Exercise 24.10a occurs in a dioxane/water mixture that is 30 per cent dioxane by mass, the rate constant fits $k_2 = (7.78 \times 10^{14})e^{-(9134 \text{ K})/T} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ near 30°C . Calculate $\Delta^\ddagger G$ for the reaction at 30°C .

24.11b A rate constant is found to fit the expression $k_2 = (6.45 \times 10^{13})e^{-(5375 \text{ K})/T} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ near 25°C . Calculate $\Delta^\ddagger G$ for the reaction at 25°C .

24.12a The gas-phase association reaction between F_2 and IF_3 is first-order in each of the reactants. The energy of activation for the reaction is 58.6 kJ mol^{-1} . At 65°C the rate constant is $7.84 \times 10^{-3} \text{ kPa}^{-1} \text{ s}^{-1}$. Calculate the entropy of activation at 65°C .

24.12b A gas-phase recombination reaction is first-order in each of the reactants. The energy of activation for the reaction is 49.6 kJ mol^{-1} . At 55°C the rate constant is $0.23 \text{ m}^3 \text{ s}^{-1}$. Calculate the entropy of activation at 55°C .

24.13a Calculate the entropy of activation for a collision between two structureless particles at 300 K, taking $M = 50 \text{ g mol}^{-1}$ and $\sigma = 0.40 \text{ nm}^2$.

24.13b Calculate the entropy of activation for a collision between two structureless particles at 500 K, taking $M = 78 \text{ g mol}^{-1}$ and $\sigma = 0.62 \text{ nm}^2$.

24.14a The pre-exponential factor for the gas-phase decomposition of ozone at low pressures is $4.6 \times 10^{12} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ and its activation energy is 10.0 kJ mol^{-1} . What are (a) the entropy of activation, (b) the enthalpy of activation, (c) the Gibbs energy of activation at 298 K ?

24.14b The pre-exponential factor for a gas-phase decomposition of ozone at low pressures is $2.3 \times 10^{13} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ and its activation energy is 30.0 kJ mol^{-1} . What are (a) the entropy of activation, (b) the enthalpy of activation, (c) the Gibbs energy of activation at 298 K ?

24.15a The rate constant of the reaction $H_2O_2(aq) + I^-(aq) + H^+(aq) \rightarrow H_2O(l) + HIO(aq)$ is sensitive to the ionic strength of the aqueous solution in which the reaction occurs. At 25°C , $k = 12.2 \text{ dm}^6 \text{ mol}^{-2} \text{ min}^{-1}$ at an ionic strength of 0.0525 . Use the Debye–Hückel limiting law to estimate the rate constant at zero ionic strength.

24.15b At 25°C , $k = 1.55 \text{ dm}^6 \text{ mol}^{-2} \text{ min}^{-1}$ at an ionic strength of 0.0241 for a reaction in which the rate-determining step involves the encounter of two singly charged cations. Use the Debye–Hückel limiting law to estimate the rate constant at zero ionic strength.

24.16a For a pair of electron donor and acceptor, $H_{AB} = 0.03 \text{ cm}^{-1}$, $\Delta_r G^\circ = -0.182 \text{ eV}$ and $k_{et} = 30.5 \text{ s}^{-1}$ at 298 K . Estimate the value of the reorganization energy.

24.16b For a pair of electron donor and acceptor, $k_{et} = 2.02 \times 10^5 \text{ s}^{-1}$ for $\Delta_r G^\circ = -0.665 \text{ eV}$. The standard reaction Gibbs energy changes to $\Delta_r G^\circ = -0.975 \text{ eV}$ when a substituent is added to the electron acceptor and the rate constant for electron transfer changes to $k_{et} = 3.33 \times 10^6 \text{ s}^{-1}$. The experiments were conducted at 298 K . Assuming that the distance between donor and acceptor is the same in both experiments, estimate the values of H_{AB} and λ .

24.17a For a pair of electron donor and acceptor, $k_{et} = 2.02 \times 10^5 \text{ s}^{-1}$ when $r = 1.11 \text{ nm}$ and $k_{et} = 4.51 \times 10^5 \text{ s}^{-1}$ when $r = 1.23 \text{ nm}$. Assuming that $\Delta_r G^\circ$ and λ are the same in both experiments, estimate the value of β .

24.17b Refer to Exercise 24.17a. Estimate the value of k_{et} when $r = 1.48 \text{ nm}$.

Problems*

Numerical problems

24.1 In the dimerization of methyl radicals at 25°C , the experimental pre-exponential factor is $2.4 \times 10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$. What are (a) the reactive cross-section, (b) the P factor for the reaction if the C–H bond length is 154 pm ?

24.2 Nitrogen dioxide reacts bimolecularly in the gas phase to give $2 \text{ NO} + \text{O}_2$. The temperature dependence of the second-order rate constant for the rate law $d[P]/dt = k[\text{NO}_2]^2$ is given below. What are the P factor and the reactive cross-section for the reaction?

* Problems denoted with the symbol ‡ were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

T/K	600	700	800	1000
$k/(\text{cm}^3 \text{mol}^{-1} \text{s}^{-1})$	4.6×10^2	9.7×10^3	1.3×10^5	3.1×10^6

Take $\sigma = 0.60 \text{ nm}^2$.

24.3 The diameter of the methyl radical is about 308 pm. What is the maximum rate constant in the expression $d[\text{C}_2\text{H}_6]/dt = k[\text{CH}_3]^2$ for second-order recombination of radicals at room temperature? 10 per cent of a 1.0-dm³ sample of ethane at 298 K and 100 kPa is dissociated into methyl radicals. What is the minimum time for 90 per cent recombination?

24.4 The rates of thermolysis of a variety of *cis*- and *trans*-azoalkanes have been measured over a range of temperatures in order to settle a controversy concerning the mechanism of the reaction. In ethanol an unstable *cis*-azoalkane decomposed at a rate that was followed by observing the N_2 evolution, and this led to the rate constants listed below (P.S. Engel and D.J. Bishop, *J. Amer. Chem. Soc.* **97**, 6754 (1975)). Calculate the enthalpy, entropy, energy, and Gibbs energy of activation at -20°C .

$\theta/^\circ\text{C}$	-24.82	-20.73	-17.02	-13.00	-8.95
$10^4 \times k/\text{s}^{-1}$	1.22	2.31	4.39	8.50	14.3

24.5 In an experimental study of a bimolecular reaction in aqueous solution, the second-order rate constant was measured at 25°C and at a variety of ionic strengths and the results are tabulated below. It is known that a singly charged ion is involved in the rate-determining step. What is the charge on the other ion involved?

I	0.0025	0.0037	0.0045	0.0065	0.0085
$k/(\text{dm}^3 \text{mol}^{-1} \text{s}^{-1})$	1.05	1.12	1.16	1.18	1.26

24.6 The rate constant of the reaction $\text{I}^-(\text{aq}) + \text{H}_2\text{O}_2(\text{aq}) \rightarrow \text{H}_2\text{O}(\text{l}) + \text{IO}^-(\text{aq})$ varies slowly with ionic strength, even though the Debye–Hückel limiting law predicts no effect. Use the following data from 25°C to find the dependence of $\log k_t$ on the ionic strength:

$I/(\text{mol kg}^{-1})$	0.0207	0.0525	0.0925	0.1575
$k_t/(\text{dm}^3 \text{mol}^{-1} \text{min}^{-1})$	0.663	0.670	0.679	0.694

Evaluate the limiting value of k_t at zero ionic strength. What does the result suggest for the dependence of $\log \gamma$ on ionic strength for a neutral molecule in an electrolyte solution?

24.7 The total cross-sections for reactions between alkali metal atoms and halogen molecules are given in the table below (R.D. Levine and R.B. Bernstein, *Molecular reaction dynamics*, Clarendon Press, Oxford, 72 (1974)). Assess the data in terms of the harpoon mechanism.

σ^*/nm^2	Cl_2	Br_2	I_2
Na	1.24	1.16	0.97
K	1.54	1.51	1.27
Rb	1.90	1.97	1.67
Cs	1.96	2.04	1.95

Electron affinities are approximately 1.3 eV (Cl_2), 1.2 eV (Br_2), and 1.7 eV (I_2), and ionization energies are 5.1 eV (Na), 4.3 eV (K), 4.2 eV (Rb), and 3.9 eV (Cs).

24.8† M. Cyfert, B. Latko, and M. Wawrzeczyk (*Int. J. Chem. Kinet.* **28**, 103 (1996)) examined the oxidation of tris(1,10-phenanthroline)iron(II) by periodate in aqueous solution, a reaction that shows autocatalytic behaviour. To assess the kinetic salt effect, they measured rate constants at a variety of concentrations of Na_2SO_4 far in excess of reactant concentrations and reported the following data:

$[\text{Na}_2\text{SO}_4]/(\text{mol kg}^{-1})$	0.2	0.15	0.1	0.05	0.25	0.0125	0.005
$k/(\text{dm}^{3/2} \text{mol}^{-1/2} \text{s}^{-1})$	0.462	0.430	0.390	0.321	0.283	0.252	0.224

What can be inferred about the charge of the activated complex of the rate-determining step?

24.9† For the thermal decomposition of F_2O by the reaction $2 \text{F}_2\text{O}(\text{g}) \rightarrow 2 \text{F}_2(\text{g}) + \text{O}_2(\text{g})$, J. Czarnowski and H.J. Schuhmacher (*Chem. Phys. Lett.* **17**, 235 (1972)) have suggested the following mechanism:

(a) Using the steady-state approximation, show that this mechanism is consistent with the experimental rate law $-d[\text{F}_2\text{O}]/dt = k[\text{F}_2\text{O}]^2 + k'[\text{F}_2\text{O}]^{3/2}$.
(b) The experimentally determined Arrhenius parameters in the range 501–583 K are $A = 7.8 \times 10^{13} \text{ dm}^3 \text{mol}^{-1} \text{s}^{-1}$, $E_a/R = 1.935 \times 10^4 \text{ K}$ for k and $A = 2.3 \times 10^{10} \text{ dm}^3 \text{mol}^{-1} \text{s}^{-1}$, $E_a/R = 1.691 \times 10^4 \text{ K}$ for k' . At 540 K, $\Delta_r H^\circ(\text{F}_2\text{O}) = +24.41 \text{ kJ mol}^{-1}$, $D(\text{F}-\text{F}) = 160.6 \text{ kJ mol}^{-1}$, and $D(\text{O}-\text{O}) = 498.2 \text{ kJ mol}^{-1}$. Estimate the bond dissociation energies of the first and second F–O bonds and the Arrhenius activation energy of reaction 2.

24.10† For the gas-phase reaction $\text{A} + \text{A} \rightarrow \text{A}_2$, the experimental rate constant, k_2 , has been fitted to the Arrhenius equation with the pre-exponential factor $A = 4.07 \times 10^5 \text{ dm}^3 \text{mol}^{-1} \text{s}^{-1}$ at 300 K and an activation energy of $65.43 \text{ kJ mol}^{-1}$. Calculate $\Delta^\ddagger S$, $\Delta^\ddagger H$, $\Delta^\ddagger U$, and $\Delta^\ddagger G$ for the reaction.

24.11† One of the most historically significant studies of chemical reaction rates was that by M. Bodenstein (*Z. physik. Chem.* **29**, 295 (1899)) of the gas-phase reaction $2 \text{HI}(\text{g}) \rightarrow \text{H}_2(\text{g}) + \text{I}_2(\text{g})$ and its reverse, with rate constants k and k' , respectively. The measured rate constants as a function of temperature are

T/K	647	666	683	700	716	781
$k/(22.4 \text{ dm}^3 \text{mol}^{-1} \text{min}^{-1})$	0.230	0.588	1.37	3.10	6.70	105.9
$k'/(22.4 \text{ dm}^3 \text{mol}^{-1} \text{min}^{-1})$	0.0140	0.0379	0.0659	0.172	0.375	3.58

Demonstrate that these data are consistent with the collision theory of bimolecular gas-phase reactions.

24.12 Use the approximate form of the Marcus relation (eqn 24.86 with $f = 1$) to estimate the rate constant for the reaction $\text{Ru}(\text{bpy})_3^{3+} + \text{Fe}(\text{H}_2\text{O})_6^{2+} \rightarrow \text{Ru}(\text{bpy})_3^{2+} + \text{Fe}(\text{H}_2\text{O})_6^{3+}$, where bpy stands for 4,4'-bipyridine. The following data are useful:

Theoretical problems

24.13 Confirm that eqn 24.40 is a solution of eqn 24.39, where $[J]_i$ is a solution of the same equation but with $k = 0$ and for the same initial conditions.

24.14 Evaluate $[J]^*$ numerically using mathematical software for integration in eqn 24.40, and explore the effect of increasing reaction rate constant on the spatial distribution of J .

24.15 Estimate the orders of magnitude of the partition functions involved in a rate expression. State the order of magnitude of q_m^T/N_A , q^R , q^V , q^E for typical molecules. Check that in the collision of two structureless molecules the order of magnitude of the pre-exponential factor is of the same order as that predicted by collision theory. Go on to estimate the P factor for a reaction in which $\text{A} + \text{B} \rightarrow \text{P}$, and A and B are nonlinear triatomic molecules.

24.16 Use the Debye–Hückel limiting law to show that changes in ionic strength can affect the rate of reaction catalysed by H^+ from the deprotonation

of a weak acid. Consider the mechanism: $\text{H}^+(\text{aq}) + \text{B}(\text{aq}) \rightarrow \text{P}$, where H^+ comes from the deprotonation of the weak acid, HA. The weak acid has a fixed concentration. First show that $\log [\text{H}^+]$, derived from the ionization of HA, depends on the activity coefficients of ions and thus depends on the ionic strength. Then find the relationship between $\log(\text{rate})$ and $\log [\text{H}^+]$ to show that the rate also depends on the ionic strength.

24.17 The Eyring equation can also be applied to physical processes. As an example, consider the rate of diffusion of an atom stuck to the surface of a solid. Suppose that in order to move from one site to another it has to reach the top of the barrier where it can vibrate classically in the vertical direction and in one horizontal direction, but vibration along the other horizontal direction takes it into the neighbouring site. Find an expression for the rate of diffusion, and evaluate it for W atoms on a tungsten surface ($E_a = 60 \text{ kJ mol}^{-1}$). Suppose that the vibration frequencies at the transition state are (a) the same as, (b) one-half the value for the adsorbed atom. What is the value of the diffusion coefficient D at 500 K? (Take the site separation as 316 pm and $v = 1 \times 10^{11} \text{ Hz}$.)

24.18 Suppose now that the adsorbed, migrating species treated in Problem 24.17 is a spherical molecule, and that it can rotate classically as well as vibrate at the top of the barrier, but that at the adsorption site itself it can only vibrate. What effect does this have on the diffusion constant? Take the molecule to be methane, for which $B = 5.24 \text{ cm}^{-1}$.

24.19 Show that the intensities of a molecular beam before and after passing through a chamber of length l containing inert scattering atoms are related by $I = I_0 e^{-N\sigma l}$, where σ is the collision cross-section and N the number density of scattering atoms.

24.20 In a molecular beam experiment to measure collision cross-sections it was found that the intensity of a CsCl beam was reduced to 60 per cent of its intensity on passage through CH_2F_2 at $10 \mu\text{Torr}$, but that when the target was Ar at the same pressure the intensity was reduced only by 10 per cent. What are the relative cross-sections of the two types of collision? Why is one much larger than the other?

24.21† Show that bimolecular reactions between nonlinear molecules are much slower than between atoms even when the activation energies of both reactions are equal. Use transition state theory and make the following assumptions. (1) All vibrational partition functions are close to unity; (2) all rotational partition functions are approximately $1 \times 10^{1.5}$, which is a reasonable order of magnitude number; (3) the translational partition function for each species is 1×10^{26} .

24.22 This exercise gives some familiarity with the difficulties involved in predicting the structure of activated complexes. It also demonstrates the importance of femtosecond spectroscopy to our understanding of chemical dynamics because direct experimental observation of the activated complex removes much of the ambiguity of theoretical predictions. Consider the attack of H on D_2 , which is one step in the $\text{H}_2 + \text{D}_2$ reaction. (a) Suppose that the H approaches D_2 from the side and forms a complex in the form of an isosceles triangle. Take the H—D distance as 30 per cent greater than in H_2 (74 pm) and the D—D distance as 20 per cent greater than in H_2 . Let the critical coordinate be the antisymmetric stretching vibration in which one H—D bond stretches as the other shortens. Let all the vibrations be at about 1000 cm^{-1} . Estimate k_2 for this reaction at 400 K using the experimental activation energy of about 35 kJ mol^{-1} . (b) Now change the model of the activated complex in part (a) and make it linear. Use the same estimated molecular bond lengths and vibrational frequencies to calculate k_2 for this choice of model. (c) Clearly, there is much scope for modifying the parameters of the models of the activated complex. Use mathematical software or write and run a program that allows you to vary the structure of the complex and the parameters in a plausible way, and look for a model (or more than one model) that gives a value of k close to the experimental value, $4 \times 10^5 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$.

Applications: to environmental science and biochemistry

24.23† R. Atkinson (*J. Phys. Chem. Ref. Data* **26**, 215 (1997)) has reviewed a large set of rate constants relevant to the atmospheric chemistry of volatile organic compounds. The recommended rate constant for the bimolecular association of O_2 with an alkyl radical R at 298 K is $4.7 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ for $\text{R} = \text{C}_2\text{H}_5$ and $8.4 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ for $\text{R} = \text{cyclohexyl}$. Assuming no energy barrier, compute the steric factor, P , for each reaction. (*Hint*. Obtain collision diameters from collision cross-sections of similar molecules in the *Data section*.)

24.24† The compound α -tocopherol, a form of vitamin E, is a powerful antioxidant that may help to maintain the integrity of biological membranes. R.H. Bisby and A.W. Parker (*J. Amer. Chem. Soc.* **117**, 5664 (1995)) studied the reaction of photochemically excited duroquinone with the antioxidant in ethanol. Once the duroquinone was photochemically excited, a bimolecular reaction took place at a rate described as diffusion-limited. (a) Estimate the rate constant for a diffusion-limited reaction in ethanol. (b) The reported rate constant was $2.77 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$; estimate the critical reaction distance if the sum of diffusion constants is $1 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$.

24.25 The study of conditions that optimize the association of proteins in solution guides the design of protocols for formation of large crystals that are amenable to analysis by the X-ray diffraction techniques discussed in Chapter 20. It is important to characterize protein dimerization because the process is considered to be the rate-determining step in the growth of crystals of many proteins. Consider the variation with ionic strength of the rate constant of dimerization in aqueous solution of a cationic protein P:

I	0.0100	0.0150	0.0200	0.0250	0.0300	0.0350
k/k°	8.10	13.30	20.50	27.80	38.10	52.00

What can be deduced about the charge of P?

24.26 A useful strategy for the study of electron transfer in proteins consists of attaching an electroactive species to the protein's surface and then measuring k_{et} between the attached species and an electroactive protein cofactor. J.W. Winkler and H.B. Gray (*Chem. Rev.* **92**, 369 (1992)) summarize data for cytochrome *c* (*Impact* I7.2) modified by replacement of the haem iron by a zinc ion, resulting in a zinc-porphyrin (ZnP) moiety in the interior of the protein, and by attachment of a ruthenium ion complex to a surface histidine aminoacid. The edge-to-edge distance between the electroactive species was thus fixed at 1.23 nm. A variety of ruthenium ion complexes with different standard reduction potentials were used. For each ruthenium-modified protein, either the $\text{Ru}^{2+} \rightarrow \text{ZnP}^+$ or the $\text{ZnP}^* \rightarrow \text{Ru}^{3+}$, in which the electron donor is an electronic excited state of the zinc-porphyrin formed by laser excitation, was monitored. This arrangement leads to different standard reaction Gibbs energies because the redox couples ZnP^+/ZnP and $\text{ZnP}^*/\text{ZnP}^+$ have different standard potentials, with the electronically excited porphyrin being a more powerful reductant. Use the following data to estimate the reorganization energy for this system:

$-\Delta_r G^\circ/\text{eV}$	0.665	0.705	0.745	0.975	1.015	1.055
$k_{\text{et}}/(10^6 \text{ s}^{-1})$	0.657	1.52	1.12	8.99	5.76	10.1

24.27 The photosynthetic reaction centre of the purple photosynthetic bacterium *Rhodospseudomonas viridis* contains a number of bound cofactors that participate in electron transfer reactions. The following table shows data compiled by Moser *et al.* (*Nature* **355**, 796 (1992)) on the rate constants for electron transfer between different cofactors and their edge-to-edge distances:

Reaction	$\text{BChl}^- \rightarrow \text{BPh}$	$\text{BPh}^- \rightarrow \text{BChl}_2^+$	$\text{BPh}^- \rightarrow \text{Q}_A$	$\text{cyt } c_{559} \rightarrow \text{BChl}_2^+$
r/nm	0.48	0.95	0.96	1.23
$k_{\text{et}}/\text{s}^{-1}$	1.58×10^{12}	3.98×10^9	1.00×10^9	1.58×10^8
Reaction	$\text{Q}_A^- \rightarrow \text{Q}_B$	$\text{Q}_A^- \rightarrow \text{BChl}_2^+$		
r/nm	1.35	2.24		
$k_{\text{et}}/\text{s}^{-1}$	3.98×10^7	63.1		

(BChl, bacteriochlorophyll; BChl₂, bacteriochlorophyll dimer, functionally distinct from BChl; BPh, bacteriopheophytin; Q_A and Q_B, quinone molecules bound to two distinct sites; cyt *c*₅₅₉, a cytochrome bound to the reaction centre complex). Are these data in agreement with the behaviour predicted by eqn 24.83? If so, evaluate the value of β .

24.28 The rate constant for electron transfer between a cytochrome *c* and the bacteriochlorophyll dimer of the reaction centre of the purple bacterium *Rhodobacter sphaeroides* (Problem 24.27) decreases with decreasing temperature in the range 300 K to 130 K. Below 130 K, the rate constant becomes independent of temperature. Account for these results.

24.29 Azurin is a protein containing a copper ion that shuttles between the +2 and +1 oxidation states, and cytochrome *c* is a protein in which a haem-bound iron ion shuttles between the +3 and +2 oxidation states. The rate constant for electron transfer from reduced azurin to oxidized cytochrome *c* is $1.6 \times 10^3 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$. Estimate the electron self-exchange rate constant for azurin from the following data:

	$k_{ii}/(\text{dm}^3 \text{ mol}^{-1} \text{ s}^{-1})$	$E^\ominus/V$
cytochrome <i>c</i>	1.5×10^2	0.260
azurin	?	0.304

Processes at solid surfaces

25

In this chapter we see how solids grow at their surfaces and how the details of the structure and composition of solid surfaces can be determined experimentally. A major part of the material concerns the extent to which a surface is covered and the variation of the extent of coverage with the pressure and temperature. This material is used to discuss how surfaces affect the rate and course of chemical change by acting as the site of catalysis. Reactions at surfaces include the processes that lie at the heart of electrochemistry. Therefore, we revisit in this chapter some of the topics treated in Chapter 7, but focus on the dynamics of electrode processes rather than the equilibrium properties treated there. Finally, we analyse the kinetics of reactions that are responsible for power production in fuel cells and for corrosion.

Processes at solid surfaces govern the viability of industry both constructively, as in catalysis, and destructively, as in corrosion. Chemical reactions at solid surfaces may differ sharply from reactions in the bulk, for reaction pathways of much lower activation energy may be provided, and hence result in catalysis. The concept of a solid surface has been extended in recent years with the availability of microporous materials as catalysts.

An important kinetic problem examined in this chapter is the rate at which oxidizable or reducible species—in short, **electroactive species**—can donate or accept electrons on the surfaces of electrodes. In Chapter 24 we explored the dynamics of electron transfer in homogeneous systems. In heterogeneous systems, the rates of processes that occur at the interface between the phases, such as an electrode immersed in an ionic solution, are very important. A measure of this rate is the **current density**, j , the charge flux through a region (the electric current divided by the area of the region). We shall discuss the properties that control the current density and its consequences.

We shall see that acronyms are widely used in surface studies; for convenience, a list of the acronyms used in this chapter is given in Table 25.7 at the end of the chapter.

The growth and structure of solid surfaces

In this section we see how surfaces are extended and crystals grow. The attachment of particles to a surface is called **adsorption**. The substance that adsorbs is the **adsorbate** and the underlying material that we are concerned with in this section is the **adsorbent** or **substrate**. The reverse of adsorption is **desorption**.

Problems

Fig. 25.1 A schematic diagram of the flat surface of a solid. This primitive model is largely supported by scanning tunnelling microscope images (see *Impact* I9.1).

Fig. 25.2 Some of the kinds of defects that may occur on otherwise perfect terraces. Defects play an important role in surface growth and catalysis.

25.1 Surface growth

A simple picture of a perfect crystal surface is as a tray of oranges in a grocery store (Fig. 25.1). A gas molecule that collides with the surface can be imagined as a ping-pong ball bouncing erratically over the oranges. The molecule loses energy as it bounces, but it is likely to escape from the surface before it has lost enough kinetic energy to be trapped. The same is true, to some extent, of an ionic crystal in contact with a solution. There is little energy advantage for an ion in solution to discard some of its solvating molecules and stick at an exposed position on the surface.

The picture changes when the surface has defects, for then there are ridges of incomplete layers of atoms or ions. A common type of surface defect is a **step** between two otherwise flat layers of atoms called **terraces** (Fig. 25.2). A step defect might itself have defects, for it might have kinks. When an atom settles on a terrace it bounces across it under the influence of the intermolecular potential, and might come to a step or a corner formed by a kink. Instead of interacting with a single terrace atom, the molecule now interacts with several, and the interaction may be strong enough to trap it. Likewise, when ions deposit from solution, the loss of the solvation interaction is offset by a strong Coulombic interaction between the arriving ions and several ions at the surface defect.

Not all kinds of defect result in sustained surface growth. As the process of settling into ledges and kinks continues, there comes a stage when an entire lower terrace has been covered. At this stage the surface defects have been eliminated, and growth will cease. For continuing growth, a surface defect is needed that propagates as the crystal grows. We can see what form of defect this must be by considering the types of **dislocations**, or discontinuities in the regularity of the lattice, that exist in the bulk of a crystal. One reason for their formation may be that the crystal grows so quickly that its particles do not have time to settle into states of lowest potential energy before being trapped in position by the deposition of the next layer.

A special kind of dislocation is the **screw dislocation** shown in Fig. 25.3. Imagine a cut in the crystal, with the atoms to the left of the cut pushed up through a distance of one unit cell. The unit cells now form a continuous spiral around the end of the cut, which is called the **screw axis**. A path encircling the screw axis spirals up to the top of the crystal, and where the dislocation breaks through to the surface it takes the form of a spiral ramp.

The surface defect formed by a screw dislocation is a step, possibly with kinks, where growth can occur. The incoming particles lie in ranks on the ramp, and successive ranks reform the step at an angle to its initial position. As deposition continues the step rotates around the screw axis and is not eliminated. Growth may therefore continue indefinitely. Several layers of deposition may occur, and the edges of the spirals might be cliffs several atoms high. Propagating spiral edges can also give rise to flat terraces (Fig. 25.4). Terraces are formed if growth occurs simultaneously at neighbouring left- and right-handed screw dislocations (Fig. 25.5). Successive tables of atoms may form as counter-rotating defects collide on successive circuits, and the terraces formed may then fill up by further deposition at their edges to give flat crystal planes.

The rapidity of growth depends on the crystal plane concerned, and the slowest growing faces dominate the appearance of the crystal. This feature is explained in Fig. 25.6, where we see that, although the horizontal face grows forward most rapidly, it grows itself out of existence, and the slower-growing faces survive.

Fig. 25.3 A screw dislocation occurs where one region of the crystal is pushed up through one or more unit cells relative to another region. The cut extends to the screw axis. As atoms lie along the step the dislocation rotates round the screw axis and is not annihilated.

Fig. 25.4 The spiral growth pattern is sometimes concealed because the terraces are subsequently completed by further deposition. This accounts for the appearance of this cadmium iodide crystal. (H.M. Rosenberg, *The solid state*. Clarendon Press, Oxford (1978).)

25.2 Surface composition

Under normal conditions, a surface exposed to a gas is constantly bombarded with molecules and a freshly prepared surface is covered very quickly. Just how quickly can be estimated using the kinetic model of gases and the expression (eqn 21.14) for the collision flux:

$$Z_W = \frac{p}{(2\pi mkT)^{1/2}} \quad (25.1a)$$

A practical form of this equation is

$$Z_W = \frac{Z_0(p/\text{Pa})}{\{(T/\text{K})(M/(\text{g mol}^{-1}))\}^{1/2}} \quad \text{with} \quad Z_0 = 2.63 \times 10^{24} \text{ m}^{-2} \text{ s}^{-1} \quad (25.1b)$$

where M is the molar mass of the gas. For air ($M \approx 29 \text{ g mol}^{-1}$) at 1 atm and 25°C the collision flux is $3 \times 10^{27} \text{ m}^{-2} \text{ s}^{-1}$. Because 1 m^2 of metal surface consists of about 10^{19} atoms, each atom is struck about 10^8 times each second. Even if only a few collisions leave a molecule adsorbed to the surface, the time for which a freshly prepared surface remains clean is very short.

The obvious way to retain cleanliness is to reduce the pressure. When it is reduced to 10^{-4} Pa (as in a simple vacuum system) the collision flux falls to about $10^{18} \text{ m}^{-2} \text{ s}^{-1}$, corresponding to one hit per surface atom in each 0.1 s. Even that is too brief in most experiments, and in **ultrahigh vacuum** (UHV) techniques pressures as low as 10^{-7} Pa (when $Z_W = 10^{15} \text{ m}^{-2} \text{ s}^{-1}$) are reached on a routine basis and as low as 10^{-9} Pa (when $Z_W = 10^{13} \text{ m}^{-2} \text{ s}^{-1}$) are reached with special care. These collision fluxes correspond to each surface atom being hit once every 10^5 to 10^6 s, or about once a day.

The layout of a typical UHV apparatus is such that the whole of the evacuated part can be heated to 150–250°C for several hours to drive gas molecules from the walls. All the taps and seals are usually of metal so as to avoid contamination from greases. The sample is usually in the form of a thin foil, a filament, or a sharp point. Where there is interest in the role of specific crystal planes the sample is a single crystal with a freshly cleaved face. Initial surface cleaning is achieved either by heating it electrically or by

Fig. 25.5 Counter-rotating screw dislocations on the same surface lead to the formation of terraces. Four stages of one cycle of growth are shown here. Subsequent deposition can complete each terrace.

Fig. 25.6 The slower-growing faces of a crystal dominate its final external appearance. Three successive stages of the growth are shown.

Fig. 25.7 Visualization by STM of the reaction $\text{SiH}_3 \rightarrow \text{SiH}_2 + \text{H}$ on a $4.7 \text{ nm} \times 4.7 \text{ nm}$ area of a Si(001) surface. (a) The Si(001) surface before exposure to $\text{Si}_2\text{H}_6(\text{g})$. (b) Adsorbed Si_2H_6 dissociates into $\text{SiH}_2(\text{surface})$, on the left of the image, and $\text{SiH}_3(\text{surface})$, on the right. (c) After 8 min, $\text{SiH}_3(\text{surface})$ dissociates to $\text{SiH}_2(\text{surface})$ and $\text{H}(\text{surface})$. (Reproduced with permission from Y. Wang, M.J. Bronikowski, and R.J. Hamers, *Surface Science* **64**, 311 (1994).)

bombarding it with accelerated gaseous ions. The latter procedure demands care because ion bombardment can shatter the surface structure and leave it an amorphous jumble of atoms. High temperature annealing is then required to return the surface to an ordered state.

We have already discussed three important techniques for the characterization of surfaces: scanning electron microscopy (*Impact* I8.1), which is often used to observe terraces, steps, kinks, and dislocations on a surface, and scanning probe microscopy (*Impact* I9.1), which reveals the atomic details of structure of the surface and of adsorbates and can be used to visualize chemical reactions as they happen on surfaces (Fig. 25.7). In the following sections, we describe additional techniques that comprise the toolbox of a surface scientist.

(a) Ionization techniques

Surface composition can be determined by a variety of ionization techniques. The same techniques can be used to detect any remaining contamination after cleaning and to detect layers of material adsorbed later in the experiment. Their common feature is that the **escape depth** of the electrons, the maximum depth from which ejected electrons come, is in the range 0.1–1.0 nm, which ensures that only surface species contribute.

One technique that may be used is photoelectron spectroscopy (Section 11.4), which in surface studies is normally called **photoemission spectroscopy**. X-rays or hard ultraviolet ionizing radiation of energy in the range 5–40 eV may be used, giving rise to the techniques denoted XPS and UPS, respectively.

In XPS, the energy of the incident photon is so great that electrons are ejected from inner cores of atoms. As a first approximation, core ionization energies are insensitive to the bonds between atoms because they are too tightly bound to be greatly affected by the changes that accompany bond formation, so core ionization energies are characteristic of the individual atom. Consequently, XPS gives lines characteristic of the elements present on a surface. For instance, the *K*-shell ionization energies of the second row elements are

Li	Be	B	C	N	O	F
50	110	190	280	400	530	690 eV

Detection of one of these values (and values corresponding to ejection from other inner shells) indicates the presence of the corresponding element (Fig. 25.8). This

Fig. 25.8 The X-ray photoelectron emission spectrum of a sample of gold contaminated with a surface layer of mercury. (M.W. Roberts and C.S. McKee, *Chemistry of the metal–gas interface*, Oxford (1978).)

application is responsible for the alternative name **electron spectroscopy for chemical analysis** (ESCA). The technique is very useful for studying the surface state of heterogeneous catalysts, the differences between surface and bulk structures, and the processes that can cause damage to high-temperature superconductors and semiconductor wafers.

UPS, which examines electrons ejected from valence shells, is more suited to establishing the bonding characteristics and the details of valence shell electronic structures of substances on the surface. Its usefulness is its ability to reveal which orbitals of the adsorbate are involved in the bond to the substrate. For instance, the principal difference between the photoemission results on free benzene and benzene adsorbed on palladium is in the energies of the π electrons. This difference is interpreted as meaning that the C_6H_6 molecules lie parallel to the surface and are attached to it by their π orbitals.

In **secondary-ion mass spectrometry** (SIMS), the surface is ionized by bombardment with other ions and the secondary ions that emerge from the surface are detected by a mass spectrometer. Among the advantages of SIMS are the ability to detect adsorbed H and He atoms, which are not easily probed by XPS, and the high sensitivity of the mass spectrometer detector. A disadvantage is that SIMS analysis erodes the part of the sample that is bombarded. However, it is possible to control the degree of erosion to one or two monolayers by controlling the bombardment parameters.

(b) Vibrational spectroscopy

Several kinds of vibrational spectroscopy have been developed to study adsorbates and to show whether dissociation has occurred. Measurement of transmitted radiation is not practical in surfaces, which are typically too opaque to infrared or visible radiation. One technique that circumvents this problem is **reflection-absorption infrared spectroscopy** (RAIRS), in which the Fourier-transform IR absorption spectrum of the adsorbate is obtained by comparing the intensity of the incident infrared beam with the intensity of infrared radiation reflected by the surface.

Raman spectroscopy is better suited for studies of surfaces because it involves the detection of scattered radiation, but spectral bands are typically very weak. However, **surface-enhanced Raman scattering** (SERS) is viable for surface studies: the strong enhancement of the Raman spectrum of the adsorbate can increase intensities by a factor as big as 10^6 . The effect is due in part to local accumulations of electron density at the features of the roughened surface and at regions where bonding occurs. The SERS effect is also observed when molecules adsorb to colloidal particles of gold and silver, with the surface of the colloid fostering the enhancement of the Raman spectrum. Disadvantages of SERS include weak enhancement observed on flat single crystal surfaces and the fact that the technique works for only certain metals.

(c) Electron spectroscopy

A hybrid version of photoemission spectroscopy and vibrational spectroscopy is **electron energy loss spectroscopy** (EELS, or HREELS, where HR denotes high resolution) in which the energy loss suffered by a beam of electrons is monitored when they are reflected from a surface. As in Raman spectroscopy, the spectrum of energy loss can be interpreted in terms of the vibrational spectrum of the adsorbate. High resolution and sensitivity are attainable, and the technique is sensitive to light elements (to which X-ray techniques are insensitive). Very tiny amounts of adsorbate can be detected, and one report estimated that about 48 atoms of phosphorus were detected in one sample. As an example, Fig. 25.9 shows the EELS result for CO on the (111) face of a platinum crystal as the extent of surface coverage increases. The main peak arises

Fig. 25.9 The electron energy loss spectrum of CO adsorbed on Pt(111). The results for three different pressures are shown, and the growth of the additional peak at about 200 meV (1600 cm^{-1}) should be noted. (Based on spectra provided by Professor H. Ibach.)

1 Bridge site

Fig. 25.10 When an electron is expelled from a solid (a) an electron of higher energy may fall into the vacated orbital and emit an X-ray photon to produce X-ray fluorescence. Alternatively, (b) the electron falling into the orbital may give up its energy to another electron, which is ejected in the Auger effect.

Fig. 25.11 A schematic diagram of the apparatus used for a LEED experiment. The electrons diffracted by the surface layers are detected by the fluorescence they cause on the phosphor screen.

from CO attached perpendicular to the surface by a single Pt atom. As the coverage increases the neighbouring smaller peak increases in intensity. This peak is due to CO at a bridge site, attached to two Pt atoms, as in (1).

A very important technique, which is widely used in the microelectronics industry, is **Auger electron spectroscopy** (AES). The **Auger effect** is the emission of a second electron after high energy radiation has expelled another. The first electron to depart leaves a hole in a low-lying orbital, and an upper electron falls into it. The energy this releases may result either in the generation of radiation, which is called **X-ray fluorescence** (Fig. 25.10a) or in the ejection of another electron (Fig. 25.10b). The latter is the secondary electron of the Auger effect. The energies of the secondary electrons are characteristic of the material present, so the Auger effect effectively takes a fingerprint of the sample. In practice, the Auger spectrum is normally obtained by irradiating the sample with an electron beam of energy in the range 1–5 keV rather than electromagnetic radiation. In **scanning Auger electron microscopy** (SAM), the finely focused electron beam is scanned over the surface and a map of composition is compiled; the resolution can reach below about 50 nm.

(d) Surface-extended X-ray absorption fine structure spectroscopy

The technique known as **surface-extended X-ray absorption fine structure spectroscopy** (SEXAFS) uses intense X-radiation from synchrotron sources (*Further information* 13.1). Oscillations in X-ray absorbance are observed on the high-frequency side of the absorption edge (the start of an X-ray absorption band) of a substance. These oscillations arise from a quantum mechanical interference between the wavefunction of a photoejected electron and parts of that electron's wavefunction that are scattered by neighbouring atoms. If the waves interfere destructively, then the photoelectron appears with lower probability and the X-ray absorption is correspondingly less. If the waves interfere constructively, then the photoelectron amplitude is higher, and the photoelectron has a higher probability of appearing; correspondingly, the X-ray absorption is greater. The oscillations therefore contain information about the number and distances of the neighbouring atoms. Such studies show that a solid's surface is much more plastic than had previously been thought, and that it undergoes **reconstruction**, or structural modification, in response to adsorbates that are present.

(e) Low-energy electron diffraction

One of the most informative techniques for determining the arrangement of the atoms close to the surface is **low energy electron diffraction** (LEED). This technique is like X-ray diffraction (Chapter 20) but uses the wave character of electrons, and the sample is now the surface of a solid. The use of low energy electrons (with energies in the range 10–200 eV, corresponding to wavelengths in the range 100–400 pm) ensures that the diffraction is caused only by atoms on and close to the surface. The experimental arrangement is shown in Fig. 25.11, and typical LEED patterns, obtained by photographing the fluorescent screen through the viewing port, are shown in Fig. 25.12.

A LEED pattern portrays the two-dimensional structure of the surface. By studying how the diffraction intensities depend on the energy of the electron beam it is also possible to infer some details about the vertical location of the atoms and to measure the thickness of the surface layer, but the interpretation of LEED data is much more complicated than the interpretation of bulk X-ray data. The pattern is sharp if the surface is well-ordered for distances long compared with the wavelength of the incident electrons. In practice, sharp patterns are obtained for surfaces ordered to depths of about 20 nm and more. Diffuse patterns indicate either a poorly ordered surface or the presence of impurities. If the LEED pattern does not correspond to the pattern

Fig. 25.12 LEED photographs of (a) a clean platinum surface and (b) after its exposure to propyne, $\text{CH}_3\text{C}\equiv\text{CH}$. (Photographs provided by Professor G.A. Somorjai.)

expected by extrapolation of the bulk surface to the surface, then either a reconstruction of the surface has occurred or there is order in the arrangement of an adsorbed layer.

The results of LEED experiments show that the surface of a crystal rarely has exactly the same form as a slice through the bulk. As a general rule, it is found that metal surfaces are simply truncations of the bulk lattice, but the distance between the top layer of atoms and the one below is contracted by around 5 per cent. Semiconductors generally have surfaces reconstructed to a depth of several layers. Reconstruction occurs in ionic solids. For example, in lithium fluoride the Li^+ and F^- ions close to the surface apparently lie on slightly different planes. An actual example of the detail that can now be obtained from refined LEED techniques is shown in Fig. 25.13 for $\text{CH}_3\text{C}-$ adsorbed on a (111) plane of rhodium.

The presence of terraces, steps, and kinks in a surface shows up in LEED patterns, and their surface density (the number of defects in a region divided by the area of the region) can be estimated. The importance of this type of measurement will emerge later. Three examples of how steps and kinks affect the pattern are shown in Fig. 25.14. The samples used were obtained by cleaving a crystal at different angles to a plane of

Fig. 25.13 The structure of a surface close to the point of attachment of $\text{CH}_3\text{C}-$ to the (110) surface of rhodium at 300 K and the changes in positions of the metal atoms that accompany chemisorption.

Fig. 25.14 LEED patterns may be used to assess the defect density of a surface. The photographs correspond to a platinum surface with (top) low defect density, (middle) regular steps separated by about six atoms, and (bottom) regular steps with kinks. (Photographs provided by Professor G.A. Somorjai.)

atoms. Only terraces are produced when the cut is parallel to the plane, and the density of steps increases as the angle of the cut increases. The observation of additional structure in the LEED patterns, rather than blurring, shows that the steps are arrayed regularly.

(f) Molecular beam techniques

Whereas many important studies have been carried out simply by exposing a surface to a gas, modern work is increasingly making use of **molecular beam scattering** (MBS). One advantage is that the activity of specific crystal planes can be investigated by directing the beam on to an orientated surface with known step and kink densities (as measured by LEED). Furthermore, if the adsorbate reacts at the surface the products (and their angular distributions) can be analysed as they are ejected from the surface and pass into a mass spectrometer. Another advantage is that the time of flight of a particle may be measured and interpreted in terms of its residence time on the surface. In this way a very detailed picture can be constructed of the events taking place during reactions at surfaces.

The extent of adsorption

The extent of surface coverage is normally expressed as the **fractional coverage**, θ :

$$\theta = \frac{\text{number of adsorption sites occupied}}{\text{number of adsorption sites available}} \quad [25.2]$$

The fractional coverage is often expressed in terms of the volume of adsorbate adsorbed by $\theta = V/V_\infty$, where V_∞ is the volume of adsorbate corresponding to complete monolayer coverage. The **rate of adsorption**, $d\theta/dt$, is the rate of change of surface coverage, and can be determined by observing the change of fractional coverage with time.

Among the principal techniques for measuring $d\theta/dt$ are flow methods, in which the sample itself acts as a pump because adsorption removes particles from the gas. One commonly used technique is therefore to monitor the rates of flow of gas into and out of the system: the difference is the rate of gas uptake by the sample. Integration of this rate then gives the fractional coverage at any stage. In **flash desorption** the sample is suddenly heated (electrically) and the resulting rise of pressure is interpreted in terms of the amount of adsorbate originally on the sample. The interpretation may be confused by the desorption of a compound (for example, WO_3 from oxygen on tungsten). **Gravimetry**, in which the sample is weighed on a microbalance during the experiment, can also be used. A common instrument for gravimetric measurements is the **quartz crystal microbalance** (QCM), in which the mass of a sample laid on the surface of a quartz crystal is related to changes in the latter's mechanical properties. The key principle behind the operation of a QCM is the ability of a quartz crystal to vibrate at a characteristic frequency when an oscillating electric field is applied. The vibrational frequency decreases when material is spread over the surface of the crystal and the change in frequency is proportional to the mass of material. Masses as small as a few nanograms ($1 \text{ ng} = 10^{-9} \text{ g}$) can be measured reliably in this way.

25.3 Physisorption and chemisorption

Molecules and atoms can attach to surfaces in two ways. In **physisorption** (an abbreviation of 'physical adsorption'), there is a van der Waals interaction (for example, a dispersion or a dipolar interaction) between the adsorbate and the substrate. Van der Waals interactions have a long range but are weak, and the energy released when a

particle is physisorbed is of the same order of magnitude as the enthalpy of condensation. Such small energies can be absorbed as vibrations of the lattice and dissipated as thermal motion, and a molecule bouncing across the surface will gradually lose its energy and finally adsorb to it in the process called **accommodation**. The enthalpy of physisorption can be measured by monitoring the rise in temperature of a sample of known heat capacity, and typical values are in the region of 20 kJ mol^{-1} (Table 25.1). This small enthalpy change is insufficient to lead to bond breaking, so a physisorbed molecule retains its identity, although it might be distorted by the presence of the surface.

In **chemisorption** (an abbreviation of ‘chemical adsorption’), the molecules (or atoms) stick to the surface by forming a chemical (usually covalent) bond, and tend to find sites that maximize their coordination number with the substrate. The enthalpy of chemisorption is very much greater than that for physisorption, and typical values are in the region of 200 kJ mol^{-1} (Table 25.2). The distance between the surface and the closest adsorbate atom is also typically shorter for chemisorption than for physisorption. A chemisorbed molecule may be torn apart at the demand of the unsatisfied valencies of the surface atoms, and the existence of molecular fragments on the surface as a result of chemisorption is one reason why solid surfaces catalyse reactions.

Except in special cases, chemisorption must be exothermic. A spontaneous process requires $\Delta G < 0$. Because the translational freedom of the adsorbate is reduced when it is adsorbed, ΔS is negative. Therefore, in order for $\Delta G = \Delta H - T\Delta S$ to be negative, ΔH must be negative (that is, the process is exothermic). Exceptions may occur if the adsorbate dissociates and has high translational mobility on the surface. For example, H_2 adsorbs endothermically on glass because there is a large increase of translational entropy accompanying the dissociation of the molecules into atoms that move quite freely over the surface. In its case, the entropy change in the process $\text{H}_2(\text{g}) \rightarrow 2 \text{H}(\text{glass})$ is sufficiently positive to overcome the small positive enthalpy change.

The enthalpy of adsorption depends on the extent of surface coverage, mainly because the adsorbate particles interact. If the particles repel each other (as for CO on palladium) the adsorption becomes less exothermic (the enthalpy of adsorption less negative) as coverage increases. Moreover, LEED studies show that such species settle on the surface in a disordered way until packing requirements demand order. If the adsorbate particles attract one another (as for O_2 on tungsten), then they tend to cluster together in islands, and growth occurs at the borders. These adsorbates also show order–disorder transitions when they are heated enough for thermal motion to overcome the particle–particle interactions, but not so much that they are desorbed.

25.4 Adsorption isotherms

The free gas and the adsorbed gas are in dynamic equilibrium, and the fractional coverage of the surface depends on the pressure of the overlying gas. The variation of θ with pressure at a chosen temperature is called the **adsorption isotherm**.

(a) The Langmuir isotherm

The simplest physically plausible isotherm is based on three assumptions:

- 1 Adsorption cannot proceed beyond monolayer coverage.
- 2 All sites are equivalent and the surface is uniform (that is, the surface is perfectly flat on a microscopic scale).
- 3 The ability of a molecule to adsorb at a given site is independent of the occupation of neighbouring sites (that is, there are no interactions between adsorbed molecules).

Synoptic table 25.1* Maximum observed enthalpies of physisorption

Adsorbate	$\Delta_{\text{ad}}H^\circ/(\text{kJ mol}^{-1})$
CH_4	–21
H_2	–84
H_2O	–59
N_2	–21

* More values are given in the *Data section*.

Synoptic table 25.2* Enthalpies of chemisorption, $\Delta_{\text{ad}}H^\circ/(\text{kJ mol}^{-1})$

Adsorbate	Adsorbent (substrate)		
	Cr	Fe	Ni
CH_4	–427	–285	–243
CO		–192	
H_2	–188	–134	
NH_3		–188	–155

* More values are given in the *Data section*.

The dynamic equilibrium is

with rate constants k_a for adsorption and k_d for desorption. The rate of change of surface coverage due to adsorption is proportional to the partial pressure p of A and the number of vacant sites $N(1 - \theta)$, where N is the total number of sites:

$$\frac{d\theta}{dt} = k_a p N (1 - \theta) \quad (25.3a)$$

The rate of change of θ due to desorption is proportional to the number of adsorbed species, $N\theta$:

$$\frac{d\theta}{dt} = -k_d N \theta \quad (25.3b)$$

At equilibrium there is no net change (that is, the sum of these two rates is zero), and solving for θ gives the **Langmuir isotherm**:

$$\theta = \frac{Kp}{1 + Kp} \quad K = \frac{k_a}{k_d} \quad (25.4)$$

Example 25.1 Using the Langmuir isotherm

The data given below are for the adsorption of CO on charcoal at 273 K. Confirm that they fit the Langmuir isotherm, and find the constant K and the volume corresponding to complete coverage. In each case V has been corrected to 1.00 atm (101.325 kPa).

p/kPa	13.3	26.7	40.0	53.3	66.7	80.0	93.3
V/cm^3	10.2	18.6	25.5	31.5	36.9	41.6	46.1

Method From eqn 25.4,

$$Kp\theta + \theta = Kp$$

With $\theta = V/V_\infty$, where V_∞ is the volume corresponding to complete coverage, this expression can be rearranged into

$$\frac{p}{V} = \frac{p}{V_\infty} + \frac{1}{KV_\infty}$$

Hence, a plot of p/V against p should give a straight line of slope $1/V_\infty$ and intercept $1/KV_\infty$.

Answer The data for the plot are as follows:

p/kPa	13.3	26.7	40.0	53.3	66.7	80.0	93.3
$(p/\text{kPa})/(V/\text{cm}^3)$	1.30	1.44	1.57	1.69	1.81	1.92	2.02

The points are plotted in Fig. 25.15. The (least squares) slope is 0.00900, so $V_\infty = 111 \text{ cm}^3$. The intercept at $p = 0$ is 1.20, so

$$K = \frac{1}{(111 \text{ cm}^3) \times (1.20 \text{ kPa cm}^{-3})} = 7.51 \times 10^{-3} \text{ kPa}^{-1}$$

Fig. 25.15 The plot of the data in Example 25.1. As illustrated here, the Langmuir isotherm predicts that a straight line should be obtained when p/V is plotted against p .

Self-test 25.1 Repeat the calculation for the following data:

p/kPa	13.3	26.7	40.0	53.3	66.7	80.0	93.3
V/cm^3	10.3	19.3	27.3	34.1	40.0	45.5	48.0

$[128 \text{ cm}^3, 6.69 \times 10^{-3} \text{ kPa}^{-1}]$

For adsorption with dissociation, the rate of adsorption is proportional to the pressure and to the probability that both atoms will find sites, which is proportional to the square of the number of vacant sites,

$$\frac{d\theta}{dt} = k_a p \{N(1 - \theta)\}^2 \quad (25.5a)$$

The rate of desorption is proportional to the frequency of encounters of atoms on the surface, and is therefore second-order in the number of atoms present:

$$\frac{d\theta}{dt} = -k_d (N\theta)^2 \quad (25.5b)$$

The condition for no net change leads to the isotherm

$$\theta = \frac{(Kp)^{1/2}}{1 + (Kp)^{1/2}} \quad (25.6)$$

The surface coverage now depends more weakly on pressure than for non-dissociative adsorption.

The shapes of the Langmuir isotherms with and without dissociation are shown in Figs. 25.16 and 25.17. The fractional coverage increases with increasing pressure, and approaches 1 only at very high pressure, when the gas is forced on to every available site of the surface. Different curves (and therefore different values of K) are obtained at different temperatures, and the temperature dependence of K can be used to determine the **isosteric enthalpy of adsorption**, $\Delta_{\text{ad}}H^\circ$, the standard enthalpy of adsorption at a fixed surface coverage. To determine this quantity we recognize that K is essentially an equilibrium constant, and then use the van 't Hoff equation (eqn 7.23) to write:

$$\left(\frac{\partial \ln K}{\partial T} \right)_\theta = \frac{\Delta_{\text{ad}}H^\circ}{RT^2} \quad (25.7)$$

Example 25.2 Measuring the isosteric enthalpy of adsorption

The data below show the pressures of CO needed for the volume of adsorption (corrected to 1.00 atm and 273 K) to be 10.0 cm^3 using the same sample as in Example 25.1. Calculate the adsorption enthalpy at this surface coverage.

T/K	200	210	220	230	240	250
p/kPa	4.00	4.95	6.03	7.20	8.47	9.85

Method The Langmuir isotherm can be rearranged to

$$Kp = \frac{\theta}{1 - \theta}$$

Therefore, when θ is constant,

$$\ln K + \ln p = \text{constant}$$

Fig. 25.16 The Langmuir isotherm for dissociative adsorption, $X_2(\text{g}) \rightarrow 2 X(\text{surface})$, for different values of K .

Exploration Using eqn 25.4, generate a family of curves showing the dependence of $1/\theta$ on $1/p$ for several values of K .

Fig. 25.17 The Langmuir isotherm for non-dissociative adsorption for different values of K .

Exploration Using eqn 25.6, generate a family of curves showing the dependence of $1/\theta$ on $1/p$ for several values of K . Taking these results together with those of the previous *Exploration*, discuss how plots of $1/\theta$ against $1/p$ can be used to distinguish between adsorption with and without dissociation.

Fig. 25.18 The isosteric enthalpy of adsorption can be obtained from the slope of the plot of $\ln p$ against $1/T$, where p is the pressure needed to achieve the specified surface coverage. The data used are from Example 25.2.

Fig. 25.19 Plots of the BET isotherm for different values of c . The value of V/V_{mon} rises indefinitely because the adsorbate may condense on the covered substrate surface.

Exploration Using eqn 25.8, generate a family of curves showing the dependence of $zV_{\text{mon}}/(1-z)V$ on z for different values of c .

It follows from eqn 25.7 that

$$\left(\frac{\partial \ln p}{\partial T}\right)_\theta = -\left(\frac{\partial \ln K}{\partial T}\right)_\theta = -\frac{\Delta_{\text{ad}}H^\ominus}{RT^2}$$

With $d(1/T)/dT = -1/T^2$, this expression rearranges to

$$\left(\frac{\partial \ln p}{\partial (1/T)}\right)_\theta = \frac{\Delta_{\text{ad}}H^\ominus}{R}$$

Therefore, a plot of $\ln p$ against $1/T$ should be a straight line of slope $\Delta_{\text{ad}}H^\ominus/R$.

Answer We draw up the following table:

T/K	200	210	220	230	240	250
$10^3/(T/\text{K})$	5.00	4.76	4.55	4.35	4.17	4.00
$\ln(p/\text{kPa})$	1.39	1.60	1.80	1.97	2.14	2.29

The points are plotted in Fig. 25.18. The slope (of the least squares fitted line) is -0.904 , so

$$\Delta_{\text{ad}}H^\ominus = -(0.904 \times 10^3 \text{ K}) \times R = -7.52 \text{ kJ mol}^{-1}$$

The value of K can be used to obtain a value of $\Delta_{\text{ad}}G^\ominus$, and then that value combined with $\Delta_{\text{ad}}H^\ominus$ to obtain the standard entropy of adsorption. The expression for $(\partial \ln p/\partial T)_\theta$ in this example is independent of the model for the isotherm.

Self-test 25.2 Repeat the calculation using the following data:

T/K	200	210	220	230	240	250
p/kPa	4.32	5.59	7.07	8.80	10.67	12.80

$[-9.0 \text{ kJ mol}^{-1}]$

(b) The BET isotherm

If the initial adsorbed layer can act as a substrate for further (for example, physical) adsorption, then, instead of the isotherm levelling off to some saturated value at high pressures, it can be expected to rise indefinitely. The most widely used isotherm dealing with multilayer adsorption was derived by Stephen Brunauer, Paul Emmett, and Edward Teller, and is called the **BET isotherm**:

$$\frac{V}{V_{\text{mon}}} = \frac{cz}{(1-z)\{1-(1-c)z\}} \quad \text{with} \quad z = \frac{p}{p^*} \quad (25.8)$$

In this expression, p^* is the vapour pressure above a layer of adsorbate that is more than one molecule thick and which resembles a pure bulk liquid, V_{mon} is the volume corresponding to monolayer coverage, and c is a constant which is large when the enthalpy of desorption from a monolayer is large compared with the enthalpy of vaporization of the liquid adsorbate:

$$c = e^{(\Delta_{\text{des}}H^\ominus - \Delta_{\text{vap}}H^\ominus)/RT} \quad (25.9)$$

Figure 25.19 illustrates the shapes of BET isotherms. They rise indefinitely as the pressure is increased because there is no limit to the amount of material that may condense when multilayer coverage may occur. A BET isotherm is not accurate at all pressures, but it is widely used in industry to determine the surface areas of solids.

Example 25.3 Using the BET isotherm

The data below relate to the adsorption of N_2 on rutile (TiO_2) at 75 K. Confirm that they fit a BET isotherm in the range of pressures reported, and determine V_{mon} and c .

p/kPa	0.160	1.87	6.11	11.67	17.02	21.92	27.29
V/mm^3	601	720	822	935	1046	1146	1254

At 75 K, $p^* = 76.0 \text{ kPa}$. The volumes have been corrected to 1.00 atm and 273 K and refer to 1.00 g of substrate.

Method Equation 25.8 can be reorganized into

$$\frac{z}{(1-z)V} = \frac{1}{cV_{\text{mon}}} + \frac{(c-1)z}{cV_{\text{mon}}}$$

It follows that $(c-1)/cV_{\text{mon}}$ can be obtained from the slope of a plot of the expression on the left against z , and cV_{mon} can be found from the intercept at $z = 0$. The results can then be combined to give c and V_{mon} .

Answer We draw up the following table:

p/kPa	0.160	1.87	6.11	11.67	17.02	21.92	27.29
$10^3 z$	2.11	24.6	80.4	154	224	288	359
$10^4 z/(1-z)(V/\text{mm}^3)$	0.035	0.350	1.06	1.95	2.76	3.53	4.47

These points are plotted in Fig. 25.20. The least squares best line has an intercept at 0.0398, so

$$\frac{1}{cV_{\text{mon}}} = 3.98 \times 10^{-6} \text{ mm}^{-3}$$

The slope of the line is 1.23×10^{-2} , so

$$\frac{c-1}{cV_{\text{mon}}} = (1.23 \times 10^{-2}) \times 10^3 \times 10^{-4} \text{ mm}^{-3} = 1.23 \times 10^{-3} \text{ mm}^{-3}$$

The solutions of these equations are $c = 310$ and $V_{\text{mon}} = 811 \text{ mm}^3$. At 1.00 atm and 273 K, 811 mm^3 corresponds to $3.6 \times 10^{-5} \text{ mol}$, or 2.2×10^{19} atoms. Because each atom occupies an area of about 0.16 nm^2 , the surface area of the sample is about 3.5 m^2 .

Self-test 25.3 Repeat the calculation for the following data:

p/kPa	0.160	1.87	6.11	11.67	17.02	21.92	27.29
V/cm^3	235	559	649	719	790	860	950

[370, 615 cm^3]

Fig. 25.20 The BET isotherm can be tested, and the parameters determined, by plotting $z/(1-z)V$ against $z = p/p^*$. The data are from Example 25.3.

When $c \gg 1$, the BET isotherm takes the simpler form

$$\frac{V}{V_{\text{mon}}} = \frac{1}{1-z} \quad (25.10)$$

This expression is applicable to unreactive gases on polar surfaces, for which $c \approx 10^2$ because $\Delta_{\text{des}} H^\ominus$ is then significantly greater than $\Delta_{\text{vap}} H^\ominus$ (eqn 25.9). The BET isotherm

fits experimental observations moderately well over restricted pressure ranges, but it errs by underestimating the extent of adsorption at low pressures and by overestimating it at high pressures.

(c) Other isotherms

An assumption of the Langmuir isotherm is the independence and equivalence of the adsorption sites. Deviations from the isotherm can often be traced to the failure of these assumptions. For example, the enthalpy of adsorption often becomes less negative as θ increases, which suggests that the energetically most favourable sites are occupied first. Various attempts have been made to take these variations into account. The **Temkin isotherm**,

$$\theta = c_1 \ln(c_2 p) \quad (25.11)$$

where c_1 and c_2 are constants, corresponds to supposing that the adsorption enthalpy changes linearly with pressure. The **Freundlich isotherm**

$$\theta = c_1 p^{1/c_2} \quad (25.12)$$

corresponds to a logarithmic change. This isotherm attempts to incorporate the role of substrate–substrate interactions on the surface (see Problem 25.24).

Different isotherms agree with experiment more or less well over restricted ranges of pressure, but they remain largely empirical. Empirical, however, does not mean useless for, if the parameters of a reasonably reliable isotherm are known, reasonably reliable results can be obtained for the extent of surface coverage under various conditions. This kind of information is essential for any discussion of heterogeneous catalysis.

Fig. 25.21 The potential energy profiles for the dissociative chemisorption of an A_2 molecule. In each case, P is the enthalpy of (non-dissociative) physisorption and C that for chemisorption (at $T=0$). The relative locations of the curves determines whether the chemisorption is (a) not activated or (b) activated.

25.5 The rates of surface processes

The rates of surface processes may be studied by techniques described in Section 25.2 and *Impact* I25.1. Another technique, **second harmonic generation** (SHG), is very important for the study of all types of surfaces, including thin films and liquid–gas interfaces. We saw in Section 20.10 that second harmonic generation is the conversion of an intense, pulsed laser beam to radiation with twice its initial frequency as it passes through a material. In addition to a number of crystals, surfaces are also suitable materials for SHG. Because pulsed lasers are the excitation sources, time-resolved measurements of the kinetics and dynamics of surface processes are possible over timescales as short as femtoseconds.

Figure 25.21 shows how the potential energy of a molecule varies with its distance from the substrate surface. As the molecule approaches the surface its energy falls as it becomes physisorbed into the **precursor state** for chemisorption. Dissociation into fragments often takes place as a molecule moves into its chemisorbed state, and after an initial increase of energy as the bonds stretch there is a sharp decrease as the adsorbate–substrate bonds reach their full strength. Even if the molecule does not fragment, there is likely to be an initial increase of potential energy as the molecule approaches the surface and the bonds adjust.

In most cases, therefore, we can expect there to be a potential energy barrier separating the precursor and chemisorbed states. This barrier, though, might be low, and might not rise above the energy of a distant, stationary particle (as in Fig. 25.21a). In this case, chemisorption is not an activated process and can be expected to be rapid. Many gas adsorptions on clean metals appear to be non-activated. In some cases the barrier rises above the zero axis (as in Fig. 25.21b); such chemisorptions are activated and slower than the non-activated kind. An example is H_2 on copper, which has an activation energy in the region of $20\text{--}40\text{ kJ mol}^{-1}$.

One point that emerges from this discussion is that rates are not good criteria for distinguishing between physisorption and chemisorption. Chemisorption can be fast if the activation energy is small or zero, but it may be slow if the activation energy is large. Physisorption is usually fast, but it can appear to be slow if adsorption is taking place on a porous medium.

(a) The rate of adsorption

The rate at which a surface is covered by adsorbate depends on the ability of the substrate to dissipate the energy of the incoming particle as thermal motion as it crashes on to the surface. If the energy is not dissipated quickly, the particle migrates over the surface until a vibration expels it into the overlying gas or it reaches an edge. The proportion of collisions with the surface that successfully lead to adsorption is called the **sticking probability**, s :

$$s = \frac{\text{rate of adsorption of particles by the surface}}{\text{rate of collision of particles with the surface}} \quad [25.13]$$

The denominator can be calculated from the kinetic model, and the numerator can be measured by observing the rate of change of pressure.

Values of s vary widely. For example, at room temperature CO has s in the range 0.1–1.0 for several d -metal surfaces, but for N_2 on rhenium $s < 10^{-2}$, indicating that more than a hundred collisions are needed before one molecule sticks successfully. Beam studies on specific crystal planes show a pronounced specificity: for N_2 on tungsten, s ranges from 0.74 on the (320) faces down to less than 0.01 on the (110) faces at room temperature. The sticking probability decreases as the surface coverage increases (Fig. 25.22). A simple assumption is that s is proportional to $1 - \theta$, the fraction uncovered, and it is common to write

$$s = (1 - \theta)s_0 \quad (25.14)$$

where s_0 is the sticking probability on a perfectly clean surface. The results in the illustration do not fit this expression because they show that s remains close to s_0 until the coverage has risen to about 6×10^{13} molecules cm^{-2} , and then falls steeply. The explanation is probably that the colliding molecule does not enter the chemisorbed state at once, but moves over the surface until it encounters an empty site.

(b) The rate of desorption

Desorption is always activated because the particles have to be lifted from the foot of a potential well. A physisorbed particle vibrates in its shallow potential well, and might shake itself off the surface after a short time. The temperature dependence of the first-order rate of departure can be expected to be Arrhenius-like, with an activation energy for desorption, E_d , comparable to the enthalpy of physisorption:

$$k_d = Ae^{-E_d/RT} \quad (25.15)$$

Therefore, the half-life for remaining on the surface has a temperature dependence

$$t_{1/2} = \frac{\ln 2}{k_d} = \tau_0 e^{E_d/RT} \quad \tau_0 = \frac{\ln 2}{A} \quad (25.16)$$

(Note the positive sign in the exponent.) If we suppose that $1/\tau_0$ is approximately the same as the vibrational frequency of the weak particle–surface bond (about 10^{12} Hz) and $E_d \approx 25$ kJ mol^{-1} , then residence half-lives of around 10 ns are predicted at room temperature. Lifetimes close to 1 s are obtained only by lowering the temperature to about 100 K. For chemisorption, with $E_d = 100$ kJ mol^{-1} and guessing that $\tau_0 = 10^{-14}$ s

Fig. 25.22 The sticking probability of N_2 on various faces of a tungsten crystal and its dependence on surface coverage. Note the very low sticking probability for the (110) and (111) faces. (Data provided by Professor D.A. King.)

Fig. 25.23 The flash desorption spectrum of H_2 on the (100) face of tungsten. The three peaks indicate the presence of three sites with different adsorption enthalpies and therefore different desorption activation energies. (P.W. Tamm and L.D. Schmidt, *J. Chem. Phys.* **51**, 5352 (1969).)

(because the adsorbate–substrate bond is quite stiff), we expect a residence half-life of about 3×10^3 s (about an hour) at room temperature, decreasing to 1 s at about 350 K.

The desorption activation energy can be measured in several ways. However, we must be guarded in its interpretation because it often depends on the fractional coverage, and so may change as desorption proceeds. Moreover, the transfer of concepts such as ‘reaction order’ and ‘rate constant’ from bulk studies to surfaces is hazardous, and there are few examples of strictly first-order or second-order desorption kinetics (just as there are few integral-order reactions in the gas phase too).

If we disregard these complications, one way of measuring the desorption activation energy is to monitor the rate of increase in pressure when the sample is maintained at a series of temperatures, and to attempt to make an Arrhenius plot. A more sophisticated technique is **temperature programmed desorption** (TPD) or **thermal desorption spectroscopy** (TDS). The basic observation is a surge in desorption rate (as monitored by a mass spectrometer) when the temperature is raised linearly to the temperature at which desorption occurs rapidly, but once the desorption has occurred there is no more adsorbate to escape from the surface, so the desorption flux falls again as the temperature continues to rise. The TPD spectrum, the plot of desorption flux against temperature, therefore shows a peak, the location of which depends on the desorption activation energy. There are three maxima in the example shown in Fig. 25.23, indicating the presence of three sites with different activation energies.

In many cases only a single activation energy (and a single peak in the TPD spectrum) is observed. When several peaks are observed they might correspond to adsorption on different crystal planes or to multilayer adsorption. For instance, Cd atoms on tungsten show two activation energies, one of 18 kJ mol^{-1} and the other of 90 kJ mol^{-1} . The explanation is that the more tightly bound Cd atoms are attached directly to the substrate, and the less strongly bound are in a layer (or layers) above the primary overlayer. Another example of a system showing two desorption activation energies is CO on tungsten, the values being 120 kJ mol^{-1} and 300 kJ mol^{-1} . The explanation is believed to be the existence of two types of metal–adsorbate binding site, one involving a simple M–CO bond, the other adsorption with dissociation into individually adsorbed C and O atoms.

(b) Mobility on surfaces

A further aspect of the strength of the interactions between adsorbate and substrate is the mobility of the adsorbate. Mobility is often a vital feature of a catalyst’s activity, because a catalyst might be impotent if the reactant molecules adsorb so strongly that they cannot migrate. The activation energy for diffusion over a surface need not be the same as for desorption because the particles may be able to move through valleys between potential peaks without leaving the surface completely. In general, the activation energy for migration is about 10–20 per cent of the energy of the surface–adsorbate bond, but the actual value depends on the extent of coverage. The defect structure of the sample (which depends on the temperature) may also play a dominant role because the adsorbed molecules might find it easier to skip across a terrace than to roll along the foot of a step, and these molecules might become trapped in vacancies in an otherwise flat terrace. Diffusion may also be easier across one crystal face than another, and so the surface mobility depends on which lattice planes are exposed.

Diffusion characteristics of an adsorbate can be examined by using STM to follow the change in surface characteristics or by **field-ionization microscopy** (FIM), which portrays the electrical characteristics of a surface by using the ionization of noble gas atoms to probe the surface (Fig. 25.24). An individual atom is imaged, the temperature is raised, and then lowered after a definite interval. A new image is then recorded, and the new position of the atom measured (Fig. 25.25). A sequence of images shows

Fig. 25.24 The events leading to an FIM image of a surface. The He atom migrates across the surface until it is ionized at an exposed atom, when it is pulled off by the externally applied potential. (The bouncing motion is due to the intermolecular potential, not gravity!)

Fig. 25.25 FIM micrographs showing the migration of Re atoms on rhenium during 3 s intervals at 375 K. (Photographs provided by Professor G. Ehrlich.)

that the atom makes a random walk across the surface, and the diffusion coefficient, D , can be inferred from the mean distance, d , travelled in an interval τ by using the two-dimensional random walk expression $d = (D\tau)^{1/2}$. The value of D for different crystal planes at different temperatures can be determined directly in this way, and the activation energy for migration over each plane obtained from the Arrhenius-like expression

$$D = D_0 e^{-E_D/RT} \quad (25.17)$$

where E_D is the activation energy for diffusion. Typical values for W atoms on tungsten have E_D in the range 57–87 kJ mol⁻¹ and $D_0 \approx 3.8 \times 10^{-11}$ m² s⁻¹. For CO on tungsten, the activation energy falls from 144 kJ mol⁻¹ at low surface coverage to 88 kJ mol⁻¹ when the coverage is high.

IMPACT ON BIOCHEMISTRY

I25.1 Biosensor analysis

Biosensor analysis is a very sensitive and sophisticated optical technique that is now used routinely to measure the kinetics and thermodynamics of interactions between biopolymers. A biosensor detects changes in the optical properties of a surface in contact with a biopolymer.

The mobility of delocalized valence electrons accounts for the electrical conductivity of metals and these mobile electrons form a **plasma**, a dense gas of charged particles. Bombardment of the plasma by light or an electron beam can cause transient changes in the distribution of electrons, with some regions becoming slightly more dense than others. Coulomb repulsion in the regions of high density causes electrons to move away from each other, so lowering their density. The resulting oscillations in electron density, called **plasmons**, can be excited both in the bulk and on the surface of a metal. Plasmons in the bulk may be visualized as waves that propagate through the solid. A surface plasmon also propagates away from the surface, but the amplitude of the wave, also called an **evanescent wave**, decreases sharply with distance from the surface.

Biosensor analysis is based on the phenomenon of **surface plasmon resonance** (SPR), the absorption of energy from an incident beam of electromagnetic radiation by surface plasmons. Absorption, or 'resonance', can be observed with appropriate choice of the wavelength and angle of incidence of the excitation beam. It is common practice to use a monochromatic beam and to vary the angle of incidence θ (Fig. 25.26). The beam passes through a prism that strikes one side of a thin film of gold or silver. The angle corresponding to light absorption depends on the refractive index of the medium in direct contact with the opposing side of the metallic film. This variation of the resonance angle with the state of the surface arises from the ability of the evanescent wave to interact with material a short distance away from the surface.

As an illustration of biosensor analysis, we consider the association of two polymers, A and B. In a typical experiment, a stream of solution containing a known concentration of A flows above the surface to which B is chemisorbed. Figure 25.27 shows that the kinetics of binding of A to B may be followed by monitoring the time dependence

Fig. 25.26 The experimental arrangement for the observation of surface plasmon resonance, as explained in the text.

Fig. 25.27 The time dependence of a surface plasmon resonance signal, R , showing the effect of binding of a ligand to a biopolymer adsorbed on to a surface. Binding leads to an increase in R until an equilibrium value, R_{eq} , is obtained. Passing a solution containing no ligand over the surface leads to dissociation and decrease in R .

of the SPR signal, denoted by R , which is typically the shift in resonance angle. The system is normally allowed to reach equilibrium, which is denoted by the plateau in Fig. 25.27. Then, a solution containing no A is flowed above the surface and the AB complex dissociates. Again, analysis of the decay of the SPR signal reveals the kinetics of dissociation of the AB complex.

The equilibrium constant for formation of the AB complex can be measured directly from data of the type displayed in Fig. 25.27. Consider the equilibrium

where k_{on} and k_{off} are the rate constants for formation and dissociation of the AB complex, and K is the equilibrium constant for formation of the AB complex. It follows that

$$\frac{d[AB]}{dt} = k_{\text{on}}[A][B] - k_{\text{off}}[AB] \quad (25.18)$$

In a typical experiment, the flow rate of A is sufficiently high that $[A] = a_0$ is essentially constant. We can also write $[B] = b_0 - [AB]$ from mass-balance considerations, where b_0 is the total concentration of B. Finally, the SPR signal is often observed to be proportional to $[AB]$. The maximum value that R can have is $R_{\text{max}} \propto b_0$, which would be measured if all B molecules were ligated to A. We may then write

$$\frac{dR}{dt} = k_{\text{on}}a_0(R_{\text{max}} - R) - k_{\text{off}}R = k_{\text{on}}a_0R_{\text{max}} - (k_{\text{on}}a_0 + k_{\text{off}})R \quad (25.19)$$

At equilibrium $R = R_{\text{eq}}$ and $dR/dt = 0$. It follows that (after some algebra)

$$R_{\text{eq}} = R_{\text{max}} \left(\frac{a_0 K}{a_0 K + 1} \right) \quad (25.20)$$

Hence, the value of K can be obtained from measurements of R_{eq} for a series of a_0 .

Biosensor analysis has been used in the study of thin films, metal–electrolyte surfaces, Langmuir–Blodgett films, and a number of biopolymer interactions, such as antibody–antigen and protein–DNA interactions. The most important advantage of the technique is its sensitivity; it is possible to measure the adsorption of nanograms of material on to a surface. For biological studies, the main disadvantage is the requirement for immobilization of at least one of the components of the system under study.

Heterogeneous catalysis

A catalyst acts by providing an alternative reaction path with a lower activation energy (Table 25.3). It does not disturb the final equilibrium composition of the system, only the rate at which that equilibrium is approached. In this section we consider heterogeneous catalysis, in which (as mentioned in the introduction to Section 23.5) the catalyst and the reagents are in different phases. For simplicity, we consider only gas/solid systems.

Many catalysts depend on **co-adsorption**, the adsorption of two or more species. One consequence of the presence of a second species may be the modification of the electronic structure at the surface of a metal. For instance, partial coverage of d -metal surfaces by alkali metals has a pronounced effect on the electron distribution and reduces the work function of the metal. Such modifiers can act as promoters (to enhance the action of catalysts) or as poisons (to inhibit catalytic action).

Synoptic table 25.3* Activation energies of catalysed reactions

Reaction	Catalyst	$E_a/(\text{kJ mol}^{-1})$
$2 \text{ HI} \rightarrow \text{H}_2 + \text{I}_2$	None	184
	Au	105
	Pt	59
$2 \text{ NH}_3 \rightarrow$	None	350
$\text{N}_2 + 3 \text{ H}_2$	W	162

* More values are given in the *Data section*.

25.6 Mechanisms of heterogeneous catalysis

Heterogeneous catalysis normally depends on at least one reactant being adsorbed (usually chemisorbed) and modified to a form in which it readily undergoes reaction. This modification often takes the form of a fragmentation of the reactant molecules. In practice, the active phase is dispersed as very small particles of linear dimension less than 2 nm on a porous oxide support. **Shape-selective catalysts**, such as the zeolites (*Impact* I25.2), which have a pore size that can distinguish shapes and sizes at a molecular scale, have high internal specific surface areas, in the range of 100–500 m² g⁻¹.

The decomposition of phosphine (PH₃) on tungsten is first-order at low pressures and zeroth-order at high pressures. To account for these observations, we write down a plausible rate law in terms of an adsorption isotherm and explore its form in the limits of high and low pressure. If the rate is supposed to be proportional to the surface coverage and we suppose that θ is given by the Langmuir isotherm, we would write

$$v = k\theta = \frac{kKp}{1 + Kp} \quad (25.21)$$

where p is the pressure of phosphine. When the pressure is so low that $Kp \ll 1$, we can neglect Kp in the denominator and obtain

$$v = kKp \quad (25.22a)$$

and the decomposition is first-order. When $Kp \gg 1$, we can neglect the 1 in the denominator, whereupon the Kp terms cancel and we are left with

$$v = k \quad (25.22b)$$

and the decomposition is zeroth-order.

Self-test 25.4 Suggest the form of the rate law for the deuteration of NH₃ in which D₂ adsorbs dissociatively but not extensively (that is, $Kp \ll 1$, with p the partial pressure of D₂), and NH₃ (with partial pressure p') adsorbs at different sites.

$$[v = k(Kp)^{1/2}K'p'/(1 + K'p')]$$

In the **Langmuir–Hinshelwood mechanism** (LH mechanism) of surface-catalysed reactions, the reaction takes place by encounters between molecular fragments and atoms adsorbed on the surface. We therefore expect the rate law to be second-order in the extent of surface coverage:

Insertion of the appropriate isotherms for A and B then gives the reaction rate in terms of the partial pressures of the reactants. For example, if A and B follow Langmuir isotherms, and adsorb without dissociation, so that

$$\theta_A = \frac{K_A p_A}{1 + K_A p_A + K_B p_B} \quad \theta_B = \frac{K_B p_B}{1 + K_A p_A + K_B p_B} \quad (25.24)$$

then it follows that the rate law is

$$v = \frac{kK_A K_B p_A p_B}{(1 + K_A p_A + K_B p_B)^2} \quad (25.25)$$

The parameters K in the isotherms and the rate constant k are all temperature-dependent, so the overall temperature dependence of the rate may be strongly non-Arrhenius (in the sense that the reaction rate is unlikely to be proportional to $e^{-E_a/RT}$).

The Langmuir–Hinshelwood mechanism is dominant for the catalytic oxidation of CO to CO₂.

In the **Eley–Rideal mechanism** (ER mechanism) of a surface-catalysed reaction, a gas-phase molecule collides with another molecule already adsorbed on the surface. The rate of formation of product is expected to be proportional to the partial pressure, p_B , of the non-adsorbed gas B and the extent of surface coverage, θ_A , of the adsorbed gas A. It follows that the rate law should be

$$A + B \rightarrow P \quad v = kp_B\theta_A \quad (25.26)$$

The rate constant, k , might be much larger than for the uncatalysed gas-phase reaction because the reaction on the surface has a low activation energy and the adsorption itself is often not activated.

If we know the adsorption isotherm for A, we can express the rate law in terms of its partial pressure, p_A . For example, if the adsorption of A follows a Langmuir isotherm in the pressure range of interest, then the rate law would be

$$v = \frac{kKp_Ap_B}{1 + Kp_A} \quad (25.27)$$

If A were a diatomic molecule that adsorbed as atoms, we would substitute the isotherm given in eqn 25.6 instead.

According to eqn 25.27, when the partial pressure of A is high (in the sense $Kp_A \gg 1$) there is almost complete surface coverage, and the rate is equal to kp_B . Now the rate-determining step is the collision of B with the adsorbed fragments. When the pressure of A is low ($Kp_A \ll 1$), perhaps because of its reaction, the rate is equal to kKp_Ap_B ; now the extent of surface coverage is important in the determination of the rate.

Almost all thermal surface-catalysed reactions are thought to take place by the LH mechanism, but a number of reactions with an ER mechanism have also been identified from molecular beam investigations. For example, the reaction between H(g) and D(ad) to form HD(g) is thought to be by an ER mechanism involving the direct collision and pick-up of the adsorbed D atom by the incident H atom. However, the two mechanisms should really be thought of as ideal limits, and all reactions lie somewhere between the two and show features of each one.

25.7 Catalytic activity at surfaces

Molecular beam reactive scattering (MBRS) studies are able to provide detailed information about catalysed reactions. It has become possible to investigate how the catalytic activity of a surface depends on its structure as well as its composition. For instance, the cleavage of C–H and H–H bonds appears to depend on the presence of steps and kinks, and a terrace often has only minimal catalytic activity. The reaction $H_2 + D_2 \rightarrow 2 HD$ has been studied in detail. For this reaction, terrace sites are inactive but one molecule in ten reacts when it strikes a step. Although the step itself might be the important feature, it may be that the presence of the step merely exposes a more reactive crystal face (the step face itself). Likewise, the dehydrogenation of hexane to hexene depends strongly on the kink density, and it appears that kinks are needed to cleave C–C bonds. These observations suggest a reason why even small amounts of impurities may poison a catalyst: they are likely to attach to step and kink sites, and so impair the activity of the catalyst entirely. A constructive outcome is that the extent of dehydrogenation may be controlled relative to other types of reactions by seeking impurities that adsorb at kinks and act as specific poisons.

Molecular beam studies can also be used to investigate the details of the reaction process, particularly by using **pulsed beams**, in which the beam is chopped into short

Table 25.4 Chemisorption abilities*

	O ₂	C ₂ H ₂	C ₂ H ₄	CO	H ₂	CO ₂	N ₂
Ti, Cr, Mo, Fe	+	+	+	+	+	+	+

Li, Na, K	+	+	–	–	–	–	–
Mg, Ag, Zn, Pb	+	–	–	–	–	–	–

* +, Strong chemisorption; ±, chemisorption; –, no chemisorption.

slugs. The angular distribution of the products, for instance, can be used to assess the length of time that a species remains on the surface during the reaction, for a long residence time will result in a loss of memory of the incident beam direction.

The activity of a catalyst depends on the strength of chemisorption as indicated by the ‘volcano’ curve in Fig. 25.28 (which is so-called on account of its general shape). To be active, the catalyst should be extensively covered by adsorbate, which is the case if chemisorption is strong. On the other hand, if the strength of the substrate–adsorbate bond becomes too great, the activity declines either because the other reactant molecules cannot react with the adsorbate or because the adsorbate molecules are immobilized on the surface. This pattern of behaviour suggests that the activity of a catalyst should initially increase with strength of adsorption (as measured, for instance, by the enthalpy of adsorption) and then decline, and that the most active catalysts should be those lying near the summit of the volcano. Most active metals are those that lie close to the middle of the *d* block.

Many metals are suitable for adsorbing gases, and the general order of adsorption strengths decreases along the series O₂, C₂H₂, C₂H₄, CO, H₂, CO₂, N₂. Some of these molecules adsorb dissociatively (for example, H₂). Elements from the *d* block, such as iron, vanadium, and chromium, show a strong activity towards all these gases, but manganese and copper are unable to adsorb N₂ and CO₂. Metals towards the left of the periodic table (for example, magnesium and lithium) can adsorb (and, in fact, react with) only the most active gas (O₂). These trends are summarized in Table 25.4.

Fig. 25.28 A volcano curve of catalytic activity arises because, although the reactants must adsorb reasonably strongly, they must not adsorb so strongly that they are immobilized. The lower curve refers to the first series of *d*-block metals, the upper curve to the second and third series *d*-block metals. The group numbers relate to the periodic table inside the back cover.

IMPACT ON TECHNOLOGY

I25.2 Catalysis in the chemical industry

Almost the whole of modern chemical industry depends on the development, selection, and application of catalysts (Table 25.5). All we can hope to do in this section is to give a brief indication of some of the problems involved. Other than the ones we consider, these problems include the danger of the catalyst being poisoned by by-products or impurities, and economic considerations relating to cost and lifetime.

An example of catalytic action is found in the hydrogenation of alkenes. The alkene (2) adsorbs by forming two bonds with the surface (3), and on the same surface there may be adsorbed H atoms. When an encounter occurs, one of the alkene–surface bonds is broken (forming 4 or 5) and later an encounter with a second H atom releases the fully hydrogenated hydrocarbon, which is the thermodynamically more stable species. The evidence for a two-stage reaction is the appearance of different isomeric alkenes in the mixture. The formation of isomers comes about because, while the hydrocarbon chain is waving about over the surface of the metal, an atom in the chain

Table 25.5 Properties of catalysts

Catalyst	Function	Examples
Metals	Hydrogenation Dehydrogenation	Fe, Ni, Pt, Ag
Semiconducting oxides and sulfides	Oxidation Desulfurization	NiO, ZnO, MgO, Bi ₂ O ₃ /MoO ₃ , MoS ₂
Insulating oxides	Dehydration	Al ₂ O ₃ , SiO ₂ , MgO
Acids	Polymerization Isomerization Cracking Alkylation	H ₃ PO ₄ , H ₂ SO ₄ , SiO ₃ /Al ₂ O ₃ , zeolites

might chemisorb again to form (6) and then desorb to (7), an isomer of the original molecule. The new alkene would not be formed if the two hydrogen atoms attached simultaneously.

A major industrial application of catalytic hydrogenation is to the formation of edible fats from vegetable and animal oils. Raw oils obtained from sources such as the soya bean have the structure $\text{CH}_2(\text{OOCR})\text{CH}(\text{OOCR}')\text{CH}_2(\text{OOCR}'')$, where R, R', and R'' are long-chain hydrocarbons with several double bonds. One disadvantage of the presence of many double bonds is that the oils are susceptible to atmospheric oxidation, and therefore are liable to become rancid. The geometrical configuration of the chains is responsible for the liquid nature of the oil, and in many applications a solid fat is at least much better and often necessary. Controlled partial hydrogenation of an oil with a catalyst carefully selected so that hydrogenation is incomplete and so that the chains do not isomerize (finely divided nickel, in fact), is used on a wide scale to produce edible fats. The process, and the industry, is not made any easier by the seasonal variation of the number of double bonds in the oils.

Catalytic oxidation is also widely used in industry and in pollution control. Although in some cases it is desirable to achieve complete oxidation (as in the production of nitric acid from ammonia), in others partial oxidation is the aim. For example, the complete oxidation of propene to carbon dioxide and water is wasteful, but its partial oxidation to propenal (acrolein, $\text{CH}_2=\text{CHCHO}$) is the start of important industrial processes. Likewise, the controlled oxidations of ethene to ethanol, ethanal (acetaldehyde), and (in the presence of acetic acid or chlorine) to chloroethene (vinyl chloride, for the manufacture of PVC), are the initial stages of very important chemical industries.

Some of these oxidation reactions are catalysed by *d*-metal oxides of various kinds. The physical chemistry of oxide surfaces is very complex, as can be appreciated by considering what happens during the oxidation of propene to propenal on bismuth molybdate. The first stage is the adsorption of the propene molecule with loss of a hydrogen to form the propenyl (allyl) radical, $\text{CH}_2=\text{CHCH}_2\cdot$. An O atom in the surface can now transfer to this radical, leading to the formation of propenal and its desorption from the surface. The H atom also escapes with a surface O atom, and goes on to form H_2O , which leaves the surface. The surface is left with vacancies and metal ions in lower oxidation states. These vacancies are attacked by O_2 molecules in the overlying gas, which then chemisorb as O_2^- ions, so reforming the catalyst. This sequence of events, which is called the **Mars van Krevelen mechanism**, involves great upheavals of the surface, and some materials break up under the stress.

Many of the small organic molecules used in the preparation of all kinds of chemical products come from oil. These small building blocks of polymers, perfumes, and petrochemicals in general, are usually cut from the long-chain hydrocarbons drawn from the Earth as petroleum. The catalytically induced fragmentation of the

long-chain hydrocarbons is called **cracking**, and is often brought about on silica–alumina catalysts. These catalysts act by forming unstable carbocations, which dissociate and rearrange to more highly branched isomers. These branched isomers burn more smoothly and efficiently in internal combustion engines, and are used to produce higher octane fuels.

Catalytic **reforming** uses a dual-function catalyst, such as a dispersion of platinum and acidic alumina. The platinum provides the metal function, and brings about dehydrogenation and hydrogenation. The alumina provides the acidic function, being able to form carbocations from alkenes. The sequence of events in catalytic reforming shows up very clearly the complications that must be unravelled if a reaction as important as this is to be understood and improved. The first step is the attachment of the long-chain hydrocarbon by chemisorption to the platinum. In this process first one and then a second H atom is lost, and an alkene is formed. The alkene migrates to a Brønsted acid site, where it accepts a proton and attaches to the surface as a carbocation. This carbocation can undergo several different reactions. It can break into two, isomerize into a more highly branched form, or undergo varieties of ring-closure. Then the adsorbed molecule loses a proton, escapes from the surface, and migrates (possibly through the gas) as an alkene to a metal part of the catalyst where it is hydrogenated. We end up with a rich selection of smaller molecules which can be withdrawn, fractionated, and then used as raw materials for other products.

The concept of a solid surface has been extended with the availability of **microporous materials**, in which the surface effectively extends deep inside the solid. Zeolites are microporous aluminosilicates with the general formula $\{[M^{n+}]_{x/n} \cdot [H_2O]_m\} \{[AlO_2]_x [SiO_2]_y\}^{x-}$, where M^{n+} cations and H_2O molecules bind inside the cavities, or pores, of the Al–O–Si framework (Fig. 25.29). Small neutral molecules, such as CO_2 , NH_3 , and hydrocarbons (including aromatic compounds), can also adsorb to the internal surfaces and we shall see that this partially accounts for the utility of zeolites as catalysts.

Some zeolites for which $M = H^+$ are very strong acids and catalyse a variety of reactions that are of particular importance to the petrochemical industry. Examples include the dehydration of methanol to form hydrocarbons such as gasoline and other fuels:

and the isomerization of *m*-xylene (**8**) to *p*-xylene (**9**). The catalytically important form of these acidic zeolites may be either a Brønsted acid (**10**) or a Lewis acid (**11**). Like enzymes, a zeolite catalyst with a specific composition and structure is very selective toward certain reactants and products because only molecules of certain sizes can enter

Fig. 25.29 A framework representation of the general layout of the Si, Al, and O atoms in a zeolite material. Each vertex corresponds to a Si or Al atom and each edge corresponds to the approximate location of a O atom. Note the large central pore, which can hold cations, water molecules, or other small molecules.

and exit the pores in which catalysis occurs. It is also possible that zeolites derive their selectivity from the ability to bind and to stabilize only transition states that fit properly in the pores. The analysis of the mechanism of zeolyte catalysis is greatly facilitated by computer simulation of microporous systems, which shows how molecules fit in the pores, migrate through the connecting tunnels, and react at the appropriate active sites.

Processes at electrodes

A special kind of surface is an electrode and the special kind of process that occurs there is the transfer of electrons. Detailed knowledge of the factors that determine the rate of electron transfer at electrodes leads to a better understanding of power production in batteries, and of electron conduction in metals, semiconductors, and nanometre-sized electronic devices. Indeed, the economic consequences of electron transfer reactions are almost incalculable. Most of the modern methods of generating electricity are inefficient, and the development of fuel cells could revolutionize our production and deployment of energy (*Impact* 125.3). Today we produce energy inefficiently to produce goods that then decay by corrosion. Each step of this wasteful sequence could be improved by discovering more about the kinetics of electrochemical processes. Similarly, the techniques of organic and inorganic electrosynthesis, where an electrode is an active component of an industrial process, depend on intimate understanding of the kinetics of electron transfer processes.

As for homogeneous systems (Chapter 24), electron transfer at the surface of an electrode involves electron tunnelling. However, the electrode possesses a nearly infinite number of closely spaced electronic energy levels rather than the small number of discrete levels of a typical complex. Furthermore, specific interactions with the electrode surface give the solute and solvent special properties that can be very different from those observed in the bulk of the solution. For this reason, we begin with a description of the electrode–solution interface. Then, we describe the kinetics of electrode processes by using a largely phenomenological (rather than strictly theoretical) approach that draws on the thermodynamic language inspired by transition state theory.

Fig. 25.30 A simple model of the electrode–solution interface treats it as two rigid planes of charge. One plane, the outer Helmholtz plane (OHP), is due to the ions with their solvating molecules and the other plane is that of the electrode itself. The plot shows the dependence of the electric potential with distance from the electrode surface according to this model. Between the electrode surface and the OHP, the potential varies linearly from ϕ_M , the value in the metal, to ϕ_S , the value in the bulk of the solution.

25.8 The electrode–solution interface

The most primitive model of the boundary between the solid and liquid phases is as an **electrical double layer**, which consists of a sheet of positive charge at the surface of the electrode and a sheet of negative charge next to it in the solution (or vice versa). We shall see that this arrangement creates an electrical potential difference, called the **Galvani potential difference**, between the bulk of the metal electrode and the bulk of the solution. More sophisticated models for the electrode–solution interface attempt to describe the gradual changes in the structure of the solution between two extremes: the charged electrode surface and the bulk of the solution.

(a) The structure of the interface

A more detailed picture of the interface can be constructed by speculating about the arrangement of ions and electric dipoles in the solution. In the **Helmholtz layer model** of the interface the solvated ions arrange themselves along the surface of the electrode but are held away from it by their hydration spheres (Fig. 25.30). The location of the sheet of ionic charge, which is called the **outer Helmholtz plane** (OHP), is identified as the plane running through the solvated ions. In this simple model, the electrical potential changes linearly within the layer bounded by the electrode surface on one side and the OHP on the other (see Exercise 25.15a). In a refinement of this

model, ions that have discarded their solvating molecules and have become attached to the electrode surface by chemical bonds are regarded as forming the **inner Helmholtz plane (IHP)**. The Helmholtz layer model ignores the disrupting effect of thermal motion, which tends to break up and disperse the rigid outer plane of charge. In the **Gouy–Chapman model of the diffuse double layer**, the disordering effect of thermal motion is taken into account in much the same way as the Debye–Hückel model describes the ionic atmosphere of an ion (Section 5.9) with the latter's single central ion replaced by an infinite, plane electrode.

Figure 25.31 shows how the local concentrations of cations and anions differ in the Gouy–Chapman model from their bulk concentrations. Ions of opposite charge cluster close to the electrode and ions of the same charge are repelled from it. The modification of the local concentrations near an electrode implies that it might be misleading to use activity coefficients characteristic of the bulk to discuss the thermodynamic properties of ions near the interface. This is one of the reasons why measurements of the dynamics of electrode processes are almost always done using a large excess of supporting electrolyte (for example, a 1 M solution of a salt, an acid, or a base). Under such conditions, the activity coefficients are almost constant because the inert ions dominate the effects of local changes caused by any reactions taking place. The use of a concentrated solution also minimizes ion migration effects.

Neither the Helmholtz nor the Gouy–Chapman model is a very good representation of the structure of the double layer. The former overemphasizes the rigidity of the local solution; the latter underemphasizes its structure. The two are combined in the **Stern model**, in which the ions closest to the electrode are constrained into a rigid Helmholtz plane while outside that plane the ions are dispersed as in the Gouy–Chapman model (Fig. 25.32). Yet another level of sophistication is found in the **Grahame model**, which adds an inner Helmholtz plane to the Stern model.

Fig. 25.31 The Gouy–Chapman model of the electrical double layer treats the outer region as an atmosphere of counter-charge, similar to the Debye–Hückel theory of ion atmospheres. The plot of electrical potential against distance from the electrode surface shows the meaning of the diffuse double layer (see text for details).

Fig. 25.32 A representation of the Stern model of the electrode–solution interface. The model incorporates the idea of an outer Helmholtz plane near the electrode surface and of a diffuse double layer further away from the surface.

Fig. 25.33 The variation of potential with distance from an electrode that has been separated from the electrolyte solution without there being an adjustment of charge. A similar diagram applies to the separated solution.

Fig. 25.34 The origin of the distance-independence of the outer potential. (a) Far from the electrode, a point charge experiences a potential arising from a wide area but each contribution is weak. (b) Close to the electrode, the point charge experiences a potential arising from a small area but each contribution is strong. Provided the point charge is in a certain range of values (and, specifically, where image charge effects can be ignored) the potential it experiences is largely independent of distance.

(b) The electric potential at the interface

The potential at the interface can be analysed by imagining the separation of the electrode from the solution, but with the charges of the metal and the solution frozen in position. A positive test charge at great distances from the isolated electrode experiences a Coulomb potential that varies inversely with distance (Fig. 25.33). As the test charge approaches the electrode, which can be a metal or membrane electrode, it enters a region where the potential varies more slowly. This change in behaviour can be traced to the fact that the surface charge is not point-like but is spread over an area. At about 100 nm from the surface the potential varies only slightly with distance because the closer the point of observation is to the surface, although the potential from a given region of charge is stronger, a smaller area of surface is sampled (Fig. 25.34). The potential in this region is called the **outer potential**, ψ . As the test charge is taken through the skin of electrons on the surface of the electrode, the potential it experiences changes until the probe reaches the inner, bulk metal environment, where the potential is called the **inner potential**, ϕ . The difference between the inner and outer potentials is called the **surface potential**, χ .

A similar sequence of changes of potential is observed as a positive test charge is brought up to and through the solution surface. The potential changes to its outer value as the charge approaches the charged medium, then to its inner value as the probe is taken into the bulk.

Now consider bringing the electrode and solution back together again but without any change of charge distribution. The potential difference between points in the bulk metal and the bulk solution is the Galvani potential difference, $\Delta\phi$. Apart from a constant, this Galvani potential difference is the electrode potential that was discussed in Chapter 7. We shall ignore the constant, which cannot be measured anyway, and identify changes in $\Delta\phi$ with changes in electrode potential (see *Further information* 25.1 for a quantitative treatment).

25.9 The rate of charge transfer

Because an electrode reaction is heterogeneous, it is natural to express its rate as the flux of products, the amount of material produced over a region of the electrode surface in an interval of time divided by the area of the region and the duration of the interval.

(a) The rate laws

A first-order heterogeneous rate law has the form

$$\text{Product flux} = k[\text{species}] \quad (25.28)$$

where [species] is the molar concentration of the relevant species in solution close to the electrode, just outside the double layer. The rate constant has dimensions of length/time (with units, for example, of centimetres per second, cm s^{-1}). If the molar concentrations of the oxidized and reduced materials outside the double layer are [Ox] and [Red], respectively, then the rate of reduction of Ox, v_{Ox} , is

$$v_{\text{Ox}} = k_c[\text{Ox}] \quad (25.29a)$$

and the rate of oxidation of Red, v_{Red} , is

$$v_{\text{Red}} = k_a[\text{Red}] \quad (25.29b)$$

(The notation k_c and k_a is justified below.)

Now consider a reaction at the electrode in which an ion is reduced by the transfer of a single electron in the rate-determining step. For instance, in the deposition of

cadmium only one electron is transferred in the rate-determining step even though overall the deposition involves the transfer of two electrons.

The net current density at the electrode is the difference between the current densities arising from the reduction of Ox and the oxidation of Red. Because the redox processes at the electrode involve the transfer of one electron per reaction event, the current densities, j , arising from the redox processes are the rates (as expressed above) multiplied by the charge transferred per mole of reaction, which is given by Faraday's constant. Therefore, there is a **cathodic current density** of magnitude

$$j_c = Fk_c[\text{Ox}] \quad \text{for} \quad \text{Ox} + e^- \rightarrow \text{Red} \quad (25.30a)$$

arising from the reduction (because, as we saw in Chapter 7, the cathode is the site of reduction). There is also an opposing **anodic current density** of magnitude

$$j_a = Fk_a[\text{Red}] \quad \text{for} \quad \text{Red} \rightarrow \text{Ox} + e^- \quad (25.30b)$$

arising from the oxidation (because the anode is the site of oxidation). The net current density at the electrode is the difference

$$j = j_a - j_c = Fk_a[\text{Red}] - Fk_c[\text{Ox}] \quad (25.30c)$$

Note that, when $j_a > j_c$, so that $j > 0$, the current is anodic (Fig. 25.35a); when $j_c > j_a$, so that $j < 0$, the current is cathodic (Fig. 25.35b).

(b) The activation Gibbs energy

If a species is to participate in reduction or oxidation at an electrode, it must discard any solvating molecules, migrate through the electrode–solution interface, and adjust its hydration sphere as it receives or discards electrons. Likewise, a species already at the inner plane must be detached and migrate into the bulk. Because both processes are activated, we can expect to write their rate constants in the form suggested by transition state theory (Section 24.4) as

$$k = Be^{-\Delta^\ddagger G/RT} \quad (25.31)$$

where $\Delta^\ddagger G$ is the activation Gibbs energy and B is a constant with the same dimensions as k .

When eqn 25.31 is inserted into eqn 25.30 we obtain

$$j = FB_a[\text{Red}]e^{-\Delta^\ddagger G_a/RT} - FB_c[\text{Ox}]e^{-\Delta^\ddagger G_c/RT} \quad (25.32)$$

This expression allows the activation Gibbs energies to be different for the cathodic and anodic processes. That they are different is the central feature of the remaining discussion.

(c) The Butler–Volmer equation

Now we relate j to the Galvani potential difference, which varies across the electrode–solution interface as shown schematically in Fig. 25.36.

Consider the reduction reaction, $\text{Ox} + e^- \rightarrow \text{Red}$, and the corresponding reaction profile. If the transition state of the activated complex is product-like (as represented by the peak of the reaction profile being close to the electrode in Fig. 25.37), the activation Gibbs energy is changed from $\Delta^\ddagger G_c(0)$, the value it has in the absence of a potential difference across the double layer, to

$$\Delta^\ddagger G_c = \Delta^\ddagger G_c(0) + F\Delta\phi \quad (25.33a)$$

Thus, if the electrode is more positive than the solution, $\Delta\phi > 0$, then more work has to be done to form an activated complex from Ox; in this case the activation Gibbs energy is increased. If the transition state is reactant-like (represented by the peak of

Fig. 25.35 The net current density is defined as the difference between the cathodic and anodic contributions. (a) When $j_a > j_c$, the net current is anodic, and there is a net oxidation of the species in solution. (b) When $j_c > j_a$, the net current is cathodic, and the net process is reduction.

Fig. 25.36 The potential, ϕ , varies linearly between two plane parallel sheets of charge, and its effect on the Gibbs energy of the transition state depends on the extent to which the latter resembles the species at the inner or outer planes.

Fig. 25.37 When the transition state resembles a species that has undergone reduction, the activation Gibbs energy for the anodic current is almost unchanged, but the full effect applies to the cathodic current. (a) Zero potential difference; (b) nonzero potential difference.

Fig. 25.38 When the transition state resembles a species that has undergone oxidation, the activation Gibbs energy for the cathodic current is almost unchanged but the activation Gibbs energy for the anodic current is strongly affected. (a) Zero potential difference; (b) nonzero potential difference.

Fig. 25.39 When the transition state is intermediate in its resemblance to reduced and oxidized species, as represented here by a peak located at an intermediate position as measured by α (with $0 < \alpha < 1$), both activation Gibbs energies are affected; here, $\alpha \approx 0.5$. (a) Zero potential difference; (b) nonzero potential difference.

the reaction profile being close to the outer plane of the double-layer in Fig. 25.38), then $\Delta^\ddagger G_c$ is independent of $\Delta\phi$. In a real system, the transition state has an intermediate resemblance to these extremes (Fig. 25.39) and the activation Gibbs energy for reduction may be written as

$$\Delta^\ddagger G_c = \Delta^\ddagger G_c(0) + \alpha F\Delta\phi \quad (25.33b)$$

The parameter α is called the (cathodic) **transfer coefficient**, and lies in the range 0 to 1. Experimentally, α is often found to be about 0.5.

Now consider the oxidation reaction, $\text{Red} + e^- \rightarrow \text{Ox}$ and its reaction profile. Similar remarks apply. In this case, Red discards an electron to the electrode, so the extra work is zero if the transition state is reactant-like (represented by a peak close to the electrode). The extra work is the full $-F\Delta\phi$ if it resembles the product (the peak close to the outer plane). In general, the activation Gibbs energy for this anodic process is

$$\Delta^\ddagger G_a = \Delta^\ddagger G_a(0) - (1 - \alpha)F\Delta\phi \quad (25.34)$$

The two activation Gibbs energies can now be inserted in place of the values used in eqn 25.32 with the result that

$$j = FB_a[\text{Red}]e^{-\Delta^\ddagger G_a(0)/RT} e^{(1-\alpha)F\Delta\phi/RT} - FB_c[\text{Ox}]e^{-\Delta^\ddagger G_c(0)/RT} e^{-\alpha F\Delta\phi/RT} \quad (25.35)$$

This is an explicit, if complicated, expression for the net current density in terms of the potential difference.

The appearance of eqn 25.35 can be simplified. First, in a purely cosmetic step we write

$$f = \frac{F}{RT} \quad (25.36)$$

Next, we identify the individual cathodic and anodic current densities:

$$\left. \begin{aligned} j_a &= FB_a[\text{Red}]e^{-\Delta^\ddagger G_a(0)/RT} e^{(1-\alpha)f\Delta\phi} \\ j_c &= FB_c[\text{Ox}]e^{-\Delta^\ddagger G_c(0)/RT} e^{-\alpha f\Delta\phi} \end{aligned} \right\} j = j_a - j_c \quad (25.37)$$

Illustration 25.1 Calculating the current density 1

To calculate the change in cathodic current density at an electrode when the potential difference changes from $\Delta\phi'$ and $\Delta\phi$, we use eqn 25.37 to express the ratio of cathodic current densities j'_c and j_c

$$\frac{j'_c}{j_c} = e^{-\alpha f(\Delta\phi' - \Delta\phi)}$$

When $\Delta\phi' - \Delta\phi = 1.0$ V, $T = 298$ K, and $\alpha = \frac{1}{2}$ (a typical value), we obtain

$$\alpha f \times (\Delta\phi' - \Delta\phi) = \frac{\frac{1}{2} \times (9.6485 \times 10^4 \text{ C mol}^{-1}) \times (1.0 \text{ V})}{(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})} = \frac{9.6485 \times 10^4 \times 1.0}{2 \times 8.3145 \times 298}$$

Hence (after using 1 J = 1 VC),

$$\frac{j'_c}{j_c} = e^{-\frac{9.6485 \times 10^4 \times 1.0}{2 \times 8.3145 \times 298}} = 4 \times 10^{-9}$$

This huge change in current density, by a factor of a billion, occurs for a very mild and easily applied change of conditions. We can appreciate why the change is so great by realizing that a change of potential difference by 1 V changes the activation Gibbs energy by $(1 \text{ V}) \times F$, or about 50 kJ mol^{-1} , which has an enormous effect on the rates.

Self-test 25.5 Calculate the change in anodic current density under the same circumstances. $[j'_a/j_a = 3 \times 10^8]$

If the cell is balanced against an external source, the Galvani potential difference, $\Delta\phi$, can be identified as the (zero-current) electrode potential, E , and we can write

$$\left. \begin{aligned} j_a &= FB_a[\text{Red}]e^{-\Delta^\ddagger G_a(0)/RT} e^{(1-\alpha)fE} \\ j_c &= FB_c[\text{Ox}]e^{-\Delta^\ddagger G_c(0)/RT} e^{-\alpha fE} \end{aligned} \right\} \quad (25.38)$$

When these equations apply, there is no net current at the electrode (as the cell is balanced), so the two current densities must be equal. From now on we denote them both as j_0 , which is called the **exchange current density**.

When the cell is producing current (that is, when a load is connected between the electrode being studied and a second counter electrode) the electrode potential changes

Comment 25.1

Here we are assuming that we can identify the Galvani potential difference and the zero-current electrode potential. As explained earlier, they differ by a constant amount, which may be regarded as absorbed into the constant B .

from its zero-current value, E , to a new value, E' , and the difference is the electrode's **overpotential**, η :

$$\eta = E' - E \quad [25.39]$$

Hence, $\Delta\phi$ changes to $\Delta\phi = E + \eta$ and the two current densities become

$$j_a = j_0 e^{(1-\alpha)f\eta} \quad j_c = j_0 e^{-\alpha f\eta} \quad (25.40)$$

Then from eqn 25.32 we obtain the **Butler–Volmer equation**:

$$j = j_0 \{e^{(1-\alpha)f\eta} - e^{-\alpha f\eta}\} \quad (25.41)$$

This equation is the basis of all that follows.

(d) The low overpotential limit

When the overpotential is so small that $f\eta \ll 1$ (in practice, η less than about 0.01 V) the exponentials in eqn 25.41 can be expanded by using $e^x = 1 + x + \dots$ to give

$$j = j_0 \{1 + (1-\alpha)f\eta + \dots - (1-\alpha f\eta + \dots)\} \approx j_0 f\eta \quad (25.42)$$

This equation shows that the current density is proportional to the overpotential, so at low overpotentials the interface behaves like a conductor that obeys Ohm's law. When there is a small positive overpotential the current is anodic ($j > 0$ when $\eta > 0$), and when the overpotential is small and negative the current is cathodic ($j < 0$ when $\eta < 0$). The relation can also be reversed to calculate the potential difference that must exist if a current density j has been established by some external circuit:

$$\eta = \frac{RTj}{Fj_0} \quad (25.43)$$

The importance of this interpretation will become clear below.

Illustration 25.2 Calculating the current density 2

The exchange current density of a Pt(s)|H₂(g)|H⁺(aq) electrode at 298 K is 0.79 mA cm⁻². Therefore, the current density when the overpotential is +5.0 mV is obtained by using eqn 25.42 and $f = F/RT = 1/(25.69 \text{ mV})$:

$$j = j_0 f\eta = \frac{(0.79 \text{ mA cm}^{-2}) \times (5.0 \text{ mV})}{25.69 \text{ mV}} = 0.15 \text{ mA cm}^{-2}$$

The current through an electrode of total area 5.0 cm² is therefore 0.75 mA.

Self-test 25.6 What would be the current at pH = 2.0, the other conditions being the same? [−18 mA (cathodic)]

(e) The high overpotential limit

When the overpotential is large and positive (in practice, $\eta \geq 0.12 \text{ V}$), corresponding to the electrode being the anode in electrolysis, the second exponential in eqn 25.41 is much smaller than the first, and may be neglected. Then

$$j = j_0 e^{(1-\alpha)f\eta} \quad (25.44)$$

so

$$\ln j = \ln j_0 + (1-\alpha)f\eta \quad (25.45)$$

When the overpotential is large but negative (in practice, $\eta \leq -0.12$ V), corresponding to the cathode in electrolysis, the first exponential in eqn 25.41 may be neglected. Then

$$j = -j_0 e^{-\alpha f \eta} \quad (25.46)$$

so

$$\ln(-j) = \ln j_0 - \alpha f \eta \quad (25.47)$$

The plot of the logarithm of the current density against the overpotential is called a **Tafel plot**. The slope gives the value of α and the intercept at $\eta = 0$ gives the exchange current density.

The experimental arrangement used for a Tafel plot is shown in Fig. 25.40. A similar arrangement is typical of all kinds of electrochemical rate measurements. The current-carrying electrodes are the **working electrode**, the electrode of interest, and the **counter electrode**, which is necessary to complete the electrical circuit. The current flowing through them is controlled externally. If the area of the working electrode is A and the current is I , the current density across its surface is I/A . The potential difference across the interface cannot be measured directly, but the potential of the working electrode relative to a third electrode, the **reference electrode**, can be measured with a high impedance voltmeter, and no current flows in that half of the circuit. The reference electrode is in contact with the solution close to the working electrode through a 'Luggin capillary', which helps to eliminate any ohmic potential difference that might arise accidentally. Changing the current flowing through the working circuit causes a change of potential of the working electrode, and that change is measured with the voltmeter. The overpotential is then obtained by taking the difference between the potentials measured with and without a flow of current through the working circuit.

Fig. 25.40 The general arrangement for electrochemical rate measurements. The external source establishes a current between the working electrode and the counter electrode, and its effect on the potential difference of either of them relative to the reference electrode is observed. No current flows in the reference circuit.

Example 25.4 Interpreting a Tafel plot

The data below refer to the anodic current through a platinum electrode of area 2.0 cm^2 in contact with an $\text{Fe}^{3+}, \text{Fe}^{2+}$ aqueous solution at 298 K. Calculate the exchange current density and the transfer coefficient for the electrode process.

η/mV	50	100	150	200	250
I/mA	8.8	25.0	58.0	131	298

Method The anodic process is the oxidation $\text{Fe}^{2+}(\text{aq}) \rightarrow \text{Fe}^{3+}(\text{aq}) + \text{e}^-$. To analyse the data, we make a Tafel plot (of $\ln j$ against η) using the anodic form (eqn 25.45). The intercept at $\eta = 0$ is $\ln j_0$ and the slope is $(1 - \alpha)f$.

Answer Draw up the following table:

η/mV	50	100	150	200	250
$j/(\text{mA cm}^{-2})$	4.4	12.5	29.0	65.5	149
$\ln(j/(\text{mA cm}^{-2}))$	1.48	2.53	3.37	4.18	5.00

The points are plotted in Fig. 25.41. The high overpotential region gives a straight line of intercept 0.88 and slope 0.0165. From the former it follows that $\ln(j_0/(\text{mA cm}^{-2})) = 0.88$, so $j_0 = 2.4 \text{ mA cm}^{-2}$. From the latter,

$$(1 - \alpha) \frac{F}{RT} = 0.0165 \text{ mV}^{-1}$$

Fig. 25.41 A Tafel plot is used to measure the exchange current density (given by the extrapolated intercept at $\eta = 0$) and the transfer coefficient (from the slope). The data are from Example 25.4.

so $\alpha = 0.58$. Note that the Tafel plot is nonlinear for $\eta < 100$ mV; in this region $\alpha f \eta = 2.3$ and the approximation that $\alpha f \eta \gg 1$ fails.

Self-test 25.7 Repeat the analysis using the following cathodic current data:

η/mV	-50	-100	-150	-200	-250	-300
I/mA	-0.3	-1.5	-6.4	-27.6	-118.6	-510

$[\alpha = 0.75, j_0 = 0.041 \text{ mA cm}^{-2}]$

Some experimental values for the Butler–Volmer parameters are given in Table 25.6. From them we can see that exchange current densities vary over a very wide range. For example, the N_2, N_3^- couple on platinum has $j_0 = 10^{-76} \text{ A cm}^{-2}$, whereas the H^+, H_2 couple on platinum has $j_0 = 8 \times 10^{-4} \text{ A cm}^{-2}$, a difference of 73 orders of magnitude. Exchange currents are generally large when the redox process involves no bond breaking (as in the $[\text{Fe}(\text{CN})_6]^{3-}, [\text{Fe}(\text{CN})_6]^{4-}$ couple) or if only weak bonds are broken (as in Cl_2, Cl^-). They are generally small when more than one electron needs to be transferred, or when multiple or strong bonds are broken, as in the N_2, N_3^- couple and in redox reactions of organic compounds.

25.10 Voltammetry

The kinetics of electrode processes can be studied by **voltammetry**, in which the current is monitored as the potential of the electrode is changed, and by **chronopotentiometry**, in which the potential is monitored as the current flow is changed. Voltammetry may also be used to identify species present in solution and to determine their concentration.

Before we describe voltammetry in detail, we need to understand how electrode potentials vary with current. Electrodes with potentials that change only slightly when a current passes through them are classified as **non-polarizable**. Those with strongly current-dependent potentials are classified as **polarizable**. From the linearized equation (eqn 25.43) it is clear that the criterion for low polarizability is high exchange current density (so η may be small even though j is large). The calomel and H_2/Pt electrodes are both highly non-polarizable, which is one reason why they are so extensively used as reference electrodes in electrochemistry.

(a) Concentration polarization

One of the assumptions in the derivation of the Butler–Volmer equation is the negligible conversion of the electroactive species at low current densities, resulting in uniformity of concentration near the electrode. This assumption fails at high current

Synoptic table 25.6* Exchange current densities and transfer coefficients at 298 K

Reaction	Electrode	$j_0/(\text{A cm}^{-2})$	α
$2 \text{H}^+ + 2 \text{e}^- \rightarrow \text{H}_2$	Pt	7.9×10^{-4}	0.58
	Ni	6.3×10^{-6}	
	Pb	5.0×10^{-12}	
$\text{Fe}^{3+} + \text{e}^- \rightarrow \text{Fe}^{2+}$	Pt	2.5×10^{-3}	0.58

* More values are given in the *Data section*.

densities because the consumption of electroactive species close to the electrode results in a concentration gradient; diffusion of the species towards the electrode from the bulk is slow and may become rate-determining. A larger overpotential is then needed to produce a given current. This effect is called **concentration polarization** and its contribution to the total overpotential is called the **polarization overpotential**, η^c .

Consider a case for which the concentration polarization dominates all the rate processes and a redox couple of the type M^{z+}, M with the reduction $M^{z+} + z e^- \rightarrow M$. Under zero-current conditions, when the net current density is zero, the electrode potential is related to the activity, a , of the ions in the solution by the Nernst equation (eqn 7.29):

$$E = E^\circ + \frac{RT}{zF} \ln a \quad (25.48)$$

As remarked earlier, electrode kinetics are normally studied using a large excess of support electrolyte so as to keep the mean activity coefficients approximately constant. Therefore, the constant activity coefficient in $a = \gamma c$ may be absorbed into E , and we write the **formal potential**, E° , of the electrode as

$$E^\circ = E^\circ + \frac{RT}{zF} \ln \gamma \quad [25.49]$$

Then the electrode potential is

$$E = E^\circ + \frac{RT}{zF} \ln c \quad (25.50)$$

When the cell is producing current, the active ion concentration at the OHP changes to c' and the electrode potential changes to

$$E' = E^\circ + \frac{RT}{zF} \ln c' \quad (25.51)$$

The concentration overpotential is therefore

$$\eta^c = E' - E = \frac{RT}{zF} \ln \left(\frac{c'}{c} \right) \quad (25.52)$$

We now suppose that the solution has its bulk concentration, c , up to a distance δ from the outer Helmholtz plane, and then falls linearly to c' at the plane itself. This **Nernst diffusion layer** is illustrated in Fig. 25.42. The thickness of the Nernst layer (which is typically 0.1 mm, and strongly dependent on the condition of hydrodynamic flow due to any stirring or convective effects) is quite different from that of the electric double layer (which is typically less than 1 nm, and unaffected by stirring). The concentration gradient through the Nernst layer is

$$\frac{dc}{dx} = \frac{c' - c}{\delta} \quad (25.53)$$

This gradient gives rise to a flux of ions towards the electrode, which replenishes the cations as they are reduced. The (molar) flux, J , is proportional to the concentration gradient, and according to Fick's first law (Section 21.4)

$$J = -D \left(\frac{\partial c}{\partial x} \right) \quad (25.54)$$

Therefore, the particle flux towards the electrode is

$$J = D \frac{c - c'}{\delta} \quad (25.55)$$

Fig. 25.42 In a simple model of the Nernst diffusion layer there is a linear variation in concentration between the bulk and the outer Helmholtz plane; the thickness of the layer depends strongly on the state of flow of the fluid. Note that the diffusion layer is much thicker relative to the OHP than shown here.

The cathodic current density towards the electrode is the product of the particle flux and the charge transferred per mole of ions, zF :

$$j = zFJ = zFD \frac{c - c'}{\delta} \quad (25.56)$$

For instance, for the couple $[\text{Fe}(\text{CN})_6]^{2-}/[\text{Fe}(\text{CN})_6]^{3-}$, $z = 1$, but for Fe^{3+}/Fe , $z = 3$. The maximum rate of diffusion across the Nernst layer occurs when the gradient is steepest, which is when $c' = 0$. This concentration occurs when an electron from an ion that diffuses across the layer is snapped over the activation barrier and on to the electrode. No flow of current can exceed the **limiting current density**, j_{lim} , which is given by

$$j_{\text{lim}} = zFJ_{\text{lim}} = \frac{zFDc}{\delta} \quad (25.57a)$$

By using the Nernst–Einstein equation (eqn 21.65, written as $D = RT\lambda/z^2F^2$), we can express j_{lim} in terms of the ionic conductivity λ :

$$j_{\text{lim}} = \frac{cRT\lambda}{zF\delta} \quad (25.57b)$$

Illustration 25.3 Estimating the limiting current density

Consider an electrode in a 0.10 M $\text{Cu}^{2+}(\text{aq})$ unstirred solution in which the thickness of the diffusion layer is about 0.3 mm. With $\lambda = 107 \text{ S cm}^2 \text{ mol}^{-1}$ (Table 21.4), $\delta = 0.3 \text{ mm}$, $c = 0.10 \text{ mol dm}^{-3}$, $z = 2$, and $T = 298 \text{ K}$, it follows from eqn 25.57b that $j_{\text{lim}} = 5 \text{ mA cm}^{-2}$. The result implies that the current towards an electrode of area 1 cm^2 electrode cannot exceed 5 mA in this (unstirred) solution.

Self-test 25.8 Evaluate the limiting current density for an $\text{Ag}(\text{s})|\text{Ag}^+(\text{aq})$ electrode in $0.010 \text{ mol dm}^{-3} \text{ Ag}^+(\text{aq})$ at 298 K. Take $\delta = 0.03 \text{ mm}$. [5 mA cm⁻²]

It follows from eqn 25.56 that the concentration c' is related to the current density at the double layer by

$$c' = c - \frac{j\delta}{zFD} \quad (25.58)$$

Hence, as the current density is increased, the concentration falls below the bulk value. However, this decline in concentration is small when the diffusion constant is large, for then the ions are very mobile and can quickly replenish any ions that have been removed.

Finally, we substitute eqn 25.58 into eqn 25.52 and obtain the following expressions for the overpotential in terms of the current density, and vice versa:

$$\eta^c = \frac{RT}{zF} \ln \left(1 - \frac{j\delta}{zcFD} \right) \quad (25.59a)$$

$$j = \frac{zcFD}{\delta} (1 - e^{zF\eta^c}) \quad (25.59b)$$

(b) Experimental techniques

The kind of output from **linear-sweep voltammetry** is illustrated in Fig. 25.43. Initially, the absolute value of the potential is low, and the cathodic current is due to the

migration of ions in the solution. However, as the potential approaches the reduction potential of the reducible solute, the cathodic current grows. Soon after the potential exceeds the reduction potential the current rises and reaches a maximum value (as specified in eqn 25.57). This maximum current is proportional to the molar concentration of the species, so that concentration can be determined from the peak height after subtraction of an extrapolated baseline. In **differential pulse voltammetry** the current is monitored before and after a pulse of potential is applied, and the processed output is the slope of a curve like that obtained by linear-sweep voltammetry (Fig. 25.44). The area under the curve (in effect, the integral of the derivative displayed in the illustration) is proportional to the concentration of the species.

In **cyclic voltammetry** the potential is applied in a sawtooth manner to the working electrode and the current is monitored. A typical cyclic voltammogram is shown in Fig. 25.45. The shape of the curve is initially like that of a linear sweep experiment, but after reversal of the sweep there is a rapid change in current on account of the high concentration of oxidizable species close to the electrode that were generated on the reductive sweep. When the potential is close to the value required to oxidize the reduced species, there is a substantial anodic current until all the oxidation is complete, and the current returns to zero.

When the reduction reaction at the electrode can be reversed, as in the case of the $[\text{Fe}(\text{CN})_6]^{3-}/[\text{Fe}(\text{CN})_6]^{4-}$ couple, the cyclic voltammogram is broadly symmetric about the standard potential of the couple (as in Fig. 25.45b). The scan is initiated with $[\text{Fe}(\text{CN})_6]^{3-}$ present in solution and, as the potential approaches E° for the couple, the $[\text{Fe}(\text{CN})_6]^{3-}$ near the electrode is reduced and current begins to flow. As the potential continues to change, the cathodic current begins to decline again because all

Fig. 25.43 The change of potential with time and the resulting current/potential curve in a voltammetry experiment. The peak value of the current density is proportional to the concentration of electroactive species (for instance, $[\text{Ox}]$) in solution.

Fig. 25.44 A differential pulse voltammetry experiment. (a) The potential is swept linearly as a mercury droplet grows on the end of a capillary dipping into the sample and then pulsed as shown by the purple line. The resulting current is shown as the blue line and is sampled at the two points shown. (b) The data output is obtained as the difference of the currents at the two sampled points.

Fig. 25.45 (a) The change of potential with time and (b) the resulting current/potential curve in a cyclic voltammetry experiment.

Fig. 25.46 (a) When a non-reversible step in a reaction mechanism has time to occur, the cyclic voltammogram may not show the reverse oxidation or reduction peak. (b) However, if the rate of sweep is increased, the return step may be caused to occur before the irreversible step has had time to intervene, and a typical 'reversible' voltammogram is obtained.

Fig. 25.47 The cyclic voltammogram referred to in Self-test 25.9.

the $[\text{Fe}(\text{CN})_6]^{3-}$ near the electrode has been reduced and the current reaches its limiting value. The potential is now returned linearly to its initial value, and the reverse series of events occurs with the $[\text{Fe}(\text{CN})_6]^{4-}$ produced during the forward scan now undergoing oxidation. The peak of current lies on the other side of $E^\ominus$, so the species present and its standard potential can be identified, as indicated in the illustration, by noting the locations of the two peaks.

The overall shape of the curve gives details of the kinetics of the electrode process and the change in shape as the rate of change of potential is altered gives information on the rates of the processes involved. For example, the matching peak on the return phase of the sawtooth change of potential may be missing, which indicates that the oxidation (or reduction) is irreversible. The appearance of the curve may also depend on the timescale of the sweep for, if the sweep is too fast, some processes might not have time to occur. This style of analysis is illustrated in the following example.

Example 25.5 Analysing a cyclic voltammetry experiment

The electroreduction of *p*-bromonitrobenzene in liquid ammonia is believed to occur by the following mechanism:

Suggest the likely form of the cyclic voltammogram expected on the basis of this mechanism.

Method Decide which steps are likely to be reversible on the timescale of the potential sweep: such processes will give symmetrical voltammograms. Irreversible processes will give unsymmetrical shapes because reduction (or oxidation) might not occur. However, at fast sweep rates, an intermediate might not have time to react, and a reversible shape will be observed.

Answer At slow sweep rates, the second reaction has time to occur, and a curve typical of a two-electron reduction will be observed, but there will be no oxidation peak on the second half of the cycle because the product, $\text{C}_6\text{H}_5\text{NO}_2$, cannot be oxidized (Fig. 25.46a). At fast sweep rates, the second reaction does not have time to take place before oxidation of the $\text{BrC}_6\text{H}_4\text{NO}_2^-$ intermediate starts to occur during the reverse scan, so the voltammogram will be typical of a reversible one-electron reduction (Fig. 25.46b).

Self-test 25.9 Suggest an interpretation of the cyclic voltammogram shown in Fig. 25.47. The electroactive material is $\text{ClC}_6\text{H}_4\text{CN}$ in acid solution; after reduction to $\text{ClC}_6\text{H}_4\text{CN}^-$, the radical anion may form $\text{C}_6\text{H}_5\text{CN}$ irreversibly.

25.11 Electrolysis

To induce current to flow through an electrolytic cell and bring about a nonspontaneous cell reaction, the applied potential difference must exceed the zero-current potential by at least the **cell overpotential**. The cell overpotential is the sum of the overpotentials at the two electrodes and the ohmic drop (IR_s , where R_s is the internal

resistance of the cell) due to the current through the electrolyte. The additional potential needed to achieve a detectable rate of reaction may need to be large when the exchange current density at the electrodes is small. For similar reasons, a working galvanic cell generates a smaller potential than under zero-current conditions. In this section we see how to cope with both aspects of the overpotential.

The relative rates of gas evolution or metal deposition during electrolysis can be estimated from the Butler–Volmer equation and tables of exchange current densities. From eqn 25.46 and assuming equal transfer coefficients, we write the ratio of the cathodic currents as

$$\frac{j'}{j} = \frac{j'_0}{j_0} e^{(\eta - \eta')\alpha f} \quad (25.60)$$

where j' is the current density for electrodeposition and j is that for gas evolution, and j'_0 and j_0 are the corresponding exchange current densities. This equation shows that metal deposition is favoured by a large exchange current density and relatively high gas evolution overpotential (so $\eta - \eta'$ is positive and large). Note that $\eta < 0$ for a cathodic process, so $-\eta' > 0$.

The exchange current density depends strongly on the nature of the electrode surface, and changes in the course of the electrodeposition of one metal on another. A very crude criterion is that significant evolution or deposition occurs only if the overpotential exceeds about 0.6 V.

Self-test 25.10 Deduce an expression for the ratio when the hydrogen evolution is limited by transport across a diffusion layer.

$$[j'/j = (\delta j'_0 / cFD) e^{-\alpha \eta' f}]$$

A glance at Table 25.6 shows the wide range of exchange current densities for a metal/hydrogen electrode. The most sluggish exchange currents occur for lead and mercury, and the value of 1 pA cm^{-2} corresponds to a monolayer of atoms being replaced in about 5 years. For such systems, a high overpotential is needed to induce significant hydrogen evolution. In contrast, the value for platinum (1 mA cm^{-2}) corresponds to a monolayer being replaced in 0.1 s, so gas evolution occurs for a much lower overpotential.

The exchange current density also depends on the crystal face exposed. For the deposition of copper on copper, the (100) face has $j_0 = 1 \text{ mA cm}^{-2}$, so for the same overpotential the (100) face grows at 2.5 times the rate of the (111) face, for which $j_0 = 0.4 \text{ mA cm}^{-2}$.

25.12 Working galvanic cells

In working galvanic cells (those not balanced against an external potential), the overpotential leads to a smaller potential than under zero-current conditions. Furthermore, we expect the cell potential to decrease as current is generated because it is then no longer working reversibly and can therefore do less than maximum work.

We shall consider the cell $M|M^+(\text{aq})||M'^+(\text{aq})|M'$ and ignore all the complications arising from liquid junctions. The potential of the cell is $E' = \Delta\phi_R - \Delta\phi_L$. Because the cell potential differences differ from their zero-current values by overpotentials, we can write $\Delta\phi_X = E_X + \eta_X$, where X is L or R for the left or right electrode, respectively. The cell potential is therefore

$$E' = E + \eta_R - \eta_L \quad (25.61a)$$

To avoid confusion about signs (η_R is negative, η_L is positive) and to emphasize that a working cell has a lower potential than a zero-current cell, we shall write this expression as

$$E' = E - |\eta_R| - |\eta_L| \quad (25.61b)$$

with E the cell emf. We should also subtract the ohmic potential difference IR_s , where R_s is the cell's internal resistance:

$$E' = E - |\eta_R| - |\eta_L| - IR_s \quad (25.61c)$$

The ohmic term is a contribution to the cell's irreversibility—it is a thermal dissipation term—so the sign of IR_s is always such as to reduce the potential in the direction of zero.

The overpotentials in eqn 25.61 can be calculated from the Butler–Volmer equation for a given current, I , being drawn. We shall simplify the equations by supposing that the areas, A , of the electrodes are the same, that only one electron is transferred in the rate-determining steps at the electrodes, that the transfer coefficients are both $\frac{1}{2}$, and that the high-overpotential limit of the Butler–Volmer equation may be used. Then from eqns 25.46 and 25.61c we find

$$E' = E - IR_s - \frac{4RT}{F} \ln \left(\frac{I}{A\bar{j}} \right) \quad \bar{j} = (j_{0L}j_{0R})^{1/2} \quad (25.62)$$

where j_{0L} and j_{0R} are the exchange current densities for the two electrodes.

The concentration overpotential also reduces the cell potential. If we use the Nernst diffusion layer model for each electrode, the total change of potential arising from concentration polarization is given by eqn 25.59 as

$$E' = E - \frac{RT}{zF} \ln \left\{ \left(1 - \frac{I}{Aj_{\text{lim,L}}} \right) \left(1 - \frac{I}{Aj_{\text{lim,R}}} \right) \right\} \quad (25.63)$$

This contribution can be added to the one in eqn 25.62 to obtain a full (but still very approximate) expression for the cell potential when a current I is being drawn:

$$E' = E - IR_s - \frac{2RT}{zF} \ln g(I) \quad (25.64a)$$

with

$$g(I) = \left(\frac{I}{A\bar{j}} \right)^{2z} \left\{ \left(1 - \frac{I}{Aj_{\text{lim,L}}} \right) \left(1 - \frac{I}{Aj_{\text{lim,R}}} \right) \right\}^{1/2} \quad (25.64b)$$

This equation depends on a lot of parameters, but an example of its general form is given in Fig. 25.48. Notice the very steep decline of working potential when the current is high and close to the limiting value for one of the electrodes.

Because the power, P , supplied by a galvanic cell is IE' , from eqn 25.64 we can write

$$P = IE - I^2R_s - \frac{2IRT}{zF} \ln g(I) \quad (25.65)$$

The first term on the right is the power that would be produced if the cell retained its zero-current potential when delivering current. The second term is the power generated uselessly as heat as a result of the resistance of the electrolyte. The third term is the reduction of the potential at the electrodes as a result of drawing current.

The general dependence of power output on the current drawn is shown in Fig. 25.48 as the purple line. Notice how maximum power is achieved just before the concentration polarization quenches the cell's performance. Information of this kind is essential if the optimum conditions for operating electrochemical devices are to be found and their performance improved.

Fig. 25.48 The dependence of the potential of a working galvanic cell on the current density being drawn (blue line) and the corresponding power output (purple line) calculated by using eqns 25.64 and 25.65, respectively. Notice the sharp decline in power just after the maximum.

Exploration Using mathematical software, and electronic spreadsheet, or the interactive applets found in the *Living graphs* section of the text's web site, confirm that the sharp decline in potential and power observed in Fig. 25.48 is true for any value of R_s .

Electric storage cells operate as galvanic cells while they are producing electricity but as electrolytic cells while they are being charged by an external supply. The lead–acid battery is an old device, but one well suited to the job of starting cars (and the only one available). During charging the cathode reaction is the reduction of Pb^{2+} and its deposition as lead on the lead electrode. Deposition occurs instead of the reduction of the acid to hydrogen because the latter has a low exchange current density on lead. The anode reaction during charging is the oxidation of Pb(II) to Pb(IV) , which is deposited as the oxide PbO_2 . On discharge, the two reactions run in reverse. Because they have such high exchange current densities the discharge can occur rapidly, which is why the lead battery can produce large currents on demand.

IMPACT ON TECHNOLOGY

I25.3 Fuel cells

A fuel cell operates like a conventional galvanic cell with the exception that the reactants are supplied from outside rather than forming an integral part of its construction. A fundamental and important example of a fuel cell is the hydrogen/oxygen cell, such as the ones used in space missions (Fig. 25.49). One of the electrolytes used is concentrated aqueous potassium hydroxide maintained at 200°C and 20–40 atm; the electrodes may be porous nickel in the form of sheets of compressed powder. The cathode reaction is the reduction

and the anode reaction is the oxidation

For the corresponding reduction, $E^\ominus = -0.83 \text{ V}$. Because the overall reaction

is exothermic as well as spontaneous, it is less favourable thermodynamically at 200°C than at 25°C , so the cell potential is lower at the higher temperature. However, the increased pressure compensates for the increased temperature, and $E \approx +1.2 \text{ V}$ at 200°C and 40 atm.

One advantage of the hydrogen/oxygen system is the large exchange current density of the hydrogen reaction. Unfortunately, the oxygen reaction has an exchange current density of only about 0.1 nA cm^{-2} , which limits the current available from the cell. One way round the difficulty is to use a catalytic surface (to increase j_0) with a large surface area. One type of highly developed fuel cell has phosphoric acid as the electrolyte and operates with hydrogen and air at about 200°C ; the hydrogen is obtained from a reforming reaction on natural gas:

This fuel cell has shown promise for *combined heat and power systems* (CHP systems). In such systems, the waste heat is used to heat buildings or to do work. Efficiency in a CHP plant can reach 80 per cent. The power output of batteries of such cells has reached the order of 10 MW. Although hydrogen gas is an attractive fuel, it has disadvantages for mobile applications: it is difficult to store and dangerous to handle. One possibility for portable fuel cells is to store the hydrogen in carbon nanotubes (Impact 20.2). It has been shown that carbon nanofibres in herringbone patterns can store huge amounts of hydrogen and result in an energy density (the magnitude of the released energy divided by the volume of the material) twice that of gasoline.

Cells with molten carbonate electrolytes at about 600°C can make use of natural gas directly. Solid-state electrolytes are also used. They include one version in which the

Fig. 25.49 A single cell of a hydrogen/oxygen fuel cell. In practice, a stack of many cells is used.

electrolyte is a solid polymeric ionic conductor at about 100°C, but in current versions it requires very pure hydrogen to operate successfully. Solid ionic conducting oxide cells operate at about 1000°C and can use hydrocarbons directly as fuel. Until these materials have been developed, one attractive fuel is methanol, which is easy to handle and is rich in hydrogen atoms:

One disadvantage of methanol, however, is the phenomenon of ‘electro-osmotic drag’ in which protons moving through the polymer electrolyte membrane separating the anode and cathode carry water and methanol with them into the cathode compartment where the potential is sufficient to oxidize CH_3OH to CO_2 , so reducing the efficiency of the cell. Solid ionic conducting oxide cells operate at about 1000°C and can use hydrocarbons directly as fuel.

A *biofuel cell* is like a conventional fuel cell but in place of a platinum catalyst it uses enzymes or even whole organisms. The electricity will be extracted through organic molecules that can support the transfer of electrons. One application will be as the power source for medical implants, such as pacemakers, perhaps using the glucose present in the bloodstream as the fuel.

25.13 Corrosion

A thermodynamic warning of the likelihood of corrosion is obtained by comparing the standard potentials of the metal reduction, such as

with the values for one of the following half-reactions:

In acidic solution:

In basic solution:

Because all three redox couples have standard potentials more positive than $E^\circ(\text{Fe}^{2+}/\text{Fe})$, all three can drive the oxidation of iron to iron(II). The electrode potentials we have quoted are standard values, and they change with the pH of the medium. For the first two:

$$E(\text{a}) = E^\circ(\text{a}) + (RT/F) \ln a(\text{H}^+) = -(0.059 \text{ V})\text{pH}$$

$$E(\text{b}) = E^\circ(\text{b}) + (RT/F) \ln a(\text{H}^+) = 1.23 \text{ V} - (0.059 \text{ V})\text{pH}$$

These expressions let us judge at what pH the iron will have a tendency to oxidize (see Chapter 7). A thermodynamic discussion of corrosion, however, only indicates whether a tendency to corrode exists. If there is a thermodynamic tendency, we must examine the kinetics of the processes involved to see whether the process occurs at a significant rate.

A model of a corrosion system is shown in Fig. 25.50a. It can be taken to be a drop of slightly acidic (or basic) water containing some dissolved oxygen in contact with the metal. The oxygen at the edges of the droplet, where the O_2 concentration is higher, is reduced by electrons donated by the iron over an area A . Those electrons are replaced by others released elsewhere as $\text{Fe} \rightarrow \text{Fe}^{2+} + 2 \text{ e}^-$. This oxidative release occurs over an area A' under the oxygen-deficient inner region of the droplet. The droplet acts as a short-circuited galvanic cell (Fig. 25.50b).

The rate of corrosion is measured by the current of metal ions leaving the metal surface in the anodic region. This flux of ions gives rise to the **corrosion current**, I_{corr} , which can be identified with the anodic current, I_a . We show in the justification below that the corrosion current is related to the cell potential of the corrosion couple by

$$I_{\text{corr}} = \bar{j}_0 \bar{A} e^{fE/4} \quad \bar{j}_0 = (j_0 j_0')^{1/2} \quad \bar{A} = (AA')^{1/2} \quad (25.66)$$

Justification 25.1 *The corrosion current*

Because any current emerging from the anodic region must find its way to the cathodic region, the cathodic current, I_c , and the anodic current, I_a , must both be equal to the corrosion current. In terms of the current densities at the oxidation and reduction sites, j and j' , respectively, we can write

$$I_{\text{corr}} = jA = j'A' = (jj'AA')^{1/2} = \bar{j}\bar{A} \quad \bar{j} = (jj')^{1/2} \quad \bar{A} = (AA')^{1/2} \quad (25.67)$$

The Butler–Volmer equation is now used to express the current densities in terms of overpotentials. For simplicity we assume that the overpotentials are large enough for the high-overpotential limit (eqn 25.46, $j = -j_0 e^{-\alpha f \eta}$) to apply, that polarization overpotential can be neglected, that the rate-determining step is the transfer of a single electron, and that the transfer coefficients are $\frac{1}{2}$. We also assume that, since the droplet is so small, there is negligible potential difference between the cathode and anode regions of the solution. Moreover, because it is short-circuited by the metal, the potential of the metal is the same in both regions, and so the potential difference between the metal and the solution is the same in both regions too; it is denoted $\Delta\phi_{\text{corr}}$. The overpotentials in the two regions are therefore $\eta = \Delta\phi_{\text{corr}} - \Delta\phi$ and $\eta' = \Delta\phi_{\text{corr}} - \Delta\phi'$, and the current densities are

$$j = j_0 e^{\eta f/2} = j_0 e^{f\Delta\phi_{\text{corr}}/2} e^{-f\Delta\phi/2} \quad j' = j'_0 e^{-\eta' f/2} = j'_0 e^{-f\Delta\phi_{\text{corr}}/2} e^{f\Delta\phi'/2}$$

These expressions can be substituted into the expression for I_{corr} and $\Delta\phi' - \Delta\phi$ replaced by the difference of electrode potentials E to give eqn 25.66.

The effect of the exchange current density on the corrosion rate can be seen by considering the specific case of iron in contact with acidified water. Thermodynamically, either hydrogen or oxygen reduction reaction (a) or (b) on p. 946 is effective. However, the exchange current density of reaction (b) on iron is only about $10^{-14} \text{ A cm}^{-2}$, whereas for (a) it is $10^{-6} \text{ A cm}^{-2}$. The latter therefore dominates kinetically, and iron corrodes by hydrogen evolution in acidic solution.

For corrosion reactions with similar exchange current densities, eqn 25.66 predicts that the rate of corrosion is high when E is large. That is, rapid corrosion can be expected when the oxidizing and reducing couples have widely differing electrode potentials.

Fig. 25.50 (a) A simple version of the corrosion process is that of a droplet of water, which is oxygen rich near its boundary with air. The oxidation of the iron takes place in the region away from the oxygen because the electrons are transported through the metal. (b) The process may be modelled as a short-circuited electrochemical cell.

IMPACT ON TECHNOLOGY

I25.4 Protecting materials against corrosion

Several techniques for inhibiting corrosion are available. First, from eqn 25.66 we see that the rate of corrosion depends on the surfaces exposed: if either A or A' is zero, then the corrosion current is zero. This interpretation points to a trivial, yet often effective, method of slowing corrosion: cover the surface with some impermeable layer, such as paint, which prevents access of damp air. Paint also increases the effective solution resistance between the cathode and anode patches on the surface. Unfortunately, this protection fails disastrously if the paint becomes porous. The oxygen then has access to the exposed metal and corrosion continues beneath the paintwork. Another form of surface coating is provided by **galvanizing**, the coating of an iron object with zinc. Because the latter's standard potential is -0.76 V , which is more negative than that of the iron couple, the corrosion of zinc is thermodynamically

Fig. 25.51 (a) In cathodic protection an anode of a more strongly reducing metal is sacrificed to maintain the integrity of the protected object (for example, a pipeline, bridge, or boat). (b) In impressed-current cathodic protection electrons are supplied from an external cell so that the object itself is not oxidized. The broken lines depict the completed circuit through the soil.

favoured and the iron survives (the zinc survives because it is protected by a hydrated oxide layer). In contrast, tin plating leads to a very rapid corrosion of the iron once its surface is scratched and the iron exposed because the tin couple ($E^\ominus = -0.14$ V) oxidizes the iron couple ($E^\ominus = -0.44$ V). Some oxides are inert kinetically in the sense that they adhere to the metal surface and form an impermeable layer over a fairly wide pH range. This **passivation**, or kinetic protection, can be seen as a way of decreasing the exchange currents by sealing the surface. Thus, aluminium is inert in air even though its standard potential is strongly negative (-1.66 V).

Another method of protection is to change the electric potential of the object by pumping in electrons that can be used to satisfy the demands of the oxygen reduction without involving the oxidation of the metal. In **cathodic protection**, the object is connected to a metal with a more negative standard potential (such as magnesium, -2.36 V). The magnesium acts as a **sacrificial anode**, supplying its own electrons to the iron and becoming oxidized to Mg^{2+} in the process (Fig. 25.51a). A block of magnesium replaced occasionally is much cheaper than the ship, building, or pipeline for which it is being sacrificed. In **impressed-current cathodic protection** (Fig. 25.51b) an external cell supplies the electrons and eliminates the need for iron to transfer its own.

Table 25.7 Summary of acronyms

AES	Auger electron spectroscopy
AFM	Atomic force microscopy
BET isotherm	Brunauer–Emmett–Teller isotherm
EELS	Electron energy-loss spectroscopy
ER mechanism	Eley–Rideal mechanism
ESCA	Electron spectroscopy for chemical analysis
FIM	Field-ionization microscopy
HREELS	High-resolution electron energy-loss spectroscopy
IHP	Inner Helmholtz plane
LEED	Low-energy electron diffraction
LH mechanism	Langmuir–Hinshelwood mechanism
MBRS	Molecular beam reactive scattering
MBS	Molecular beam scattering
OHP	Outer Helmholtz plane
QCM	Quartz crystal microbalance
RAIRS	Reflection–absorption infrared spectroscopy
SAM	Scanning Auger electron microscopy
SAM	Self-assembled monolayer
SEM	Scanning electron microscopy
SERS	Surface-enhanced Raman scattering
SEXAFS	Surface-extended X-ray absorption fine structure spectroscopy
SHG	Second harmonic generation
SIMS	Secondary ion mass spectrometry
SPM	Scanning probe microscopy
SPR	Surface plasmon resonance
STM	Scanning tunnelling microscopy
TDS	Thermal desorption spectroscopy
TPD	Temperature programmed desorption
UHV	Ultra-high vacuum
UPS	Ultraviolet photoemission spectroscopy
XPS	X-ray photoemission spectroscopy

Checklist of key ideas

- ☐ 1. Adsorption is the attachment of molecules to a surface; the substance that adsorbs is the adsorbate and the underlying material is the adsorbent or substrate. The reverse of adsorption is desorption.
- ☐ 2. The collision flux, Z_w , of gas molecules bombarding a solid surface is related to the gas pressure by $Z_w = p/(2\pi mkT)^{1/2}$.
- ☐ 3. Techniques for studying surface composition and structure include scanning electron microscopy (SEM), scanning probe microscopy (STM), photoemission spectroscopy, secondary-ion mass spectrometry, surface-enhanced Raman scattering (SERS), Auger electron spectroscopy (AES), low energy electron diffraction (LEED), and molecular beam scattering (MBS).
- ☐ 4. The fractional coverage, θ , is the ratio of the number of occupied sites to the number of available sites.
- ☐ 5. Techniques for studying the rates of surface processes include flash desorption, biosensor analysis, second harmonic generation (SHG), gravimetry by using a quartz crystal microbalance (QCM), and molecular beam reactive scattering (MRS).
- ☐ 6. Physisorption is adsorption by a van der Waals interaction; chemisorption is adsorption by formation of a chemical (usually covalent) bond.
- ☐ 7. The Langmuir isotherm is a relation between the fractional coverage and the partial pressure of the adsorbate: $\theta = Kp/(1 + Kp)$.
- ☐ 8. The isosteric enthalpy of adsorption is determined from a plot of $\ln K$ against $1/T$.
- ☐ 9. The BET isotherm is an isotherm applicable when multilayer adsorption is possible: $V/V_{\text{mon}} = cz/(1 - z)\{1 - (1 - c)z\}$, with $z = p/p^*$.
- ☐ 10. The sticking probability, s , is the proportion of collisions with the surface that successfully lead to adsorption.
- ☐ 11. Desorption is an activated process with half-life $t_{1/2} = \tau_0 e^{E_d/RT}$; the desorption activation energy is measured by temperature-programmed desorption (TPD) or thermal desorption spectroscopy (TDS).
- ☐ 12. In the Langmuir–Hinshelwood mechanism (LH mechanism) of surface-catalysed reactions, the reaction takes place by encounters between molecular fragments and atoms adsorbed on the surface.
- ☐ 13. In the Eley–Rideal mechanism (ER mechanism) of a surface-catalysed reaction, a gas-phase molecule collides with another molecule already adsorbed on the surface.
- ☐ 14. An electrical double layer consists of a sheet of positive charge at the surface of the electrode and a sheet of negative charge next to it in the solution (or vice versa).
- ☐ 15. The Galvani potential difference is the potential difference between the bulk of the metal electrode and the bulk of the solution.
- ☐ 16. Models of the double layer include the Helmholtz layer model and the Gouy–Chapman model.
- ☐ 17. The current density, j , at an electrode is expressed by the Butler–Volmer equation, $j = j_0\{e^{(1-\alpha)f\eta} - e^{-\alpha f\eta}\}$, where η is the overpotential, $\eta = E' - E$, α is the transfer coefficient, and j_0 is the exchange-current density.
- ☐ 18. A Tafel plot is a plot of the logarithm of the current density against the overpotential: the slope gives the value of α and the intercept at $\eta = 0$ gives the exchange-current density.
- ☐ 19. Voltammetry is the study of the current through an electrode as a function of the applied potential difference. Experimental techniques include linear-sweep voltammetry, differential pulse voltammetry, and cyclic voltammetry.
- ☐ 20. To induce current to flow through an electrolytic cell and bring about a nonspontaneous cell reaction, the applied potential difference must exceed the cell emf by at least the cell overpotential.
- ☐ 21. The corrosion current is a current proportional to the rate at which metal ions leave a metal surface in the anodic region during corrosion.

Further information

Further information 25.1 The relation between electrode potential and the Galvani potential

To demonstrate the relation between $\Delta\phi$ and E , consider the cell $\text{Pt}|\text{H}_2(\text{g})|\text{H}^+(\text{aq})||\text{M}^+(\text{aq})|\text{M}(\text{s})$ and the half-reactions

The Gibbs energies of these two half-reactions can be expressed in terms of the chemical potentials, μ , of all the species. However, we must take into account the fact that the species are present in phases with different electric potentials. Thus, a cation in a region of positive potential has a higher chemical potential (is chemically more active in a thermodynamic sense) than in a region of zero potential.

The contribution of an electric potential to the chemical potential is calculated by noting that the electrical work of adding a charge ze to a region where the potential is ϕ is $ze\phi$, and therefore that the work per mole is $zF\phi$, where F is Faraday's constant. Because at constant temperature and pressure the maximum electrical work can be identified with the change in Gibbs energy (Section 7.7), the difference in chemical potential of an ion with and without the electrical potential present is $zF\phi$. The chemical potential of an ion in the presence of an electric potential is called its **electrochemical potential**, $\bar{\mu}$. It follows that

$$\bar{\mu} = \mu + zF\phi \quad [25.68]$$

where μ is the chemical potential of the species when the electrical potential is zero. When $z = 0$ (a neutral species), the electrochemical potential is equal to the chemical potential.

To express the Gibbs energy for the half-reactions in terms of the electrochemical potentials of the species we note that the cations M^+ are in the solution where the inner potential is ϕ_S and the electrons are in the electrode where it is ϕ_M . It follows that

$$\begin{aligned} \Delta_r G_R &= \bar{\mu}(\text{M}) - \{\bar{\mu}(\text{M}^+) + \bar{\mu}(\text{e}^-)\} \\ &= \mu(\text{M}) - \{\mu(\text{M}^+) + F\phi_S + \mu(\text{e}^-) - F\phi_M\} \\ &= \mu(\text{M}) - \mu(\text{M}^+) - \mu(\text{e}^-) + F\Delta\phi_R \end{aligned}$$

where $\Delta\phi_R = \phi_M - \phi_S$ is the Galvani potential difference at the right-hand electrode. Likewise, in the hydrogen half-reaction, the electrons are in the platinum electrode at a potential ϕ_{Pt} and the H^+ ions are in the solution where the potential is ϕ_S :

$$\begin{aligned} \Delta_r G_L &= \frac{1}{2}\bar{\mu}(\text{H}_2) - \{\bar{\mu}(\text{H}^+) + \bar{\mu}(\text{e}^-)\} \\ &= \frac{1}{2}\mu(\text{H}_2) - \mu(\text{H}^+) - \mu(\text{e}^-) + F\Delta\phi_L \end{aligned}$$

where $\Delta\phi_L = \phi_{Pt} - \phi_S$ is the Galvani potential difference at the left-hand electrode.

The overall reaction Gibbs energy is

$$\begin{aligned} \Delta_r G_R - \Delta_r G_L &= \mu(\text{M}) + \mu(\text{H}^+) - \mu(\text{M}^+) - \frac{1}{2}\mu(\text{H}_2) + F(\Delta\phi_R - \Delta\phi_L) \\ &= \Delta_r G + F(\Delta\phi_R - \Delta\phi_L) \end{aligned}$$

where $\Delta_r G$ is the Gibbs energy of the cell reaction. When the cell is balanced against an external source of potential the entire system is at equilibrium. The overall reaction Gibbs energy is then zero (because its tendency to change is balanced against the external source of potential and overall there is stalemate), and the last equation becomes

$$0 = \Delta_r G + F(\Delta\phi_R - \Delta\phi_L)$$

which rearranges to

$$\Delta_r G = -F(\Delta\phi_R - \Delta\phi_L) \quad (25.69)$$

If we compare this with the result established in Section 7.7 that $\Delta_r G = -FE$ and $E = E_R - E_L$, we can conclude that (ignoring the effects of any metal-platinum and liquid junction potentials that may be present in an actual cell)

$$E_R - E_L = \Delta\phi_R - \Delta\phi_L \quad (25.70)$$

This is the result we wanted to show, for it implies that the Galvani potential difference at each electrode can differ from the electrode potential by a constant at most; that constant cancels when the difference is taken.

Discussion questions

25.1 (a) Distinguish between a step and a terrace. (b) Describe how steps and terraces can be formed by dislocations.

25.2 (a) Describe the advantages and limitations of each of the spectroscopic techniques designated by the acronyms AES, EELS, HREELS, RAIRS, SERS, SEXAFS, SHG, UPS, and XPS. (b) Describe the advantages and

limitations of each of the microscopy, diffraction, and scattering techniques designated by the acronyms AFM, FIM, LEED, MBRS, MBS, SAM, SEM, and STM.

25.3 Distinguish between the following adsorption isotherms: Langmuir, BET, Temkin, and Freundlich.

25.4 Consider the analysis of surface plasmon resonance data (as in biosensor analysis) and discuss how a plot of a_0/R_{eq} against a_0 may be used to evaluate R_{max} and K .

25.5 Describe the essential features of the Langmuir–Hinshelwood, Eley–Rideal, and Mars van Krevelen mechanisms for surface-catalysed reactions.

25.6 Account for the dependence of catalytic activity of a surface on the strength of chemisorption, as shown in Fig. 25.28.

25.7 Discuss the unique physical and chemical properties of zeolites that make them useful heterogeneous catalysts.

25.8 (a) Discuss the main structural features of the electrical double layer. (b) Distinguish between the electrical double layer and the Nernst diffusion layer.

25.9 Define the terms in and limit the generality of the following expressions: (a) $j = j_0 f \eta$, (b) $j = j_0 e^{(1-\alpha)f\eta}$, and (c) $j = -j_0 e^{-\alpha f \eta}$.

25.10 Discuss the technique of cyclic voltammetry and account for the characteristic shape of a cyclic voltammogram, such as those shown in Figs. 25.45 and 25.46.

25.11 Discuss the principles of operation of a fuel cell.

25.12 Discuss the chemical origins of corrosion and useful strategies for preventing it.

Exercises

25.1a Calculate the frequency of molecular collisions per square centimetre of surface in a vessel containing (a) hydrogen, (b) propane at 25°C when the pressure is (i) 100 Pa, (ii) 0.10 μTorr .

25.1b Calculate the frequency of molecular collisions per square centimetre of surface in a vessel containing (a) nitrogen, (b) methane at 25°C when the pressure is (i) 10.0 Pa, (ii) 0.150 μTorr .

25.2a What pressure of argon gas is required to produce a collision rate of $4.5 \times 10^{20} \text{ s}^{-1}$ at 425 K on a circular surface of diameter 1.5 mm?

25.2b What pressure of nitrogen gas is required to produce a collision rate of $5.00 \times 10^{19} \text{ s}^{-1}$ at 525 K on a circular surface of diameter 2.0 mm?

25.3a Calculate the average rate at which He atoms strike a Cu atom in a surface formed by exposing a (100) plane in metallic copper to helium gas at 80 K and a pressure of 35 Pa. Crystals of copper are face-centred cubic with a cell edge of 361 pm.

25.3b Calculate the average rate at which He atoms strike an iron atom in a surface formed by exposing a (100) plane in metallic iron to helium gas at 100 K and a pressure of 24 Pa. Crystals of iron are body-centred cubic with a cell edge of 145 pm.

25.4a A monolayer of N_2 molecules (effective area 0.165 nm^2) is adsorbed on the surface of 1.00 g of an $\text{Fe}/\text{Al}_2\text{O}_3$ catalyst at 77 K, the boiling point of liquid nitrogen. Upon warming, the nitrogen occupies 2.86 cm^3 at 0°C and 760 Torr. What is the surface area of the catalyst?

25.4b A monolayer of CO molecules (effective area 0.165 nm^2) is adsorbed on the surface of 1.00 g of an $\text{Fe}/\text{Al}_2\text{O}_3$ catalyst at 77 K, the boiling point of liquid nitrogen. Upon warming, the carbon monoxide occupies 4.25 cm^3 at 0°C and 1.00 bar. What is the surface area of the catalyst?

25.5a The volume of oxygen gas at 0°C and 101 kPa adsorbed on the surface of 1.00 g of a sample of silica at 0°C was 0.284 cm^3 at 142.4 Torr and 1.430 cm^3 at 760 Torr. What is the value of V_{mon} ?

25.5b The volume of gas at 20°C and 1.00 bar adsorbed on the surface of 1.50 g of a sample of silica at 0°C was 1.60 cm^3 at 52.4 kPa and 2.73 cm^3 at 104 kPa. What is the value of V_{mon} ?

25.6a The enthalpy of adsorption of CO on a surface is found to be -120 kJ mol^{-1} . Estimate the mean lifetime of a CO molecule on the surface at 400 K.

25.6b The enthalpy of adsorption of ammonia on a nickel surface is found to be -155 kJ mol^{-1} . Estimate the mean lifetime of an NH_3 molecule on the surface at 500 K.

25.7a The average time for which an oxygen atom remains adsorbed to a tungsten surface is 0.36 s at 2548 K and 3.49 s at 2362 K. Find the activation

energy for desorption. What is the pre-exponential factor for these tightly chemisorbed atoms?

25.7b The chemisorption of hydrogen on manganese is activated, but only weakly so. Careful measurements have shown that it proceeds 35 per cent faster at 1000 K than at 600 K. What is the activation energy for chemisorption?

25.8a The adsorption of a gas is described by the Langmuir isotherm with $K = 0.85 \text{ kPa}^{-1}$ at 25°C. Calculate the pressure at which the fractional surface coverage is (a) 0.15, (b) 0.95.

25.8b The adsorption of a gas is described by the Langmuir isotherm with $K = 0.777 \text{ kPa}^{-1}$ at 25°C. Calculate the pressure at which the fractional surface coverage is (a) 0.20, (b) 0.75.

25.9a A certain solid sample adsorbs 0.44 mg of CO when the pressure of the gas is 26.0 kPa and the temperature is 300 K. The mass of gas adsorbed when the pressure is 3.0 kPa and the temperature is 300 K is 0.19 mg. The Langmuir isotherm is known to describe the adsorption. Find the fractional coverage of the surface at the two pressures.

25.9b A certain solid sample adsorbs 0.63 mg of CO when the pressure of the gas is 36.0 kPa and the temperature is 300 K. The mass of gas adsorbed when the pressure is 4.0 kPa and the temperature is 300 K is 0.21 mg. The Langmuir isotherm is known to describe the adsorption. Find the fractional coverage of the surface at the two pressures.

25.10a For how long on average would an H atom remain on a surface at 298 K if its desorption activation energy were (a) 15 kJ mol^{-1} , (b) 150 kJ mol^{-1} ? Take $\tau_0 = 0.10 \text{ ps}$. For how long on average would the same atoms remain at 1000 K?

25.10b For how long on average would an atom remain on a surface at 400 K if its desorption activation energy were (a) 20 kJ mol^{-1} , (b) 200 kJ mol^{-1} ? Take $\tau_0 = 0.12 \text{ ps}$. For how long on average would the same atoms remain at 800 K?

25.11a A solid in contact with a gas at 12 kPa and 25°C adsorbs 2.5 mg of the gas and obeys the Langmuir isotherm. The enthalpy change when 1.00 mmol of the adsorbed gas is desorbed is $+10.2 \text{ J}$. What is the equilibrium pressure for the adsorption of 2.5 mg of gas at 40°C?

25.11b A solid in contact with a gas at 8.86 kPa and 25°C adsorbs 4.67 mg of the gas and obeys the Langmuir isotherm. The enthalpy change when 1.00 mmol of the adsorbed gas is desorbed is $+12.2 \text{ J}$. What is the equilibrium pressure for the adsorption of the same mass of gas at 45°C?

25.12a Hydrogen iodide is very strongly adsorbed on gold but only slightly adsorbed on platinum. Assume the adsorption follows the Langmuir isotherm and predict the order of the HI decomposition reaction on each of the two metal surfaces.

25.12b Suppose it is known that ozone adsorbs on a particular surface in accord with a Langmuir isotherm. How could you use the pressure dependence of the fractional coverage to distinguish between adsorption (a) without dissociation, (b) with dissociation into $\text{O} + \text{O}_2$, (c) with dissociation into $\text{O} + \text{O} + \text{O}$?

25.13a Nitrogen gas adsorbed on charcoal to the extent of $0.921 \text{ cm}^3 \text{ g}^{-1}$ at 490 kPa and 190 K, but at 250 K the same amount of adsorption was achieved only when the pressure was increased to 3.2 MPa. What is the enthalpy of adsorption of nitrogen on charcoal?

25.13b Nitrogen gas adsorbed on a surface to the extent of $1.242 \text{ cm}^3 \text{ g}^{-1}$ at 350 kPa and 180 K, but at 240 K the same amount of adsorption was achieved only when the pressure was increased to 1.02 MPa. What is the enthalpy of adsorption of nitrogen on the surface?

25.14a In an experiment on the adsorption of oxygen on tungsten it was found that the same volume of oxygen was desorbed in 27 min at 1856 K and 2.0 min at 1978 K. What is the activation energy of desorption? How long would it take for the same amount to desorb at (a) 298 K, (b) 3000 K?

25.14b In an experiment on the adsorption of ethene on iron it was found that the same volume of the gas was desorbed in 1856 s at 873 K and 8.44 s at 1012 K. What is the activation energy of desorption? How long would it take for the same amount of ethene to desorb at (a) 298 K, (b) 1500 K?

25.15a The Helmholtz model of the electric double layer is equivalent to a parallel plate capacitor. Hence the potential difference across the double layer is given by $\Delta\phi = \sigma d/\epsilon$, where d is the distance between the plates and σ is the surface charge density. Assuming that this model holds for concentrated salt solutions calculate the magnitude of the electric field at the surface of silica in 5.0 M NaCl(aq) if the surface charge density is 0.10 C m^{-2} .

25.15b Refer to the preceding exercise. Calculate the magnitude of the electric field at the surface of silica in 4.5 M NaCl(aq) if the surface charge density is 0.12 C m^{-2} .

25.16a The transfer coefficient of a certain electrode in contact with M^{3+} and M^{4+} in aqueous solution at 25°C is 0.39. The current density is found to be 55.0 mA cm^{-2} when the overvoltage is 125 mV. What is the overvoltage required for a current density of 75 mA cm^{-2} ?

25.16b The transfer coefficient of a certain electrode in contact with M^{2+} and M^{3+} in aqueous solution at 25°C is 0.42. The current density is found to be 17.0 mA cm^{-2} when the overvoltage is 105 mV. What is the overvoltage required for a current density of 72 mA cm^{-2} ?

25.17a Determine the exchange current density from the information given in Exercise 25.16a.

25.17b Determine the exchange current density from the information given in Exercise 25.16b.

25.18a To a first approximation, significant evolution or deposition occurs in electrolysis only if the overpotential exceeds about 0.6 V. To illustrate this criterion determine the effect that increasing the overpotential from 0.40 V to 0.60 V has on the current density in the electrolysis of 1.0 M NaOH(aq) , which is 1.0 mA cm^{-2} at 0.4 V and 25°C . Take $\alpha = 0.5$.

25.18b Determine the effect that increasing the overpotential from 0.50 V to 0.60 V has on the current density in the electrolysis of 1.0 M NaOH(aq) , which is 1.22 mA cm^{-2} at 0.50 V and 25°C . Take $\alpha = 0.50$.

25.19a Use the data in Table 25.6 for the exchange current density and transfer coefficient for the reaction $2 \text{H}^+ + 2 \text{e}^- \rightarrow \text{H}_2$ on nickel at 25°C to determine what current density would be needed to obtain an overpotential of 0.20 V as calculated from (a) the Butler–Volmer equation, and (b) the Tafel equation. Is the validity of the Tafel approximation affected at higher overpotentials (of 0.4 V and more)?

25.19b Use the data in Table 25.6 for the exchange current density and transfer coefficient for the reaction $\text{Fe}^{3+} + \text{e}^- \rightarrow \text{Fe}^{2+}$ on platinum at 25°C to determine what current density would be needed to obtain an overpotential of 0.30 V as calculated from (a) the Butler–Volmer equation, and (b) the Tafel equation. Is the validity of the Tafel approximation affected at higher overpotentials (of 0.4 V and more)?

25.20a Estimate the limiting current density at an electrode in which the concentration of Ag^+ ions is 2.5 mmol dm^{-3} at 25°C . The thickness of the Nernst diffusion layer is 0.40 mm. The ionic conductivity of Ag^+ at infinite dilution and 25°C is $6.19 \text{ mS m}^2 \text{ mol}^{-1}$.

25.20b Estimate the limiting current density at an electrode in which the concentration of Mg^{2+} ions is 1.5 mmol dm^{-3} at 25°C . The thickness of the Nernst diffusion layer is 0.32 mm. The ionic conductivity of Mg^{2+} at infinite dilution and 25°C is $10.60 \text{ mS m}^2 \text{ mol}^{-1}$.

25.21a A $0.10 \text{ M CdSO}_4(\text{aq})$ solution is electrolysed between a cadmium cathode and a platinum anode with a current density of 1.00 mA cm^{-2} . The hydrogen overpotential is 0.60 V. What will be the concentration of Cd^{2+} ions when evolution of H_2 just begins at the cathode? Assume all activity coefficients are unity.

25.21b A $0.10 \text{ M FeSO}_4(\text{aq})$ solution is electrolysed between a magnesium cathode and a platinum anode with a current density of 1.50 mA cm^{-2} . The hydrogen overpotential is 0.60 V. What will be the concentration of Fe^{2+} ions when evolution of H_2 just begins at the cathode? Assume all activity coefficients are unity.

25.22a A typical exchange current density, that for H^+ discharge at platinum, is 0.79 mA cm^{-2} at 25°C . What is the current density at an electrode when its overpotential is (a) 10 mV, (b) 100 mV, (c) -5.0 V ? Take $\alpha = 0.5$.

25.22b The exchange current density for a $\text{Pt}|\text{Fe}^{3+}, \text{Fe}^{2+}$ electrode is 2.5 mA cm^{-2} . The standard potential of the electrode is $+0.77 \text{ V}$. Calculate the current flowing through an electrode of surface area 1.0 cm^2 as a function of the potential of the electrode. Take unit activity for both ions.

25.23a Suppose that the electrode potential is set at 1.00 V. The exchange current density is $6.0 \times 10^{-4} \text{ A cm}^{-2}$ and $\alpha = 0.50$. Calculate the current density for the ratio of activities $a(\text{Fe}^{3+})/a(\text{Fe}^{2+})$ in the range 0.1 to 10.0 and at 25°C .

25.23b Suppose that the electrode potential is set at 0.50 V. Calculate the current density for the ratio of activities $a(\text{Cr}^{3+})/a(\text{Cr}^{2+})$ in the range 0.1 to 10.0 and at 25°C .

25.24a What overpotential is needed to sustain a current of 20 mA at a $\text{Pt}|\text{Fe}^{3+}, \text{Fe}^{2+}$ electrode in which both ions are at a mean activity $a = 0.10$? The surface area of the electrode is 1.0 cm^2 .

25.24b What overpotential is needed to sustain a current of 15 mA at a $\text{Pt}|\text{Ce}^{4+}, \text{Ce}^{3+}$ electrode in which both ions are at a mean activity $a = 0.010$?

25.25a How many electrons or protons are transported through the double layer in each second when the $\text{Pt}, \text{H}_2|\text{H}^+$, $\text{Pt}|\text{Fe}^{3+}, \text{Fe}^{2+}$, and $\text{Pb}, \text{H}_2|\text{H}^+$ electrodes are at equilibrium at 25°C ? Take the area as 1.0 cm^2 in each case. Estimate the number of times each second a single atom on the surface takes part in a electron transfer event, assuming an electrode atom occupies about $(280 \text{ pm})^2$ of the surface.

25.25b How many electrons or protons are transported through the double layer in each second when the $\text{Cu}, \text{H}_2|\text{H}^+$ and $\text{Pt}|\text{Ce}^{4+}, \text{Ce}^{3+}$ electrodes are at equilibrium at 25°C ? Take the area as 1.0 cm^2 in each case. Estimate the number of times each second a single atom on the surface takes part in a electron transfer event, assuming an electrode atom occupies about $(260 \text{ pm})^2$ of the surface.

25.26a What is the effective resistance at 25°C of an electrode interface when the overpotential is small? Evaluate it for 1.0 cm^2 (a) $\text{Pt}, \text{H}_2|\text{H}^+$, (b) $\text{Hg}, \text{H}_2|\text{H}^+$ electrodes.

25.26b Evaluate the effective resistance at 25°C of an electrode interface for 1.0 cm² (a) Pb, H₂|H⁺, (b) Pt|Fe²⁺, Fe³⁺ electrodes.

25.27a State what happens when a platinum electrode in an aqueous solution containing both Cu²⁺ and Zn²⁺ ions at unit activity is made the cathode of an electrolysis cell.

25.27b State what happens when a platinum electrode in an aqueous solution containing both Fe²⁺ and Ni²⁺ ions at unit activity is made the cathode of an electrolysis cell.

25.28a What are the conditions that allow a metal to be deposited from aqueous acidic solution before hydrogen evolution occurs significantly at 293 K? Why may silver be deposited from aqueous silver nitrate?

25.28b The overpotential for hydrogen evolution on cadmium is about 1 V at current densities of 1 mA cm⁻². Why may cadmium be deposited from aqueous cadmium sulfate?

25.29a The exchange current density for H⁺ discharge at zinc is about 50 pA cm⁻². Can zinc be deposited from a unit activity aqueous solution of a zinc salt?

25.29b The standard potential of the Zn²⁺|Zn electrode is -0.76 V at 25°C. The exchange current density for H⁺ discharge at platinum is 0.79 mA cm⁻². Can zinc be plated on to platinum at that temperature? (Take unit activities.)

25.30a Can magnesium be deposited on a zinc electrode from a unit activity acid solution at 25°C?

25.30b Can iron be deposited on a copper electrode from a unit activity acid solution at 25°C?

25.31a Calculate the maximum (zero-current) potential difference of a nickel-cadmium cell, and the maximum possible power output when 100 mA is drawn at 25°C.

25.31b Calculate the maximum (zero-current) potential difference of a lead-acid cell, and the maximum possible power output when 100 mA is drawn at 25°C.

25.32a The corrosion current density j_{corr} at an iron anode is 1.0 A m⁻². What is the corrosion rate in millimetres per year? Assume uniform corrosion.

25.32b The corrosion current density j_{corr} at a zinc anode is 2.0 A m⁻². What is the corrosion rate in millimetres per year? Assume uniform corrosion.

Problems*

Numerical problems

25.1 The movement of atoms and ions on a surface depends on their ability to leave one position and stick to another, and therefore on the energy changes that occur. As an illustration, consider a two-dimensional square lattice of univalent positive and negative ions separated by 200 pm, and consider a cation on the upper terrace of this array. Calculate, by direct summation, its Coulombic interaction when it is in an empty lattice point directly above an anion. Now consider a high step in the same lattice, and let the cation move into the corner formed by the step and the terrace. Calculate the Coulombic energy for this position, and decide on the likely settling point for the cation.

25.2 In a study of the catalytic properties of a titanium surface it was necessary to maintain the surface free from contamination. Calculate the collision frequency per square centimetre of surface made by O₂ molecules at (a) 100 kPa, (b) 1.00 Pa and 300 K. Estimate the number of collisions made with a single surface atom in each second. The conclusions underline the importance of working at very low pressures (much lower than 1 Pa, in fact) in order to study the properties of uncontaminated surfaces. Take the nearest-neighbour distance as 291 pm.

25.3 Nickel is face-centred cubic with a unit cell of side 352 pm. What is the number of atoms per square centimetre exposed on a surface formed by (a) (100), (b) (110), (c) (111) planes? Calculate the frequency of molecular collisions per surface atom in a vessel containing (a) hydrogen, (b) propane at 25°C when the pressure is (i) 100 Pa, (ii) 0.10 μTorr.

25.4 The data below are for the chemisorption of hydrogen on copper powder at 25°C. Confirm that they fit the Langmuir isotherm at low coverages. Then find the value of K for the adsorption equilibrium and the adsorption volume corresponding to complete coverage.

p/Pa	25	129	253	540	1000	1593
V/cm^3	0.042	0.163	0.221	0.321	0.411	0.471

25.5 The data for the adsorption of ammonia on barium fluoride are reported below. Confirm that they fit a BET isotherm and find values of c and V_{mon} .

(a) $\theta = 0^\circ\text{C}$, $p^* = 429.6$ kPa:

p/kPa	14.0	37.6	65.6	79.2	82.7	100.7	106.4
V/cm^3	11.1	13.5	14.9	16.0	15.5	17.3	16.5

(b) $\theta = 18.6^\circ\text{C}$, $p^* = 819.7$ kPa:

p/kPa	5.3	8.4	14.4	29.2	62.1	74.0	80.1	102.0
V/cm^3	9.2	9.8	10.3	11.3	12.9	13.1	13.4	14.1

25.6 The following data have been obtained for the adsorption of H₂ on the surface of 1.00 g of copper at 0°C. The volume of H₂ below is the volume that the gas would occupy at STP (0°C and 1 atm).

p/atm	0.050	0.100	0.150	0.200	0.250
V/cm^3	1.22	1.33	1.31	1.36	1.40

Determine the volume of H₂ necessary to form a monolayer and estimate the surface area of the copper sample. The density of liquid hydrogen is 0.708 g cm⁻³.

25.7 The adsorption of solutes on solids from liquids often follows a Freundlich isotherm. Check the applicability of this isotherm to the following data for the adsorption of acetic acid on charcoal at 25°C and find the values of the parameters c_1 and c_2 .

[acid]/(mol dm ⁻³)	0.05	0.10	0.50	1.0	1.5
w ₂ /g	0.04	0.06	0.12	0.16	0.19

w_a is the mass adsorbed per unit mass of charcoal.

25.8 In some catalytic reactions the products may adsorb more strongly than the reacting gas. This is the case, for instance, in the catalytic decomposition of ammonia on platinum at 1000°C. As a first step in examining the kinetics of

* Problems denoted with the symbol ‡ were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

this type of process, show that the rate of ammonia decomposition should follow

$$\frac{dp_{\text{NH}_3}}{dt} = -k_c \frac{p_{\text{NH}_3}}{p_{\text{H}_2}}$$

in the limit of very strong adsorption of hydrogen. Start by showing that, when a gas J adsorbs very strongly, and its pressure is p_j , the fraction of uncovered sites is approximately $1/Kp_j$. Solve the rate equation for the catalytic decomposition of NH_3 on platinum and show that a plot of $F(t) = (1/t) \ln(p/p_0)$ against $G(t) = (p - p_0)/t$, where p is the pressure of ammonia, should give a straight line from which k_c can be determined. Check the rate law on the basis of the data below, and find k_c for the reaction.

t/s	0	30	60	100	160	200	250
p/kPa	13.3	11.7	11.2	10.7	10.3	9.9	9.6

25.9† A. Akgerman and M. Zardkoohi (*J. Chem. Eng. Data* **41**, 185 (1996)) examined the adsorption of phenol from aqueous solution on to fly ash at 20°C. They fitted their observations to a Freundlich isotherm of the form $c_{\text{ads}} = Kc_{\text{sol}}^{1/n}$, where c_{ads} is the concentration of adsorbed phenol and c_{sol} is the concentration of aqueous phenol. Among the data reported are the following:

$c_{\text{sol}}/(\text{mg g}^{-1})$	8.26	15.65	25.43	31.74	40.00
$c_{\text{ads}}/(\text{mg g}^{-1})$	4.4	19.2	35.2	52.0	67.2

Determine the constants K and n . What further information would be necessary in order to express the data in terms of fractional coverage, θ ?

25.10† C. Huang and W.P. Cheng (*J. Colloid Interface Sci.* **188**, 270 (1997)) examined the adsorption of the hexacyanoferrate(III) ion, $[\text{Fe}(\text{CN})_6]^{3-}$, on $\gamma\text{-Al}_2\text{O}_3$ from aqueous solution. They modelled the adsorption with a modified Langmuir isotherm, obtaining the following values of K at pH = 6.5:

T/K	283	298	308	318
$10^{-11}K$	2.642	2.078	1.286	1.085

Determine the isosteric enthalpy of adsorption, $\Delta_{\text{ads}}H^\circ$, at this pH. The researchers also reported $\Delta_{\text{ads}}S^\circ = +146 \text{ J mol}^{-1} \text{ K}^{-1}$ under these conditions. Determine $\Delta_{\text{ads}}G^\circ$.

25.11† M.-G. Olivier and R. Jadot (*J. Chem. Eng. Data* **42**, 230 (1997)) studied the adsorption of butane on silica gel. They report the following amounts of absorption (in moles per kilogram of silica gel) at 303 K:

p/kPa	31.00	38.22	53.03	76.38	101.97
$n/(\text{mol kg}^{-1})$	1.00	1.17	1.54	2.04	2.49
p/kPa	130.47	165.06	182.41	205.75	219.91
$n/(\text{mol kg}^{-1})$	2.90	3.22	3.30	3.35	3.36

Fit these data to a Langmuir isotherm, and determine the value of n that corresponds to complete coverage and the constant K .

25.12† The following data were obtained for the extent of adsorption, s , of acetone on charcoal from an aqueous solution of molar concentration, c , at 18°C.

$c/(\text{mmol dm}^{-3})$	15.0	23.0	42.0	84.0	165	390	800
$s/(\text{mmol acetone/g charcoal})$	0.60	0.75	1.05	1.50	2.15	3.50	5.10

Which isotherm fits this data best, Langmuir, Freundlich, or Temkin?

25.13 In an experiment on the $\text{Pt}|\text{H}_2|\text{H}^+$ electrode in dilute H_2SO_4 the following current densities were observed at 25°C. Evaluate α and j_0 for the electrode.

η/mV	50	100	150	200	250
$j/(\text{mA cm}^{-2})$	2.66	8.91	29.9	100	335

How would the current density at this electrode depend on the overpotential of the same set of magnitudes but of opposite sign?

25.14 The standard potentials of lead and tin are -126 mV and -136 mV respectively at 25°C, and the overvoltage for their deposition are close to zero. What should their relative activities be in order to ensure simultaneous deposition from a mixture?

25.15 The limiting current density for the reaction $\text{I}_3^- + 2\text{e}^- \rightarrow 3\text{I}^-$ at a platinum electrode is $28.9 \mu\text{A cm}^{-2}$ when the concentration of KI is $6.6 \times 10^{-4} \text{ mol dm}^{-3}$ and the temperature 25°C. The diffusion coefficient of I_3^- is $1.14 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$. What is the thickness of the diffusion layer?

25.16 Estimating the power output and potential of a cell under operating conditions is very difficult, but eqn 25.65 summarizes, in an approximate way, some of the parameters involved. As a first step in manipulating this expression, identify all the quantities that depend on the ionic concentrations. Express E in terms of the concentration and conductivities of the ions present in the cell. Estimate the parameters for $\text{Zn(s)}|\text{ZnSO}_4(\text{aq})||\text{CuSO}_4(\text{aq})|\text{Cu(s)}$. Take electrodes of area 5 cm^2 separated by 5 cm. Ignore both potential differences and resistance of the liquid junction. Take the concentration as 1 mol dm^{-3} , the temperature 25°C, and neglect activity coefficients. Plot E as a function of the current drawn. On the same graph, plot the power output of the cell. What current corresponds to maximum power?

25.17 Consider a cell in which the current is activation-controlled. Show that the current for maximum power can be estimated by plotting $\log(I/I_0)$ and $c_1 - c_2I$ against I (where $I_0 = A^2j_0'/j_0$ and c_1 and c_2 are constants), and looking for the point of intersection of the curves. Carry through this analysis for the cell in Problem 25.16 ignoring all concentration overpotentials.

25.18† The rate of deposition of iron, v , on the surface of an iron electrode from an aqueous solution of Fe^{2+} has been studied as a function of potential, E , relative to the standard hydrogen electrode, by J. Kanya (*J. Electroanal. Chem.* **84**, 83 (1977)). The values in the table below are based on the data obtained with an electrode of surface area 9.1 cm^2 in contact with a solution of concentration $1.70 \mu\text{mol dm}^{-3}$ in Fe^{2+} . (a) Assuming unit activity coefficients, calculate the zero current potential of the Fe^{2+}/Fe cathode and the overpotential at each value of the working potential. (b) Calculate the cathodic current density, j_c , from the rate of deposition of Fe^{2+} for each value of E . (c) Examine the extent to which the data fit the Tafel equation and calculate the exchange current density.

$v/(\text{pmol s}^{-1})$	1.47	2.18	3.11	7.26
$-E/\text{mV}$	702	727	752	812

25.19† The thickness of the diffuse double layer according to the Gouy–Chapman model is given by eqn 19.46. Use this equation to calculate and plot the thickness as a function of concentration and electrolyte type at 25°C. For examples, choose aqueous solutions of NaCl and Na_2SO_4 ranging in concentration from 0.1 to 100 mmol dm^{-3} .

25.20† V.V. Losev and A.P. Pchel'nikov (*Soviet Electrochem.* **6**, 34 (1970)) obtained the following current–voltage data for an indium anode relative to a standard hydrogen electrode at 293 K:

$-E/\text{V}$	0.388	0.365	0.350	0.335
$j/(\text{A m}^{-2})$	0	0.590	1.438	3.507

Use these data to calculate the transfer coefficient and the exchange current density. What is the cathodic current density when the potential is 0.365 V?

25.21† The redox reactions of quinones have been the subject of many studies over the years and they continue to be of interest to electrochemists. In a study of methone (1,1-dimethyl-3,5-cyclohexanedione) by E. Kariv, J. Hermolin, and E. Gileadi (*Electrochim. Acta* **16**, 1437 (1971)), the following current–voltage data were obtained for the reduction of the quinone in anhydrous butanol on a mercury electrode:

$-E/\text{V}$	1.50	1.58	1.63	1.72	1.87	1.98	≥ 2.10
$j/(\text{A m}^{-2})$	10	30	50	100	200	250	290

(a) How well do these data fit the empirical Tafel equation? (b) The authors postulate that the reduction product is the dimer HMMH formed by the following mechanism (where the quinone is denoted M):

- (1) $M(\text{sol}) \rightleftharpoons M(\text{ads})$
- (2) $M(\text{ads}) + H^+ + e^- \rightarrow MH(\text{ads})$
- (3) $MH(\text{ads}) + MH(\text{ads}) \rightleftharpoons HMMH$

The affixes sol and ads refer to species in solution and on the surface of the electrode, respectively. Does this mechanism help to explain the current–voltage data?

25.22† An early study of the hydrogen overpotential is that of H. Bowden and T. Rideal (*Proc. Roy. Soc. A* **120**, 59 (1928)), who measured the overpotential for H_2 evolution with a mercury electrode in dilute aqueous solutions of H_2SO_4 at 25°C. Determine the exchange current density and transfer coefficient, α , from their data:

$j/(\text{mA m}^{-2})$	2.9	6.3	28	100	250	630	1650	3300
η/V	0.60	0.65	0.73	0.79	0.84	0.89	0.93	0.96

Explain any deviations from the result expected from the Tafel equation.

Theoretical problems

25.23 Although the attractive van der Waals interaction between individual molecules varies as R^{-6} , the interaction of a molecule with a nearby solid (a homogeneous collection of molecules) varies as R^{-3} , where R is its vertical distance above the surface. Confirm this assertion. Calculate the interaction energy between an Ar atom and the surface of solid argon on the basis of a Lennard-Jones (6,12)-potential. Estimate the equilibrium distance of an atom above the surface.

25.24 Use the Gibbs adsorption isotherm (another name for eqn 19.50), to show that the volume adsorbed per unit area of solid, V_a/σ , is related to the pressure of the gas by $V_a = -(\sigma/RT)(d\mu/d \ln p)$, where μ is the chemical potential of the adsorbed gas.

25.25 If the dependence of the chemical potential of the gas on the extent of surface coverage is known, the Gibbs adsorption isotherm, eqn 19.50, can be integrated to give a relation between V_a and p , as in a normal adsorption isotherm. For instance, suppose that the change in the chemical potential of a gas when it adsorbs is of the form $d\mu = -c_2(RT/\sigma)dV_a$, where c_2 is a constant of proportionality: show that the Gibbs isotherm leads to the Freundlich isotherm in this case.

25.26 Finally we come full circle and return to the Langmuir isotherm. Find the form of $d\mu$ that, when inserted in the Gibbs adsorption isotherm, leads to the Langmuir isotherm.

25.27 Show that, for the association part of the surface plasmon resonance experiment in Fig. 25.27, $R(t) = R_{eq}(1 - e^{-k_{obs}t})$ and write an expression for k_{obs} . Then, derive an expression for $R(t)$ that applies to the dissociation part of the surface plasmon resonance experiment in Fig. 25.27.

25.28 If $\alpha = \frac{1}{2}$, an electrode interface is unable to rectify alternating current because the current density curve is symmetrical about $\eta = 0$. When $\alpha \neq \frac{1}{2}$, the magnitude of the current density depends on the sign of the overpotential, and so some degree of ‘faradaic rectification’ may be obtained. Suppose that the overpotential varies as $\eta = \eta_0 \cos \omega t$. Derive an expression for the mean flow of current (averaged over a cycle) for general α , and confirm that the mean current is zero when $\alpha = \frac{1}{2}$. In each case work in the limit of small η_0 but to second order in $\eta_0 F/RT$. Calculate the mean direct current at 25°C for a 1.0 cm^2 hydrogen–platinum electrode with $\alpha = 0.38$ when the overpotential varies between $\pm 10 \text{ mV}$ at 50 Hz.

25.29 Now suppose that the overpotential is in the high overpotential region at all times even though it is oscillating. What waveform will the current across

the interface show if it varies linearly and periodically (as a sawtooth waveform) between η_- and η_+ around η_0 ? Take $\alpha = \frac{1}{2}$.

25.30 Derive an expression for the current density at an electrode where the rate process is diffusion-controlled and η_c is known. Sketch the form of j/j_L as a function of η_c . What changes occur if anion currents are involved?

Applications: to chemical engineering and environmental science

25.31 The designers of a new industrial plant wanted to use a catalyst code-named CR-1 in a step involving the fluorination of butadiene. As a first step in the investigation they determined the form of the adsorption isotherm. The volume of butadiene adsorbed per gram of CR-1 at 15°C varied with pressure as given below. Is the Langmuir isotherm suitable at this pressure?

p/kPa	13.3	26.7	40.0	53.3	66.7	80.0
V/cm^3	17.9	33.0	47.0	60.8	75.3	91.3

Investigate whether the BET isotherm gives a better description of the adsorption of butadiene on CR-1. At 15°C, p^* (butadiene) = 200 kPa. Find V_{mon} and c .

25.32† In a study relevant to automobile catalytic converters, C.E. Wartnaby, A. Stuck, Y.Y. Yeo, and D.A. King (*J. Phys. Chem.* **100**, 12483 (1996)) measured the enthalpy of adsorption of CO, NO, and O_2 on initially clean platinum 110 surfaces. They report $\Delta_{\text{ads}}H^\circ$ for NO to be -160 kJ mol^{-1} . How much more strongly adsorbed is NO at 500°C than at 400°C?

25.33† The removal or recovery of volatile organic compounds (VOCs) from exhaust gas streams is an important process in environmental engineering. Activated carbon has long been used as an adsorbent in this process, but the presence of moisture in the stream reduces its effectiveness. M.-S. Chou and J.-H. Chiou (*J. Envir. Engrg.* ASCE, **123**, 437 (1997)) have studied the effect of moisture content on the adsorption capacities of granular activated carbon (GAC) for normal hexane and cyclohexane in air streams. From their data for dry streams containing cyclohexane, shown in the table below, they conclude that GAC obeys a Langmuir type model in which $q_{\text{VOC,RH}=0} = abc_{\text{VOC}}/(1 + bc_{\text{VOC}})$, where $q = m_{\text{VOC}}/m_{\text{GAC}}$, RH denotes relative humidity, a the maximum adsorption capacity, b is an affinity parameter, and c is the abundance in parts per million (ppm). The following table gives values of $q_{\text{VOC,RH}=0}$ for cyclohexane:

c/ppm	33.6°C	41.5°C	57.4°C	76.4°C	99°C
200	0.080	0.069	0.052	0.042	0.027
500	0.093	0.083	0.072	0.056	0.042
1000	0.101	0.088	0.076	0.063	0.045
2000	0.105	0.092	0.083	0.068	0.052
3000	0.112	0.102	0.087	0.072	0.058

(a) By linear regression of $1/q_{\text{VOC,RH}=0}$ against $1/c_{\text{VOC}}$, test the goodness of fit and determine values of a and b . (b) The parameters a and b can be related to $\Delta_{\text{ads}}H$, the enthalpy of adsorption, and $\Delta_b H$, the difference in activation energy for adsorption and desorption of the VOC molecules, through Arrhenius type equations of the form $a = k_a \exp(-\Delta_{\text{ads}}H/RT)$ and $b = k_b \exp(-\Delta_b H/RT)$. Test the goodness of fit of the data to these equations and obtain values for k_a , k_b , $\Delta_{\text{ads}}H$, and $\Delta_b H$. (c) What interpretation might you give to k_a and k_b ?

25.34† M.-S. Chou and J.-H. Chiou (*J. Envir. Engrg.*, ASCE, **123**, 437 (1997)) have studied the effect of moisture content on the adsorption capacities of granular activated carbon (GAC, Norit PK 1–3) for the volatile organic compounds (VOCs) normal hexane and cyclohexane in air streams. The following table shows the adsorption capacities ($q_{\text{water}} = m_{\text{water}}/m_{\text{GAC}}$) of GAC for pure water from moist air streams as a function of relative humidity (RH) in the absence of VOCs at 41.5°C.

RH	0.00	0.26	0.49	0.57	0.80	1.00
q_{water}	0.00	0.026	0.072	0.091	0.161	0.229

The authors conclude that the data at this and other temperatures obey a Freundlich type isotherm, $q_{\text{water}} = k(\text{RH})^{1/n}$. (a) Test this hypothesis for their data at 41.5°C and determine the constants k and n . (b) Why might VOCs obey the Langmuir model, but water the Freundlich model? (c) When both water vapour and cyclohexane were present in the stream the values given in the table below were determined for the ratio $r_{\text{VOC}} = q_{\text{VOC}}/q_{\text{VOC, RH=0}}$ at 41.5°C.

RH	0.00	0.10	0.25	0.40	0.53	0.76	0.81
r_{VOC}	1.00	0.98	0.91	0.84	0.79	0.67	0.61

The authors propose that these data fit the equation $r_{\text{VOC}} = 1 - q_{\text{water}}$. Test their proposal and determine values for k and n and compare to those obtained in part (b) for pure water. Suggest reasons for any differences.

25.35‡ The release of petroleum products by leaky underground storage tanks is a serious threat to clean ground water. BTEX compounds (benzene, toluene, ethylbenzene, and xylenes) are of primary concern due to their ability to cause health problems at low concentrations. D.S. Kershaw, B.C. Kulik, and S. Pamukcu (*J. Geotech. & Geoenviron. Engrg.* **123**, 324(1997)) have studied the ability of ground tyre rubber to sorb (adsorb and absorb) benzene and *o*-xylene. Though sorption involves more than surface interactions, sorption data are usually found to fit one of the adsorption isotherms. In this study, the authors have tested how well their data fit the linear ($q = Kc_{\text{eq}}$), Freundlich ($q = K_{\text{F}}c_{\text{eq}}^{1/n}$), and Langmuir ($q = K_{\text{L}}Mc_{\text{eq}}/(1 + K_{\text{L}}c_{\text{eq}})$) type isotherms, where q is the mass of solvent sorbed per gram of ground rubber (in milligrams per gram), the K s and M are empirical constants, and c_{eq} the equilibrium concentration of contaminant in solution (in milligrams per litre). (a) Determine the units of the empirical constants. (b) Determine which of the isotherms best fits the data in the table below for the sorption of benzene on ground rubber.

$c_{\text{eq}}/(\text{mg dm}^{-3})$	97.10	36.10	10.40	6.51	6.21	2.48
$q/(\text{mg g}^{-1})$	7.13	4.60	1.80	1.10	0.55	0.31

(c) Compare the sorption efficiency of ground rubber to that of granulated activated charcoal, which for benzene has been shown to obey the Freundlich isotherm in the form $q = 1.0c_{\text{eq}}^{1.6}$ with coefficient of determination $R^2 = 0.94$.

25.36 Calculate the thermodynamic limit to the zero-current potential of fuel cells operating on (a) hydrogen and oxygen, (b) methane and air, and (c) propane and air. Use the Gibbs energy information in the *Data section*, and take the species to be in their standard states at 25°C.

25.37 For each group below, determine which metal has a thermodynamic tendency to corrode in moist air at pH = 7. Take as a criterion of corrosion a metal ion concentration of at least $10^{-6} \text{ mol dm}^{-3}$.

- (a) Fe, Cu, Pb, Al, Ag, Cr, Co
- (b) Ni, Cd, Mg, Ti, Mn

25.38 Estimate the magnitude of the corrosion current for a patch of zinc of area 0.25 cm^2 in contact with a similar area of iron in an aqueous environment at 25°C. Take the exchange current densities as $1 \text{ }\mu\text{A cm}^{-2}$ and the local ion concentrations as $1 \text{ }\mu\text{mol dm}^{-3}$.

25.39 The corrosion potential of iron immersed in a de-aerated acidic solution of pH = 3 is -0.720 V as measured at 25°C relative to the standard calomel electrode with potential 0.2802 V . A Tafel plot of cathodic current density against overpotential yields a slope of 18 V^{-1} and the hydrogen ion exchange current density $j_0 = 0.10 \text{ }\mu\text{A cm}^{-2}$. Calculate the corrosion rate in milligrams of iron per square centimetre per day ($\text{mg cm}^{-2} \text{ d}^{-1}$).

Appendix 1

Quantities, units, and notational conventions

A1

The result of a measurement is a **physical quantity** (such as mass or density) that is reported as a numerical multiple of an agreed **unit**:

$$\text{physical quantity} = \text{numerical value} \times \text{unit}$$

For example, the mass of an object may be reported as $m = 2.5 \text{ kg}$ and its density as $d = 1.010 \text{ kg dm}^{-3}$ where the units are, respectively, 1 kilogram (1 kg) and 1 kilogram per decimetre cubed (1 kg dm^{-3}). Units are treated like algebraic quantities, and may be multiplied, divided, and cancelled. Thus, the expression (physical quantity)/unit is simply the numerical value of the measurement in the specified units, and hence is a dimensionless quantity. For instance, the mass reported above could be denoted $m/\text{kg} = 2.5$ and the density as $d/(\text{kg dm}^{-3}) = 1.01$.

Physical quantities are denoted by italic or (sloping) Greek letters (as in m for mass and Π for osmotic pressure). Units are denoted by Roman letters (as in m for metre).

Names of quantities

A **substance** is a distinct, pure form of matter. The **amount of substance**, n (more colloquially ‘number of moles’ or ‘chemical amount’), in a sample is reported in terms of the **mole** (mol): 1 mol is the amount of substance that contains as many objects (atoms, molecules, ions, or other specified entities) as there are atoms in exactly 12 g of carbon-12. This number is found experimentally to be approximately 6.02×10^{23} (see the endpapers for more precise values). If a sample contains N entities, the amount of substance it contains is $n = N/N_A$, where N_A is the Avogadro constant: $N_A = 6.02 \times 10^{23} \text{ mol}^{-1}$. Note that N_A is a quantity with units, not a pure number.

An **extensive property** is a property that depends on the amount of substance in the sample. Two examples are mass and volume. An **intensive property** is a property that is independent of the amount of substance in the sample. Examples are temperature, mass density (mass divided by volume), and pressure.

A **molar property**, X_m , is the value of an extensive property, X , of the sample divided by the amount of substance present in the sample: $X_m = X/n$. A molar property is intensive. An example is the **molar volume**, V_m , the volume of a sample divided by the amount of substance in the sample (the volume per mole). The one exception to the notation X_m is the **molar mass**, which is denoted M . The molar mass of an element is the mass per mole of its atoms. The molar mass of a molecular compound is the

Names of quantities

Units

Notational conventions

Further reading

mass per mole of molecules, and the molar mass of an ionic compound is the mass per mole of formula units. A **formula unit** of an ionic compound is an assembly of ions corresponding to the chemical formula of the compound; so the formula unit NaCl consists of one Na^+ ion and one Cl^- ion. The names *atomic weight* and *molecular weight* are still widely used in place of molar mass (often with the units omitted), but we shall not use them in this text.

The **molar concentration** ('molarity') of a solute in a solution is the amount of substance of the solute divided by the volume of the solution. Molar concentration is usually expressed in moles per decimetre cubed (mol dm^{-3} or mol L^{-1} ; 1 dm^3 is identical to 1 L). A solution in which the molar concentration of the solute is 1 mol dm^{-3} is prepared by dissolving 1 mol of the solute in sufficient solvent to prepare 1 dm^3 of solution. Such a solution is widely called a '1 molar' solution and denoted 1 M . The term **molality** refers to the amount of substance of solute divided by the mass of solvent used to prepare the solution. Its units are typically moles of solute per kilogram of solvent (mol kg^{-1}).

Units

In the **International System** of units (SI, from the French *Système International d'Unités*), the units are formed from seven **base units** listed in Table A1.1. All other physical quantities may be expressed as combinations of these physical quantities and reported in terms of **derived units**. Thus, volume is $(\text{length})^3$ and may be reported as a multiple of 1 metre cubed (1 m^3), and density, which is mass/volume, may be reported as a multiple of $1 \text{ kilogram per metre cubed}$ (1 kg m^{-3}).

A number of derived units have special names and symbols. The names of units derived from names of people are lower case (as in torr, joule, pascal, and kelvin), but their symbols are upper case (as in Torr, J, Pa, and K). Among the most important for our purposes are those listed in Table A1.2. In all cases (both for base and derived quantities), the units may be modified by a prefix that denotes a factor of a power of 10. In a perfect world, Greek prefixes of units are upright (as in μm) and sloping for physical properties (as in μ for chemical potential), but available typefaces are not always so obliging. Among the most common prefixes are those listed in Table A1.3. Examples of the use of these prefixes are

$$1 \text{ nm} = 10^{-9} \text{ m} \quad 1 \text{ ps} = 10^{-12} \text{ s} \quad 1 \mu\text{mol} = 10^{-6} \text{ mol}$$

Table A1.1 The SI base units

Physical quantity	Symbol for quantity	Base unit
Length	l	metre, m
Mass	M	kilogram, kg
Time	t	second, s
Electric current	I	ampere, A
Thermodynamic temperature	T	kelvin, K
Amount of substance	n	mole, mol
Luminous intensity	I	candela, cd

Table A1.2 A selection of derived units

Physical quantity	Derived unit*	Name of derived unit
Force	1 kg m s ⁻²	newton, N
Pressure	1 kg m ⁻¹ s ⁻²	pascal, Pa
Energy	1 N m ⁻²	joule, J
	1 kg m ² s ⁻²	
	1 N m	
	1 Pa m ³	
Power	kg m ² s ⁻³	watt, W
	1 J s ⁻¹	

* Equivalent definitions in terms of derived units are given following the definition in terms of base units.

Table A1.3 Common SI prefixes

Prefix	z	a	f	p	n	–	m	c	d
Name	zepto	atto	femto	pico	nano	micro	milli	centi	deci
Factor	10 ⁻²¹	10 ⁻¹⁸	10 ⁻¹⁵	10 ⁻¹²	10 ⁻⁹	10 ⁻⁶	10 ⁻³	10 ⁻²	10 ⁻¹
Prefix	k	M	G	T					
Name	kilo	mega	giga	tera					
Factor	10 ³	10 ⁶	10 ⁹	10 ¹²					

The kilogram (kg) is anomalous: although it is a base unit, it is interpreted as 10³ g, and prefixes are attached to the gram (as in 1 mg = 10⁻³ g). Powers of units apply to the prefix as well as the unit they modify:

$$1 \text{ cm}^3 = 1 (\text{cm})^3 = 1 (10^{-2} \text{ m})^3 = 10^{-6} \text{ m}^3$$

Note that 1 cm³ does not mean 1 c(m³). When carrying out numerical calculations, it is usually safest to write out the numerical value of an observable as powers of 10.

There are a number of units that are in wide use but are not a part of the International System. Some are exactly equal to multiples of SI units. These include the *litre* (L), which is exactly 10³ cm³ (or 1 dm³) and the *atmosphere* (atm), which is exactly 101.325 kPa. Others rely on the values of fundamental constants, and hence are liable to change when the values of the fundamental constants are modified by more accurate or more precise measurements. Thus, the size of the energy unit *electronvolt* (eV), the energy acquired by an electron that is accelerated through a potential difference of exactly 1 V, depends on the value of the charge of the electron, and the present (2005) conversion factor is 1 eV = 1.602 177 33 × 10⁻¹⁹ J. Table A1.4 gives the conversion factors for a number of these convenient units.

Notational conventions

We use SI units and IUPAC conventions throughout (see *Further reading*), except in a small number of cases. The default numbering of equations is (C.n), where C is the chapter; however, [C.n] is used to denote a definition and {C.n} is used to indicate that a variable x should be interpreted as x/x[⊖], where x[⊖] is a standard value. A subscript r

Table A1.4 Some common units

Physical quantity	Name of unit	Symbol for unit	Value*
Time	minute	min	60 s
	hour	h	3600 s
	day	d	86 400 s
Length	ångström	Å	10^{-10} m
Volume	litre	L, l	1 dm ³
Mass	tonne	t	10 ³ kg
Pressure	bar	bar	10 ⁵ Pa
	atmosphere	atm	101.325 kPa
Energy	electronvolt	eV	$1.602\,177\,33 \times 10^{-19}$ J
			96.485 31 kJ mol ⁻¹

* All values in the final column are exact, except for the definition of 1 eV, which depends on the measured value of e .

attached to an equation number indicates that the equation is valid only for a reversible change. A superscript ° indicates that the equation is valid for an ideal system, such as a perfect gas or an ideal solution.

We use

$$p^{\ominus} = 1 \text{ bar} \quad b^{\ominus} = 1 \text{ mol kg}^{-1} \quad 1 c^{\ominus} = 1 \text{ mol dm}^{-3}$$

When referring to temperature, T denotes a thermodynamic temperature (for instance, on the Kelvin scale) and θ a temperature on the Celsius scale.

For numerical calculations, we take special care to use the proper number of significant figures. Unless otherwise specified, assume that zeros in data like 10, 100, 1000, etc are significant (that is, interpret such data as 10., 100., 100., etc).

Appendix 2

Mathematical techniques

A2

Basic procedures

A2.1 Logarithms and exponentials

The **natural logarithm** of a number x is denoted $\ln x$, and is defined as the power to which $e = 2.718 \dots$ must be raised for the result to be equal to x . It follows from the definition of logarithms that

$$\ln x + \ln y + \dots = \ln xy \dots \quad (\text{A2.1})$$

$$\ln x - \ln y = \ln(x/y) \quad (\text{A2.2})$$

$$a \ln x = \ln x^a \quad (\text{A2.3})$$

We also encounter the **common logarithm** of a number, $\log x$, the logarithm compiled with 10 in place of e . Common logarithms follow the same rules of addition and subtraction as natural logarithms. Common and natural logarithms are related by

$$\ln x = \ln 10 \log x \approx 2.303 \log x \quad (\text{A2.4})$$

The **exponential function**, e^x , plays a very special role in the mathematics of chemistry. The following properties are important:

$$e^x e^y e^z \dots = e^{x+y+z+\dots} \quad (\text{A2.5})$$

$$e^x / e^y = e^{x-y} \quad (\text{A2.6})$$

$$(e^x)^a = e^{ax} \quad (\text{A2.7})$$

A2.2 Complex numbers and complex functions

Complex numbers have the form

$$z = x + iy \quad (\text{A2.8})$$

where $i = (-1)^{1/2}$. The real numbers x and y are, respectively, the real and imaginary parts of z , denoted $\text{Re}(z)$ and $\text{Im}(z)$. We write the **complex conjugate** of z , denoted z^* , by replacing i by $-i$:

$$z^* = x - iy \quad (\text{A2.9})$$

The **absolute value** or **modulus** of the complex number z is denoted $|z|$ and is given by:

$$|z| = (z^* z)^{1/2} = (x^2 + y^2)^{1/2} \quad (\text{A2.10})$$

The following rules apply for arithmetic operations involving complex numbers:

1 Addition. If $z = x + iy$ and $z' = x' + iy'$, then

$$z \pm z' = (x \pm x') + i(y \pm y') \quad (\text{A2.11})$$

Fig. A2.1 The vector $\mathbf{v}$ has components v_x , v_y , and v_z on the x , y , and z axes with magnitudes v_x , v_y , and v_z , respectively.

Fig. A2.2 (a) The vectors $\mathbf{v}$ and $\mathbf{u}$ make an angle θ . (b) To add $\mathbf{u}$ to $\mathbf{v}$, we first join the tail of $\mathbf{u}$ to the head of $\mathbf{v}$, making sure that the angle θ between the vectors remains unchanged. (c) To finish the process, we draw the resultant vector by joining the tail of $\mathbf{u}$ to the head of $\mathbf{v}$.

Fig. A2.3 The result of adding the vector $\mathbf{v}$ to the vector $\mathbf{u}$, with both vectors defined in Fig. A2.2a. Comparison with the result shown in Fig. A2.2c for the addition of $\mathbf{u}$ to $\mathbf{v}$ shows that reversing the order of vector addition does not affect the result.

2 Multiplication. For z and z' defined above,

$$z \times z' = (x + iy)(x' + iy') = (xx' - yy') + i(xy' + yx') \quad (\text{A2.12})$$

3 Division. For z and z' defined above,

$$\frac{z}{z'} = \frac{z(z')^*}{|z'|^2} \quad (\text{A2.13})$$

Functions of complex arguments are useful in the discussion of wave equations (Chapter 8). We write the complex conjugate, f^* , of a complex function, f , by replacing i wherever it occurs by $-i$. For instance, the complex conjugate of e^{ix} is e^{-ix} .

Complex exponential functions may be written in terms of trigonometric functions. For example,

$$e^{\pm ix} = \cos x \pm i \sin x \quad (\text{A2.14})$$

which implies that

$$\cos x = \frac{1}{2}(e^{ix} + e^{-ix}) \quad (\text{A2.15})$$

$$\sin x = -\frac{1}{2}i(e^{ix} - e^{-ix}) \quad (\text{A2.16})$$

A2.3 Vectors

A vector quantity has both magnitude and direction. The vector shown in Fig. A2.1 has components on the x , y , and z axes with magnitudes v_x , v_y , and v_z , respectively. The vector may be represented as

$$\mathbf{v} = v_x \mathbf{i} + v_y \mathbf{j} + v_z \mathbf{k} \quad (\text{A2.17})$$

where $\mathbf{i}$, $\mathbf{j}$, and $\mathbf{k}$ are **unit vectors**, vectors of magnitude 1, pointing along the positive directions on the x , y , and z axes. The magnitude of the vector is denoted v or $|\mathbf{v}|$ and is given by

$$v = (v_x^2 + v_y^2 + v_z^2)^{1/2} \quad (\text{A2.18})$$

Using this representation, we can define the following vector operations:

1 Addition and subtraction. If $\mathbf{v} = v_x \mathbf{i} + v_y \mathbf{j} + v_z \mathbf{k}$ and $\mathbf{u} = u_x \mathbf{i} + u_y \mathbf{j} + u_z \mathbf{k}$, then

$$\mathbf{v} \pm \mathbf{u} = (v_x \pm u_x) \mathbf{i} + (v_y \pm u_y) \mathbf{j} + (v_z \pm u_z) \mathbf{k} \quad (\text{A2.19})$$

A graphical method for adding and subtracting vectors is sometimes desirable, as we saw in Chapters 10 and 18. Consider two vectors $\mathbf{v}$ and $\mathbf{u}$ making an angle θ (Fig. A2.2a). The first step in the addition of $\mathbf{u}$ to $\mathbf{v}$ consists of joining the tail of $\mathbf{u}$ to the head of $\mathbf{v}$, as shown in Fig. A2.2b. In the second step, we draw a vector $\mathbf{v}_{\text{res}}$, the **resultant vector**, originating from the tail of $\mathbf{v}$ to the head of $\mathbf{u}$, as shown in Fig. A2.2c. Reversing the order of addition leads to the same result. That is, we obtain the same $\mathbf{v}_{\text{res}}$ whether we add $\mathbf{u}$ to $\mathbf{v}$ (Fig. 2.2c) or $\mathbf{v}$ to $\mathbf{u}$ (Fig. 2.3).

To calculate the magnitude of $\mathbf{v}_{\text{res}}$, we note that $\mathbf{v}$, $\mathbf{u}$, and $\mathbf{v}_{\text{res}}$ form a triangle and that we know the magnitudes of two of its sides (v and u) and of the angle between them ($180^\circ - \theta$; see Fig. A2.2c). To calculate the magnitude of the third side, v_{res} , we make use of the *law of cosines*, which states that:

For a triangle with sides a , b , and c , and angle C facing side c :

$$c^2 = a^2 + b^2 - 2ab \cos C$$

This law is summarized graphically in Fig. A2.4 and its application to the case shown in Fig. A2.2c leads to the expression

Fig. A2.4 The graphical representation of the law of cosines.

Fig. A2.5 The graphical method for subtraction of the vector $\mathbf{u}$ from the vector $\mathbf{v}$ (as shown in Fig. A2.2a) consists of two steps: (a) reversing the direction of $\mathbf{u}$ to form $-\mathbf{u}$, and (b) adding $-\mathbf{u}$ to $\mathbf{v}$.

$$v_{\text{res}}^2 = v^2 + u^2 - 2vu \cos (180^\circ - \theta)$$

Because $\cos (180^\circ - \theta) = -\cos \theta$, it follows after taking the square-root of both sides of the preceding expression that

$$v_{\text{res}} = (v^2 + u^2 + 2vu \cos \theta)^{1/2} \quad (\text{A2.20})$$

The subtraction of vectors follows the same principles outlined above for addition. Consider again the vectors shown in Fig. A2.2a. We note that subtraction of $\mathbf{u}$ from $\mathbf{v}$ amounts to addition of $-\mathbf{u}$ to $\mathbf{v}$. It follows that in the first step of subtraction we draw $-\mathbf{u}$ by reversing the direction of $\mathbf{u}$ (Fig. A2.5a). Then, the second step consists of adding the $-\mathbf{u}$ to $\mathbf{v}$ by using the strategy shown in Fig. A2.2c: we draw a resultant vector $\mathbf{v}_{\text{res}}$ by joining the tail of $-\mathbf{u}$ to the head of $\mathbf{v}$.

2 Multiplication. There are two ways to multiply vectors. In one procedure, the **cross-product** of two vectors $\mathbf{u}$ and $\mathbf{v}$ is a vector defined as

$$\mathbf{u} \times \mathbf{v} = (uv \sin \theta) \mathbf{l} \quad (\text{A2.21a})$$

where θ is the angle between the two vectors and $\mathbf{l}$ is a unit vector perpendicular to both $\mathbf{u}$ and $\mathbf{v}$, with a direction determined as in Fig. A2.6. An equivalent definition is

$$\mathbf{u} \times \mathbf{v} = \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ u_x & u_y & u_z \\ v_x & v_y & v_z \end{vmatrix} = (u_y v_z - u_z v_y) \mathbf{i} - (u_x v_z - u_z v_x) \mathbf{j} + (u_x v_y - u_y v_x) \mathbf{k} \quad (\text{A2.21b})$$

where the structure in the middle is a determinant (see below). The second type of vector multiplication is the **scalar product** (or **dot product**) of two vectors $\mathbf{u}$ and $\mathbf{v}$:

$$\mathbf{u} \cdot \mathbf{v} = uv \cos \theta \quad (\text{A2.22})$$

As its name suggests, the scalar product of two vectors is a scalar.

Calculus

A2.4 Differentiation and integration

Rates of change of functions—slopes of their graphs—are best discussed in terms of the infinitesimal calculus. The slope of a function, like the slope of a hill, is obtained by dividing the rise of the hill by the horizontal distance (Fig. A2.7). However, because

Fig. A2.6 The direction of the cross-products of two vectors $\mathbf{u}$ and $\mathbf{v}$ with an angle θ between them: (a) $\mathbf{u} \times \mathbf{v}$ and (b) $\mathbf{v} \times \mathbf{u}$. Note that the cross-product, and the unit vector $\mathbf{l}$ of eqn A2.21, are perpendicular to both $\mathbf{u}$ and $\mathbf{v}$ but the direction depends on the order in which the product is taken.

Fig. A2.7 The slope of $f(x)$ at x , df/dx , is obtained by making a series of approximations to the value of $f(x + \delta x) - f(x)$ divided by the change in x , denoted δx , and allowing δx to approach 0 (as indicated by the vertical lines getting closer to x).

the slope may vary from point to point, we should make the horizontal distance between the points as small as possible. In fact, we let it become infinitesimally small—hence the name *infinitesimal* calculus. The values of a function f at two locations x and $x + \delta x$ are $f(x)$ and $f(x + \delta x)$, respectively. Therefore, the slope of the function f at x is the vertical distance, which we write δf , divided by the horizontal distance, which we write δx :

$$\text{Slope} = \frac{\text{rise in value}}{\text{horizontal distance}} = \frac{\delta f}{\delta x} = \frac{f(x + \delta x) - f(x)}{\delta x} \quad (\text{A2.23})$$

The slope at x itself is obtained by letting the horizontal distance become zero, which we write $\lim \delta x \rightarrow 0$. In this limit, the δ is replaced by a d , and we write

$$\text{Slope at } x = \frac{df}{dx} = \lim_{\delta x \rightarrow 0} \frac{f(x + \delta x) - f(x)}{\delta x} \quad (\text{A2.24})$$

To work out the slope of any function, we work out the expression on the right: this process is called **differentiation** and the expression for df/dx is the **derivative** of the function f with respect to the variable x . Some important derivatives are given inside the front cover of the text. Most of the functions encountered in chemistry can be differentiated by using the following rules (noting that in these expressions, derivatives df/dx are written as df):

Rule 1 For two functions f and g :

$$d(f + g) = df + dg \quad (\text{A2.25})$$

Rule 2 (the product rule) For two functions f and g :

$$d(fg) = f dg + g df \quad (\text{A2.26})$$

Rule 3 (the quotient rule) For two functions f and g :

$$d\frac{f}{g} = \frac{1}{g} df - \frac{f}{g^2} dg \quad (\text{A2.27})$$

Rule 4 (the chain rule) For a function $f = f(g)$, where $g = g(t)$,

$$\frac{df}{dt} = \frac{df}{dg} \frac{dg}{dt} \quad (\text{A2.28})$$

The area under a graph of any function f is found by the techniques of **integration**. For instance, the area under the graph of the function f drawn in Fig. A2.8 can be written as the value of f evaluated at a point multiplied by the width of the region, δx , and then all those products $f(x)\delta x$ summed over all the regions:

$$\text{Area between } a \text{ and } b = \sum f(x)\delta x$$

When we allow δx to become infinitesimally small, written dx , and sum an infinite number of strips, we write:

$$\text{Area between } a \text{ and } b = \int_a^b f(x)dx \quad (\text{A2.29})$$

The elongated S symbol on the right is called the **integral** of the function f . When written as $\int$ alone, it is the **indefinite integral** of the function. When written with limits (as in eqn A2.29), it is the **definite integral** of the function. The definite integral is the indefinite integral evaluated at the upper limit (b) minus the indefinite integral evaluated at the lower limit (a). The **average value** of a function $f(x)$ in the range $x = a$ to $x = b$ is

Fig. A2.8 The shaded area is equal to the definite integral of $f(x)$ between the limits a and b .

$$\text{Average value of } f(x) \text{ from } a \text{ to } b = \frac{1}{b-a} \int_a^b f(x) dx \quad (\text{A2.30})$$

The **mean value theorem** states that a continuous function has its mean value at least once in the range.

Integration is the inverse of differentiation. That is, if we integrate a function and then differentiate the result, we get back the original function. Some important integrals are given on the front back cover of the text. Many other standard forms are found in tables (see *Further reading*) and it is also possible to calculate definite and indefinite integrals with mathematical software. Two integration techniques are useful:

Technique 1 (integration by parts) For two functions f and g :

$$\int f \frac{dg}{dx} dx = fg - \int g \frac{df}{dx} dx \quad (\text{A2.31})$$

Technique 2 (method of partial fractions) To solve an integral of the form $\int \frac{1}{(a-x)(b-x)} dx$, where a and b are constants, we write

$$\frac{1}{(a-x)(b-x)} = \frac{1}{b-a} \left(\frac{1}{a-x} - \frac{1}{b-x} \right)$$

and integrate the expression on the right. It follows that

$$\begin{aligned} \int \frac{dx}{(a-x)(b-x)} &= \frac{1}{b-a} \left[\int \frac{dx}{a-x} - \int \frac{dx}{b-x} \right] \\ &= \frac{1}{b-a} \left(\ln \frac{1}{a-x} - \ln \frac{1}{b-x} \right) + \text{constant} \end{aligned} \quad (\text{A2.32})$$

A2.5 Power series and Taylor expansions

A **power series** has the form

$$c_0 + c_1(x-a) + c_2(x-a)^2 + \cdots + c_n(x-a)^n + \cdots = \sum_{n=0}^{\infty} c_n(x-a)^n \quad (\text{A2.33})$$

where c_n and a are constants. It is often useful to express a function $f(x)$ in the vicinity of $x = a$ as a special power series called the **Taylor series**, or **Taylor expansion**, which has the form:

$$\begin{aligned} f(x) &= f(a) + \left(\frac{df}{dx} \right) (x-a) + \frac{1}{2!} \left(\frac{d^2f}{dx^2} \right)_a (x-a)^2 + \cdots + \frac{1}{n!} \left(\frac{d^n f}{dx^n} \right)_a (x-a)^n \\ &= \sum_{n=0}^{\infty} \frac{1}{n!} \left(\frac{d^n f}{dx^n} \right)_a (x-a)^n \end{aligned} \quad (\text{A2.34})$$

where $n!$ denotes a **factorial**, given by

$$n! = n(n-1)(n-2) \cdots 1 \quad (\text{A2.35})$$

By definition $0! = 1$. The following Taylor expansions are often useful:

$$\frac{1}{1+x} = 1 - x + x^2 - \cdots$$

$$e^x = 1 + x + \frac{1}{2}x^2 + \cdots$$

$$\ln x = (x-1) - \frac{1}{2}(x-1)^2 + \frac{1}{3}(x-1)^3 - \frac{1}{4}(x-1)^4 + \cdots$$

$$\ln(1+x) = x - \frac{1}{2}x^2 + \frac{1}{3}x^3 - \cdots$$

If $x \ll 1$, then $(1+x)^{-1} \approx 1-x$, $e^x \approx 1+x$, and $\ln(1+x) \approx x$.

A2.6 Partial derivatives

A **partial derivative** of a function of more than one variable, such as $f(x, y)$, is the slope of the function with respect to one of the variables, all the other variables being held constant (see Fig. 2.21). Although a partial derivative shows how a function changes when one variable changes, it may be used to determine how the function changes when more than one variable changes by an infinitesimal amount. Thus, if f is a function of x and y , then when x and y change by dx and dy , respectively, f changes by

$$df = \left(\frac{\partial f}{\partial x} \right)_y dx + \left(\frac{\partial f}{\partial y} \right)_x dy \quad (\text{A2.36})$$

where the symbol ∂ is used (instead of d) to denote a partial derivative. The quantity df is also called the **differential** of f . For example, if $f = ax^3y + by^2$, then

$$\left(\frac{\partial f}{\partial x} \right)_y = 3ax^2y \quad \left(\frac{\partial f}{\partial y} \right)_x = ax^3 + 2by$$

Then, when x and y undergo infinitesimal changes, f changes by

$$df = 3ax^2y dx + (ax^3 + 2by) dy$$

Partial derivatives may be taken in any order:

$$\frac{\partial^2 f}{\partial x \partial y} = \frac{\partial^2 f}{\partial y \partial x} \quad (\text{A2.37})$$

For the function f given above, it is easy to verify that

$$\left(\frac{\partial}{\partial y} \left(\frac{\partial f}{\partial x} \right)_y \right)_x = 3ax^2 \quad \left(\frac{\partial}{\partial x} \left(\frac{\partial f}{\partial y} \right)_x \right)_y = 3ax^2$$

In the following, z is a variable on which x and y depend (for example, x , y , and z might correspond to p , V , and T).

Relation 1 When x is changed at constant z :

$$\left(\frac{\partial f}{\partial x} \right)_z = \left(\frac{\partial f}{\partial x} \right)_y + \left(\frac{\partial f}{\partial y} \right)_x \left(\frac{\partial y}{\partial x} \right)_z \quad (\text{A2.38})$$

Relation 2

$$\left(\frac{\partial y}{\partial x} \right)_z = \frac{1}{(\partial x / \partial y)_z} \quad (\text{A2.39})$$

Relation 3

$$\left(\frac{\partial x}{\partial y} \right)_z = - \left(\frac{\partial x}{\partial z} \right)_y \left(\frac{\partial z}{\partial y} \right)_x \quad (\text{A2.40})$$

By combining this relation and Relation 2 we obtain the **Euler chain relation**:

$$\left(\frac{\partial y}{\partial x} \right)_z \left(\frac{\partial x}{\partial z} \right)_y \left(\frac{\partial z}{\partial y} \right)_x = -1 \quad (\text{A2.41})$$

Relation 4 This relation establishes whether or not df is an **exact differential**.

$$df = g(x, y) dx + h(x, y) dy \quad \text{is exact if} \quad \left(\frac{\partial g}{\partial y} \right)_x = \left(\frac{\partial h}{\partial x} \right)_y \quad (\text{A2.42})$$

If df is exact, its integral between specified limits is independent of the path.

A2.7 Functionals and functional derivatives

Just as a function f can be regarded as a set of mathematical procedures that associates a number $f(x)$ to a specified value of a variable x , so a **functional** G gives a prescription for associating a number $G[f]$ to a function $f(x)$ over a specified range of the variable x . That is, the functional is a function of a function. Functionals are important in quantum chemistry. We saw in Chapter 11 that the energy of a molecule is a functional of the electron density, which in turn is a function of the position.

To make the following discussion more concrete, consider the functional

$$G[f] = \int_0^1 f(x)^2 dx \quad (\text{A2.43})$$

If we let $f(x) = x$, then $G[f] = \frac{1}{3}$ over the range $0 \leq x \leq 1$. However, if $f(x) = \sin \pi x$, then $G[f] = \frac{1}{2}$ over the range $0 \leq x \leq 1$.

Just as the derivative of a function $f(x)$ tells us how the function changes with small changes δx in the variable x , so a **functional derivative** tells us about the variation δG of a functional $G[f]$ with small changes δf in the function $f(x)$. By analogy with eqn A2.24, we can write the following definition of the functional derivative as

$$\frac{\delta G}{\delta f} = \lim_{\delta f \rightarrow 0} \frac{G[f + \delta f] - G[f]}{\delta f} \quad (\text{A2.44})$$

However, this equation does not give us a simple method for calculating the functional derivative. It can be shown that an alternative definition of $\delta G/\delta f$ is (see *Further reading*):

$$G[f + \delta f] - G[f] = \int_a^b \left(\frac{\delta G}{\delta f} \delta f(x) \right) dx \quad (\text{A2.45})$$

where the integral is evaluated in the range over which x varies.

To see how eqn A2.45 is used to calculate a functional derivative, consider the functional given by eqn A2.43. We begin by writing

$$\begin{aligned} G[f + \delta f] &= \int_0^1 \{f(x) + \delta f(x)\}^2 dx = \int_0^1 \{f(x)^2 + 2f(x)\delta f(x) + \delta f(x)^2\} dx \\ &= \int_0^1 \{f(x)^2 + 2f(x)\delta f(x)\} dx = G[f] + \int_0^1 2f(x)\delta f(x) dx \end{aligned}$$

where we have ignored the minute contribution from δf^2 to arrive at the penultimate expression and then used eqn A2.43 to write the final expression. It follows that

$$G[f + \delta f] - G[f] = \int_0^1 2f(x)\delta f(x) dx$$

By comparing this expression with eqn A2.45, we see that the functional derivative is

$$\frac{\delta G}{\delta f} = 2f(x)$$

A2.8 Undetermined multipliers

Suppose we need to find the maximum (or minimum) value of some function f that depends on several variables $x_1, x_2, \dots, x_n$. When the variables undergo a small change from x_i to $x_i + \delta x_i$ the function changes from f to $f + \delta f$, where

$$\delta f = \sum_i^n \left(\frac{\partial f}{\partial x_i} \right) \delta x_i \quad (\text{A2.46})$$

At a minimum or maximum, $\delta f = 0$, so then

$$\sum_i^n \left(\frac{\partial f}{\partial x_i} \right) \delta x_i = 0 \quad (\text{A2.47})$$

If the x_i were all independent, all the δx_i would be arbitrary, and this equation could be solved by setting each $(\partial f / \partial x_i) = 0$ individually. When the x_i are not all independent, the δx_i are not all independent, and the simple solution is no longer valid. We proceed as follows.

Let the constraint connecting the variables be an equation of the form $g = 0$. For example, in Chapter 16, one constraint was $n_0 + n_1 + \dots = N$, which can be written

$$g = 0, \quad \text{with} \quad g = (n_0 + n_1 + \dots) - N$$

The constraint $g = 0$ is always valid, so g remains unchanged when the x_i are varied:

$$\delta g = \sum_i \left(\frac{\partial g}{\partial x_i} \right) \delta x_i = 0 \quad (\text{A2.48})$$

Because δg is zero, we can multiply it by a parameter, λ , and add it to eqn A2.47:

$$\sum_i^n \left\{ \left(\frac{\partial f}{\partial x_i} \right) + \lambda \left(\frac{\partial g}{\partial x_i} \right) \right\} \delta x_i = 0 \quad (\text{A2.49})$$

This equation can be solved for one of the δx_i , δx_n for instance, in terms of all the other δx_i . All those other δx_i ($i = 1, 2, \dots, n-1$) are independent, because there is only one constraint on the system. But here is the trick: λ is arbitrary; therefore we can choose it so that the coefficient of δx_n in eqn A2.49 is zero. That is, we choose λ so that

$$\left(\frac{\partial f}{\partial x_n} \right) + \lambda \left(\frac{\partial g}{\partial x_n} \right) = 0 \quad (\text{A2.50})$$

Then eqn A2.49 becomes

$$\sum_i^{n-1} \left\{ \left(\frac{\partial f}{\partial x_i} \right) + \lambda \left(\frac{\partial g}{\partial x_i} \right) \right\} \delta x_i = 0 \quad (\text{A2.51})$$

Now the $n-1$ variations δx_i are independent, so the solution of this equation is

$$\left(\frac{\partial f}{\partial x_i} \right) + \lambda \left(\frac{\partial g}{\partial x_i} \right) = 0 \quad i = 1, 2, \dots, n-1 \quad (\text{A2.52})$$

However, eqn A2.50 has exactly the same form as this equation, so the maximum or minimum of f can be found by solving

$$\left(\frac{\partial f}{\partial x_i} \right) + \lambda \left(\frac{\partial g}{\partial x_i} \right) = 0 \quad i = 1, 2, \dots, n \quad (\text{A2.53})$$

The use of this approach was illustrated in the text for two constraints and therefore two undetermined multipliers λ_1 and λ_2 (α and $-\beta$).

The multipliers λ cannot always remain undetermined. One approach is to solve eqn A2.50 instead of incorporating it into the minimization scheme. In Chapter 16 we used the alternative procedure of keeping λ undetermined until a property was calculated for which the value was already known. Thus, we found that $\beta = 1/kT$ by calculating the internal energy of a perfect gas.

A2.9 Differential equations

(a) Ordinary differential equations

An **ordinary differential equation** is a relation between derivatives of a function of one variable and the function itself, as in

$$a \frac{d^2 y}{dx^2} + b \frac{dy}{dx} + cy = 0 \quad (\text{A2.54})$$

The coefficients a , b , etc. may be functions of x . The **order** of the equation is the order of the highest derivative that occurs in it, so eqn A2.54 is a second-order equation. Only rarely in science is a differential equation of order higher than 2 encountered. A solution of a differential equation is an expression for y as a function of x . The process of solving a differential equation is commonly termed ‘integration’, and in simple cases simple integration can be employed to find $y(x)$. A **general solution** of a differential equation is the most general solution of the equation and is expressed in terms of a number of constants. When the constants are chosen to accord with certain specified **initial conditions** (if one variable is the time) or certain **boundary conditions** (to fulfil certain spatial restrictions on the solutions), we obtain the **particular solution** of the equation. A first-order differential equation requires the specification of *one* boundary (or initial) condition; a second-order differential equation requires the specification of *two* such conditions, and so on.

First-order differential equations may often be solved by direct integration. For example, the equation

$$\frac{dy}{dx} = axy$$

with a constant may be rearranged into

$$\frac{dy}{y} = ax dx$$

and then integrated to

$$\ln y = \frac{1}{2} ax^2 + A$$

where A is a constant. If we know that $y = y_0$ when $x = 0$ (for instance), then it follows that $A = \ln y_0$, and hence the particular solution of the equation is

$$\ln y = \frac{1}{2} ax^2 + \ln y_0$$

This expression rearranges to

$$y = y_0 e^{ax^2/2}$$

First-order equations of a more complex form can often be solved by the appropriate substitution. For example, it is sensible to try the substitution $y = sx$, and to change the variables from x and y to x and s . An alternative useful transformation is to write $x = u + a$ and $y = v + b$, and then to select a and b to simplify the form of the resulting expression.

Solutions to complicated differential equations may also be found by referring to tables (see *Further reading*). For example, first-order equations of the form

$$\frac{dy}{dx} + yf(x) = g(x) \quad (\text{A2.55})$$

appear in the study of chemical kinetics. The solution is given by

$$ye^{\int f(x)dx} = \int e^{\int f(x)dx} g(x)dx + \text{constant} \quad (\text{A2.56})$$

Mathematical software is now capable of finding analytical solutions of a wide variety of differential equations.

Second-order differential equations are in general much more difficult to solve than first-order equations. One powerful approach commonly used to lay siege to second-order differential equations is to express the solution as a power series:

$$y = \sum_{n=0}^{\infty} c_n x^n \quad (\text{A2.57})$$

and then to use the differential equation to find a relation between the coefficients. This approach results, for instance, in the Hermite polynomials that form part of the solution of the Schrödinger equation for the harmonic oscillator (Section 9.4). All the second-order differential equations that occur in this text are tabulated in compilations of solutions or can be solved with mathematical software, and the specialized techniques that are needed to establish the form of the solutions may be found in mathematical texts.

(b) Numerical integration of differential equations

Many of the differential equations that describe physical phenomena are so complicated that their solutions cannot be cast as functions. In such cases, we resort to numerical methods, in which approximations are made in order to integrate the differential equation. Software packages are now readily available that can be used to solve almost any equation numerically. The general form of such programs to solve $df/dx = g(x)$, for instance, replaces the infinitesimal quantity $df = g(x)dx$ by the small quantity $\Delta f = g(x)\Delta x$, so that

$$f(x + \Delta x) \approx f(x) + g(x)\Delta x$$

and then proceeds numerically to step along the x -axis, generating $f(x)$ as it goes. The actual algorithms adopted are much more sophisticated than this primitive scheme, but stem from it. Among the simple numerical methods, the fourth-order **Runge–Kutta method** is one of the most accurate.

The *Further reading* section lists monographs that discuss the derivation of the fourth-order Runge–Kutta method. Here we illustrate the procedure with a first-order differential equation of the form:

$$\frac{dy}{dx} = f(x, y) \quad (\text{A2.58})$$

One example of this differential equation in chemical kinetics is eqn 22.36, which describes the time dependence of the concentration of an intermediate I in the reaction sequence $A \rightarrow I \rightarrow P$.

To obtain an approximate value of the integral of eqn A2.58, we proceed by rewriting it in terms of finite differences instead of differentials:

$$\frac{\Delta y}{\Delta x} = f(x, y)$$

where Δy may also be written as $y(x + \Delta x) - y(x)$. The fourth-order Runge–Kutta method is based on the following approximation:

$$y(x + \Delta x) = y(x) + \frac{1}{6}(k_1 + 2k_2 + 2k_3 + k_4) \quad (\text{A2.59})$$

where

$$k_1 = f(x, y) \Delta x \quad (\text{A2.60a})$$

$$k_2 = f\left(x + \frac{1}{2} \Delta x, y + \frac{1}{2} k_1\right) \Delta x \quad (\text{A2.60b})$$

$$k_3 = f\left(x + \frac{1}{2} \Delta x, y + \frac{1}{2} k_2\right) \Delta x \quad (\text{A2.60c})$$

$$k_4 = f(x + \Delta x, y + k_3) \Delta x \quad (\text{A2.60d})$$

Therefore, if we know the functional form of $f(x, y)$ and $y(0)$, we can use eqns A2.60(a–d) to calculate values of y for a range of x values. The process can be automated easily with an electronic spreadsheet or with mathematical software. The accuracy of the calculation increases with decreasing values of the increment Δx .

(c) Partial differential equations

A **partial differential equation** is a differential in more than one variable. An example is

$$\frac{\partial^2 y}{\partial t^2} = a \frac{\partial^2 y}{\partial x^2} \quad (\text{A2.61})$$

with y a function of the two variables x and t . In certain cases, partial differential equations may be separated into ordinary differential equations. Thus, the Schrödinger equation for a particle in a two-dimensional square well (Section 9.2) may be separated by writing the wavefunction, $\psi(x, y)$, as the product $X(x)Y(y)$, which results in the separation of the second-order partial differential equation into two second-order differential equations in the variables x and y . A good guide to the likely success of such a **separation of variables** procedure is the symmetry of the system.

Statistics and probability

Throughout the text, but especially in Chapters 16, 17, 19, and 21, we use several elementary results from two branches of mathematics: **probability theory**, which deals with quantities and events that are distributed randomly, and **statistics**, which provides tools for the analysis of large collections of data. Here we introduce some of the fundamental ideas from these two fields.

A2.10 Random selections

Combinatorial functions allow us to express the number of ways in which a system of particles may be configured; they are especially useful in statistical thermodynamics (Chapters 16 and 17). Consider a simple coin-toss problem. If n coins are tossed, the number $N(n, i)$ of outcomes that have i heads and $(n - i)$ tails, regardless of the order of the results, is given by the coefficients of the **binomial expansion** of $(1 + x)^n$:

$$(1 + x)^n = 1 + \sum_{i=1}^n N(n, i) x^i, \quad N(n, i) = \frac{n!}{(n - i)! i!} \quad (\text{A2.62})$$

The numbers $N(n, i)$, which are sometimes denoted $\binom{n}{i}$, are also called **binomial coefficients**.

Suppose that, unlike the coin-toss problem, there are more than two possible results for each event. For example, there are six possible results for the roll of a die. For n rolls of the die, the number of ways, W , that correspond to n_1 occurrences of the number 1, n_2 occurrences of the number 2, and so on, is given by

$$W = \frac{n!}{n_1!n_2!n_3!n_4!n_5!n_6!}, \quad n = \sum_{i=1}^6 n_i$$

This is an example of a **multinomial coefficient**, which has the form

$$W = \frac{n!}{n_1!n_2!\dots n_m!}, \quad n = \sum_{i=1}^m n_i \quad (\text{A2.63})$$

where W is the number of ways of achieving an outcome, n is the number of events, and m is the number of possible results. In Chapter 16 we use the multinomial coefficient to determine the number of ways to configure a system of identical particles given a specific distribution of particles into discrete energy levels.

In chemistry it is common to deal with a very large number of particles and outcomes and it is useful to express factorials in different ways. We can simplify factorials of large numbers by using **Stirling's approximation**:

$$n! \approx (2\pi)^{1/2} n^{n+1/2} e^{-n} \quad (\text{A2.64})$$

The approximation is in error by less than 1 per cent when n is greater than about 10. For very large values of n , it is possible to use another form of the approximation:

$$\ln n! \approx n \ln n - n \quad (\text{A2.65})$$

A2.11 Some results of probability theory

Here we develop two general results of probability theory: the mean value of a variable and the mean value of a function. The calculation of mean values is useful in the description of random coils (Chapter 19) and molecular diffusion (Chapter 21).

The mean value (also called the *expectation value*) $\langle X \rangle$ of a variable X is calculated by first multiplying each discrete value x_i that X can have by the probability p_i that x_i occurs and then summing these products over all possible N values of X :

$$\langle X \rangle = \sum_{i=1}^N x_i p_i$$

When N is very large and the x_i values are so closely spaced that X can be regarded as varying continuously, it is useful to express the probability that X can have a value between x and $x + dx$ as

$$\text{Probability of finding a value of } X \text{ between } x \text{ and } x + dx = f(x)dx$$

where the function $f(x)$ is the *probability density*, a measure of the distribution of the probability values over x , and dx is an infinitesimally small interval of x values. It follows that the probability that X has a value between $x = a$ and $x = b$ is the integral of the expression above evaluated between a and b :

$$\text{Probability of finding a value of } X \text{ between } a \text{ and } b = \int_a^b f(x)dx$$

The mean value of the continuously varying X is given by

$$\langle X \rangle = \int_{-\infty}^{+\infty} x f(x) dx \quad (\text{A2.66})$$

This expression is similar to that written for the case of discrete values of X , with $f(x)dx$ as the probability term and integration over the closely spaced x values replacing summation over widely spaced x_i .

The mean value of a function $g(X)$ can be calculated with a formula similar to that for $\langle X \rangle$:

$$\langle g(X) \rangle = \int_{-\infty}^{+\infty} g(x)f(x)dx \quad (\text{A2.67})$$

Matrix algebra

A **matrix** is an array of numbers. Matrices may be combined together by addition or multiplication according to generalizations of the rules for ordinary numbers. Most numerical matrix manipulations are now carried out with mathematical software.

Consider a square matrix $\mathbf{M}$ of n^2 numbers arranged in n columns and n rows. These n^2 numbers are the **elements** of the matrix, and may be specified by stating the row, r , and column, c , at which they occur. Each element is therefore denoted M_{rc} . For example, in the matrix

$$\mathbf{M} = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}$$

the elements are $M_{11} = 1$, $M_{12} = 2$, $M_{21} = 3$, and $M_{22} = 4$. This is an example of a 2×2 matrix. The **determinant**, $|\mathbf{M}|$, of this matrix is

$$|\mathbf{M}| = \begin{vmatrix} 1 & 2 \\ 3 & 4 \end{vmatrix} = 1 \times 4 - 2 \times 3 = -2$$

A **diagonal matrix** is a matrix in which the only nonzero elements lie on the major diagonal (the diagonal from M_{11} to M_{nn}). Thus, the matrix

$$\mathbf{D} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

is diagonal. The condition may be written

$$M_{rc} = m_r \delta_{rc} \quad (\text{A2.68})$$

where δ_{rc} is the **Kronecker delta**, which is equal to 1 for $r = c$ and to 0 for $r \neq c$. In the above example, $m_1 = 1$, $m_2 = 2$, and $m_3 = 1$. The **unit matrix**, $\mathbf{1}$ (and occasionally $\mathbf{I}$), is a special case of a diagonal matrix in which all nonzero elements are 1.

The **transpose** of a matrix $\mathbf{M}$ is denoted $\mathbf{M}^T$ and is defined by

$$M_{mn}^T = M_{nm} \quad (\text{A2.69})$$

Thus, for the matrix $\mathbf{M}$ we have been using,

$$\mathbf{M}^T = \begin{pmatrix} 1 & 3 \\ 2 & 4 \end{pmatrix}$$

Matrices are very useful in chemistry. They simplify some mathematical tasks, such as solving systems of simultaneous equations, the treatment of molecular symmetry (Chapter 12), and quantum mechanical calculations (Chapter 11).

A2.12 Matrix addition and multiplication

Two matrices $\mathbf{M}$ and $\mathbf{N}$ may be added to give the sum $\mathbf{S} = \mathbf{M} + \mathbf{N}$, according to the rule

$$S_{rc} = M_{rc} + N_{rc} \quad (\text{A2.70})$$

(that is, corresponding elements are added). Thus, with $\mathbf{M}$ given above and

$$\mathbf{N} = \begin{pmatrix} 5 & 6 \\ 7 & 8 \end{pmatrix}$$

the sum is

$$\mathbf{S} = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix} + \begin{pmatrix} 5 & 6 \\ 7 & 8 \end{pmatrix} = \begin{pmatrix} 6 & 8 \\ 10 & 12 \end{pmatrix}$$

Two matrices may also be multiplied to give the product $\mathbf{P} = \mathbf{MN}$ according to the rule

$$P_{rc} = \sum_n M_{rn} N_{nc} \quad (\text{A2.71})$$

For example, with the matrices given above,

$$\mathbf{P} = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix} \begin{pmatrix} 5 & 6 \\ 7 & 8 \end{pmatrix} = \begin{pmatrix} 1 \times 5 + 2 \times 7 & 1 \times 6 + 2 \times 8 \\ 3 \times 5 + 4 \times 7 & 3 \times 6 + 4 \times 8 \end{pmatrix} = \begin{pmatrix} 19 & 22 \\ 43 & 50 \end{pmatrix}$$

It should be noticed that in general $\mathbf{MN} \neq \mathbf{NM}$, and matrix multiplication is in general non-commutative.

The **inverse** of a matrix $\mathbf{M}$ is denoted $\mathbf{M}^{-1}$, and is defined so that

$$\mathbf{M}\mathbf{M}^{-1} = \mathbf{M}^{-1}\mathbf{M} = \mathbf{1} \quad (\text{A2.72})$$

The inverse of a matrix can be constructed by using mathematical software, but in simple cases the following procedure can be carried through without much effort:

1 Form the determinant of the matrix. For example, for our matrix $\mathbf{M}$, $|\mathbf{M}| = -2$.

2 Form the transpose of the matrix. For example, $\mathbf{M}^T = \begin{pmatrix} 1 & 3 \\ 2 & 4 \end{pmatrix}$.

3 Form $\tilde{\mathbf{M}}'$, where $\tilde{\mathbf{M}}'_{rc}$ is the **cofactor** of the element M_{rc} , that is, it is the determinant formed from $\mathbf{M}$ with the row r and column c struck out. For example,

$$\tilde{\mathbf{M}}' = \begin{pmatrix} 4 & -2 \\ -3 & 1 \end{pmatrix}$$

4 Construct the inverse as $\mathbf{M}^{-1} = \tilde{\mathbf{M}}' / |\mathbf{M}|$. For example,

$$\mathbf{M}^{-1} = \frac{1}{-2} \begin{pmatrix} 4 & -2 \\ -3 & 1 \end{pmatrix} = \begin{pmatrix} -2 & 1 \\ \frac{3}{2} & -\frac{1}{2} \end{pmatrix}$$

A2.13 Simultaneous equations

A set of n **simultaneous equations**

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}x_n &= b_1 \\ a_{21}x_1 + a_{22}x_2 + \cdots + a_{2n}x_n &= b_2 \\ &\vdots \\ a_{n1}x_1 + a_{n2}x_2 + \cdots + a_{nn}x_n &= b_n \end{aligned} \quad (\text{A2.73})$$

can be written in matrix notation if we introduce the **column vectors** $\mathbf{x}$ and $\mathbf{b}$:

$$\mathbf{x} = \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{pmatrix} \quad \mathbf{b} = \begin{pmatrix} b_1 \\ b_2 \\ \vdots \\ b_n \end{pmatrix}$$

Then, with the $\mathbf{a}$ matrix of coefficients a_{rc} , the n equations may be written as

$$\mathbf{ax} = \mathbf{b} \quad (\text{A2.74})$$

The formal solution is obtained by multiplying both sides of this matrix equation by $\mathbf{a}^{-1}$, for then

$$\mathbf{x} = \mathbf{a}^{-1}\mathbf{b} \quad (\text{A2.75})$$

A2.14 Eigenvalue equations

An **eigenvalue equation** is a special case of eqn A2.74 in which

$$\mathbf{ax} = \lambda\mathbf{x} \quad (\text{A2.76})$$

where λ is a constant, the **eigenvalue**, and $\mathbf{x}$ is the **eigenvector**. In general, there are n eigenvalues $\lambda^{(i)}$, and they satisfy the n simultaneous equations

$$(\mathbf{a} - \lambda\mathbf{1})\mathbf{x} = 0 \quad (\text{A2.77})$$

There are n corresponding eigenvectors $\mathbf{x}^{(i)}$. Equation A2.77 has a solution only if the determinant of the coefficients is zero. However, this determinant is just $|\mathbf{a} - \lambda\mathbf{1}|$, so the n eigenvalues may be found from the solution of the **secular equation**:

$$|\mathbf{a} - \lambda\mathbf{1}| = 0 \quad (\text{A2.78})$$

The n eigenvalues the secular equation yields may be used to find the n eigenvectors. These eigenvectors (which are $n \times 1$ matrices), may be used to form an $n \times n$ matrix $\mathbf{X}$. Thus, because

$$\mathbf{x}^{(1)} = \begin{pmatrix} x_1^{(1)} \\ x_2^{(1)} \\ \vdots \\ x_n^{(1)} \end{pmatrix} \quad \mathbf{x}^{(2)} = \begin{pmatrix} x_1^{(2)} \\ x_2^{(2)} \\ \vdots \\ x_n^{(2)} \end{pmatrix} \quad \text{etc.}$$

we may form the matrix

$$\mathbf{X} = (\mathbf{x}^{(1)}, \mathbf{x}^{(2)}, \dots, \mathbf{x}^{(n)}) = \begin{pmatrix} x_1^{(1)} & x_1^{(2)} & \dots & x_1^{(n)} \\ x_2^{(1)} & x_2^{(2)} & \dots & x_2^{(n)} \\ \vdots & \vdots & \dots & \vdots \\ x_n^{(1)} & x_n^{(2)} & \dots & x_n^{(n)} \end{pmatrix}$$

so that $X_{rc} = x_r^{(c)}$. If further we write $\Lambda_{rc} = \lambda_r \delta_{rc}$, so that $\mathbf{\Lambda}$ is a diagonal matrix with the elements $\lambda_1, \lambda_2, \dots, \lambda_n$ along the diagonal, then all the eigenvalue equations $\mathbf{ax}^{(i)} = \lambda_i \mathbf{x}^{(i)}$ may be confined into the single equation

$$\mathbf{aX} = \mathbf{X\Lambda} \quad (\text{A2.79})$$

because this expression is equal to

$$\sum_n a_{rn} X_{nc} = \sum_n X_{rn} \Lambda_{nc}$$

or

$$\sum_n a_{rn} x_n^{(c)} = \sum_n x_r^{(n)} \lambda_n \delta_{nc} = \lambda_c x_r^{(c)}$$

as required. Therefore, if we form $\mathbf{X}^{-1}$ from $\mathbf{X}$, we construct a **similarity transformation**

$$\mathbf{\Lambda} = \mathbf{X}^{-1}\mathbf{aX} \quad (\text{A2.80})$$

that makes $\mathbf{a}$ diagonal (because $\mathbf{A}$ is diagonal). It follows that if the matrix $\mathbf{X}$ that causes $\mathbf{X}^{-1}\mathbf{aX}$ to be diagonal is known, then the problem is solved: the diagonal matrix so produced has the eigenvalues as its only nonzero elements, and the matrix $\mathbf{X}$ used to bring about the transformation has the corresponding eigenvectors as its columns. The solutions of eigenvalue equations are best found by using mathematical software.

Essential concepts of physics

A3

Energy

The central concept of all explanations in physical chemistry, as in so many other branches of physical science, is that of **energy**, the capacity to do work. We make use of the apparently universal law of nature that *energy is conserved*, that is, energy can neither be created nor destroyed. Although energy can be transferred from one location to another, the total energy is constant.

A3.1 Kinetic and potential energy

The **kinetic energy**, E_K , of a body is the energy the body possesses as a result of its motion. For a body of mass m travelling at a speed v ,

$$E_K = \frac{1}{2}mv^2 \quad (\text{A3.1})$$

The **potential energy**, E_P or V , of a body is the energy it possesses as a result of its position. The zero of potential energy is arbitrary. For example, the gravitational potential energy of a body is often set to zero at the surface of the Earth; the electrical potential energy of two charged particles is set to zero when their separation is infinite. No universal expression for the potential energy can be given because it depends on the type of interaction the body experiences. One example that gives rise to a simple expression is the potential energy of a body of mass m in the gravitational field close to the surface of the Earth (a gravitational field acts on the mass of a body). If the body is at a height h above the surface of the Earth, then its potential energy is mgh , where g is a constant called the **acceleration of free fall**, $g = 9.81 \text{ m s}^{-2}$, and $V = 0$ at $h = 0$ (the arbitrary zero mentioned previously).

The total energy is the sum of the kinetic and potential energies of a particle:

$$E = E_K + E_P \quad (\text{A3.2})$$

A3.2 Energy units

The SI unit of energy is the *joule* (J), which is defined as

$$1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2} \quad (\text{A3.3})$$

Calories (cal) and kilocalories (kcal) are still encountered in the chemical literature: by definition, $1 \text{ cal} = 4.184 \text{ J}$. An energy of 1 cal is enough to raise the temperature of 1 g of water by 1°C .

The rate of change of energy is called the **power**, P , expressed as joules per second, or *watt*, W:

$$1 \text{ W} = 1 \text{ J s}^{-1} \quad (\text{A3.4})$$

Fig. A3.1 The linear momentum of a particle is a vector property and points in the direction of motion.

Fig. A3.2 The force acting on a particle is determined by the slope of the potential energy at each point. The force points in the direction of lower potential energy.

Classical mechanics

Classical mechanics describes the behaviour of objects in terms of two equations. One expresses the fact that the total energy is constant in the absence of external forces; the other expresses the response of particles to the forces acting on them.

A3.3 The trajectory in terms of the energy

The **velocity**, v , of a particle is the rate of change of its position:

$$v = \frac{dr}{dt} \quad (\text{A3.5})$$

The velocity is a vector, with both direction and magnitude. The magnitude of the velocity is the **speed**, v . The **linear momentum**, p , of a particle of mass m is related to its velocity, v , by

$$p = mv \quad (\text{A3.6})$$

Like the velocity vector, the linear momentum vector points in the direction of travel of the particle (Fig. A3.1). In terms of the linear momentum, the total energy of a particle is

$$E = \frac{p^2}{2m} + V(x) \quad (\text{A3.7})$$

This equation can be used to show that a particle will have a definite **trajectory**, or definite position and momentum at each instant. For example, consider a particle free to move in one direction (along the x -axis) in a region where $V = 0$ (so the energy is independent of position). Because $v = dx/dt$, it follows from eqns A3.6 and A3.7 that

$$\frac{dx}{dt} = \left(\frac{2E_K}{m} \right)^{1/2} \quad (\text{A3.8})$$

A solution of this differential equation is

$$x(t) = x(0) + m \left(\frac{2E_K}{m} \right)^{1/2} t \quad (\text{A3.9})$$

The linear momentum is a constant:

$$p(t) = mv(t) = m \frac{dx}{dt} = (2mE_K)^{1/2} \quad (\text{A3.10})$$

Hence, if we know the initial position and momentum, we can predict all later positions and momenta exactly.

A3.4 Newton's second law

The **force**, F , experienced by a particle free to move in one dimension is related to its potential energy, V , by

$$F = -\frac{dV}{dx} \quad (\text{A3.11a})$$

This relation implies that the direction of the force is towards decreasing potential energy (Fig. A3.2). In three dimensions,

$$\mathbf{F} = -\nabla V \quad \nabla = \mathbf{i} \frac{\partial}{\partial x} + \mathbf{j} \frac{\partial}{\partial y} + \mathbf{k} \frac{\partial}{\partial z} \quad (\text{A3.11b})$$

Newton's second law of motion states that *the rate of change of momentum is equal to the force acting on the particle*. In one dimension:

$$\frac{dp}{dt} = F \quad (\text{A3.12a})$$

Because $p = m(dx/dt)$ in one dimension, it is sometimes more convenient to write this equation as

$$m \frac{d^2x}{dt^2} = F \quad (\text{A3.12b})$$

The second derivative, d^2x/dt^2 , is the **acceleration** of the particle, its rate of change of velocity (in this instance, along the x -axis). It follows that, if we know the force acting everywhere and at all times, then solving eqn A3.12 will also give the trajectory. This calculation is equivalent to the one based on E , but is more suitable in some applications. For example, it can be used to show that, if a particle of mass m is initially stationary and is subjected to a constant force F for a time τ , then its kinetic energy increases from zero to

$$E_K = \frac{F^2 \tau^2}{2m} \quad (\text{A3.13})$$

and then remains at that energy after the force ceases to act. Because the applied force, F , and the time, τ , for which it acts may be varied at will, the solution implies that the energy of the particle may be increased to any value.

A3.5 Rotational motion

The rotational motion of a particle about a central point is described by its **angular momentum**, J . The angular momentum is a vector: its magnitude gives the rate at which a particle circulates and its direction indicates the axis of rotation (Fig. A3.3). The magnitude of the angular momentum, J , is given by the expression

$$J = I\omega \quad (\text{A3.14})$$

where ω is the **angular velocity** of the body, its rate of change of angular position (in radians per second), and I is the **moment of inertia**. The analogous roles of m and I , of v and ω , and of p and J in the translational and rotational cases, respectively, should be remembered, because they provide a ready way of constructing and recalling equations. For a point particle of mass m moving in a circle of radius r , the moment of inertia about the axis of rotation is given by the expression

$$I = mr^2 \quad (\text{A3.15})$$

To accelerate a rotation it is necessary to apply a **torque**, T , a twisting force. Newton's equation is then

$$\frac{dJ}{dt} = T \quad (\text{A3.16})$$

If a constant torque is applied for a time τ , the rotational energy of an initially stationary body is increased to

Fig. A3.3 The angular momentum of a particle is represented by a vector along the axis of rotation and perpendicular to the plane of rotation. The length of the vector denotes the magnitude of the angular momentum. The direction of motion is clockwise to an observer looking in the direction of the vector.

Fig. A3.4 The force acting on a particle that undergoes harmonic motion. The force is directed towards zero displacement and is proportional to the displacement. The corresponding potential energy is parabolic (proportional to x^2).

$$E_K = \frac{T^2 \tau^2}{2I} \quad (\text{A3.17})$$

The implication of this equation is that an appropriate torque and period for which it is applied can excite the rotation to an arbitrary energy.

A3.6 The harmonic oscillator

A **harmonic oscillator** consists of a particle that experiences a restoring force proportional to its displacement from its equilibrium position:

$$F = -kx \quad (\text{A3.18})$$

An example is a particle joined to a rigid support by a spring. The constant of proportionality k is called the **force constant**, and the stiffer the spring the greater the force constant. The negative sign in F signifies that the direction of the force is opposite to that of the displacement (Fig. A3.4).

The motion of a particle that undergoes harmonic motion is found by substituting the expression for the force, eqn A3.18, into Newton's equation, eqn A3.12b. The resulting equation is

$$m \frac{d^2x}{dt^2} = -kx$$

A solution is

$$x(t) = A \sin \omega t \quad p(t) = m\omega A \cos \omega t \quad \omega = (k/m)^{1/2} \quad (\text{A3.19})$$

These solutions show that the position of the particle varies **harmonically** (that is, as $\sin \omega t$) with a frequency $\nu = \omega/2\pi$. They also show that the particle is stationary ($p = 0$) when the displacement, x , has its maximum value, A , which is called the **amplitude** of the motion.

The total energy of a classical harmonic oscillator is proportional to the square of the amplitude of its motion. To confirm this remark we note that the kinetic energy is

$$E_K = \frac{p^2}{2m} = \frac{(m\omega A \cos \omega t)^2}{2m} = \frac{1}{2}m\omega^2 A^2 \cos^2 \omega t \quad (\text{A3.20})$$

Then, because $\omega = (k/m)^{1/2}$, this expression may be written

$$E_K = \frac{1}{2}kA^2 \cos^2 \omega t \quad (\text{A3.21})$$

The force on the oscillator is $F = -kx$, so it follows from the relation $F = -dV/dx$ that the potential energy of a harmonic oscillator is

$$V = \frac{1}{2}kx^2 = \frac{1}{2}kA^2 \sin^2 \omega t \quad (\text{A3.22})$$

The total energy is therefore

$$E = \frac{1}{2}kA^2 \cos^2 \omega t + \frac{1}{2}kA^2 \sin^2 \omega t = \frac{1}{2}kA^2 \quad (\text{A3.23})$$

(We have used $\cos^2 \omega t + \sin^2 \omega t = 1$.) That is, the energy of the oscillator is constant and, for a given force constant, is determined by its maximum displacement. It follows that the energy of an oscillating particle can be raised to any value by stretching the spring to any desired amplitude A . Note that the frequency of the motion depends only on the inherent properties of the oscillator (as represented by k and m) and is independent of the energy; the amplitude governs the energy, through $E = \frac{1}{2}kA^2$, and is independent of the frequency. In other words, the particle will oscillate at the same frequency regardless of the amplitude of its motion.

Waves

Waves are disturbances that travel through space with a finite velocity. Examples of disturbances include the collective motion of water molecules in ocean waves and of gas particles in sound waves. Waves can be characterized by a **wave equation**, a differential equation that describes the motion of the wave in space and time. **Harmonic waves** are waves with displacements that can be expressed as sine or cosine functions. These concepts are used in classical physics to describe the wave character of electromagnetic radiation, which is the focus of the following discussion.

A3.7 The electromagnetic field

In classical physics, electromagnetic radiation is understood in terms of the **electromagnetic field**, an oscillating electric and magnetic disturbance that spreads as a harmonic wave through empty space, the vacuum. The wave travels at a constant speed called the *speed of light*, c , which is about $3 \times 10^8 \text{ m s}^{-1}$. As its name suggests, an electromagnetic field has two components, an **electric field** that acts on charged particles (whether stationary or moving) and a **magnetic field** that acts only on moving charged particles. The electromagnetic field is characterized by a **wavelength**, λ (lambda), the distance between the neighbouring peaks of the wave, and its **frequency**, ν (nu), the number of times per second at which its displacement at a fixed point returns to its original value (Fig. A3.5). The frequency is measured in *hertz*, where $1 \text{ Hz} = 1 \text{ s}^{-1}$. The wavelength and frequency of an electromagnetic wave are related by

$$\lambda \nu = c \quad (\text{A3.24})$$

Therefore, the shorter the wavelength, the higher the frequency. The characteristics of a wave are also reported by giving the **wavenumber**, $\tilde{\nu}$ (nu tilde), of the radiation, where

$$\tilde{\nu} = \frac{\nu}{c} = \frac{1}{\lambda} \quad (\text{A3.25})$$

A wavenumber can be interpreted as the number of complete wavelengths in a given length. Wavenumbers are normally reported in reciprocal centimetres (cm^{-1}), so a wavenumber of 5 cm^{-1} indicates that there are 5 complete wavelengths in 1 cm. The classification of the electromagnetic field according to its frequency and wavelength is summarized in Fig. A3.6.

A3.8 Features of electromagnetic radiation

Consider an electromagnetic disturbance travelling along the x direction with wavelength λ and frequency ν . The functions that describe the oscillating electric field, $\mathcal{E}(x,t)$, and magnetic field, $\mathcal{B}(x,t)$, may be written as

$$\mathcal{E}(x,t) = \mathcal{E}_0 \cos\{2\pi \nu t - (2\pi/\lambda)x + \phi\} \quad (\text{A3.26a})$$

$$\mathcal{B}(x,t) = \mathcal{B}_0 \cos\{2\pi \nu t - (2\pi/\lambda)x + \phi\} \quad (\text{A3.26b})$$

where $\mathcal{E}_0$ and $\mathcal{B}_0$ are the amplitudes of the electric and magnetic fields, respectively, and the parameter ϕ is the **phase** of the wave, which varies from $-\pi$ to π and gives the relative location of the peaks of two waves. If two waves, in the same region of space, with the same wavelength are shifted by $\phi = \pi$ or $-\pi$ (so the peaks of one wave coincide with the troughs of the other), then the resultant wave will have diminished

Fig. A3.5 (a) The wavelength, λ , of a wave is the peak-to-peak distance. (b) The wave is shown travelling to the right at a speed c . At a given location, the instantaneous amplitude of the wave changes through a complete cycle (the four dots show half a cycle) as it passes a given point. The frequency, ν , is the number of cycles per second that occur at a given point. Wavelength and frequency are related by $\lambda \nu = c$.

Fig. A3.6 The regions of the electromagnetic spectrum and the types of excitation that give rise to each region.

amplitudes. The waves are said to interfere destructively. A value of $\phi = 0$ (coincident peaks) corresponds to constructive interference, or the enhancement of the amplitudes.

Equations A3.26a and A3.26b represent electromagnetic radiation that is **plane-polarized**; it is so called because the electric and magnetic fields each oscillate in a single plane (in this case the xy -plane, Fig. A3.7). The plane of polarization may be orientated in any direction around the direction of propagation (the x -direction in Fig. A3.7), with the electric and magnetic fields perpendicular to that direction (and perpendicular to each other). An alternative mode of polarization is **circular polarization**, in which the electric and magnetic fields rotate around the direction of propagation in either a clockwise or a counterclockwise sense but remain perpendicular to it and each other.

It is easy to show by differentiation that eqns A3.26a and A3.26b satisfy the following equations:

$$\frac{\partial^2}{\partial x^2} \psi(x, t) = -\frac{4\pi^2}{\lambda^2} \psi(x, t) \quad \frac{\partial^2}{\partial t^2} \psi(x, t) = -4\pi^2 v^2 \psi(x, t) \quad (\text{A3.27})$$

where $\psi(x, t)$ is either $\mathcal{E}(x, t)$ or $\mathcal{B}(x, t)$.

According to classical electromagnetic theory, the intensity of electromagnetic radiation is proportional to the square of the amplitude of the wave. For example, the light detectors discussed in *Further information* 16.1 are based on the interaction between the electric field of the incident radiation and the detecting element, so light intensities are proportional to $\mathcal{E}_0^2$.

A3.9 Refraction

A beam of light changes direction ('bends') when it passes from one transparent medium to another. This effect, called **refraction**, depends on the **refractive index**, n_r , of the medium, the ratio of the speed of light in a vacuum, c , to its speed c' in the medium:

$$n_r = \frac{c}{c'} \quad [\text{A3.28}]$$

It follows from the Maxwell equations (see *Further reading*), that the refractive index at a (visible or ultraviolet) specified frequency is related to the relative permittivity ϵ_r (discussed in Section 20.10) at that frequency by

$$n_r = \epsilon_r^{1/2} \quad (\text{A3.29})$$

Table A3.1 lists refractive indices of some materials.

Because the relative permittivity of a medium is related to its polarizability by eqn 20.10, the refractive index is related to the polarizability. To see why this is so, we need to realize that propagation of light through a medium induces an oscillating dipole moment, which then radiates light of the same frequency. The newly generated radiation is delayed slightly by this process, so it propagates more slowly through the medium than through a vacuum. Because photons of high-frequency light carry more energy than those of low-frequency light, they can distort the electronic distributions of the molecules in their path more effectively. Therefore, after allowing for the loss of contributions from low-frequency modes of motion, we can expect the electronic polarizabilities of molecules, and hence the refractive index, to increase as the incident frequency rises towards an absorption frequency. This dependence on frequency is the origin of the dispersion of white light by a prism: the refractive index is greater for blue light than for red, and therefore the blue rays are bent more than the red. The

term **dispersion** is a term carried over from this phenomenon to mean the variation of the refractive index, or of any property, with frequency.

A3.10 Optical activity

The concept of refractive index is closely related to the property of optical activity. An **optically active** substance is a substance that rotates the plane of polarization of plane-polarized light. To understand this effect, it is useful to regard the incident plane-polarized beam as a superposition of two oppositely rotating circularly polarized components. By convention, in right-handed circularly polarized light the electric vector rotates clockwise as seen by an observer facing the oncoming beam (Fig. A3.8). On entering the medium, one component propagates faster than the other if their refractive indices are different. If the sample is of length l , the difference in the times of passage is

$$\Delta t = \frac{l}{c_L} - \frac{l}{c_R}$$

where c_R and c_L are the speeds of the two components in the medium. In terms of the refractive indices, the difference is

$$\Delta t = (n_R - n_L) \frac{l}{c}$$

The phase difference between the two components when they emerge from the sample is therefore

$$\Delta\theta = 2\pi\nu\Delta t = \frac{2\pi c\Delta t}{\lambda} = (n_R - n_L) \frac{2\pi l}{\lambda}$$

where λ is the wavelength of the light. The two rotating electric vectors have a different phase when they leave the sample from the value they had initially, so their superposition gives rise to a plane-polarized beam rotated through an angle $\Delta\theta$ relative to the plane of the incoming beam. It follows that the angle of optical rotation is proportional to the difference in refractive index, $n_R - n_L$. A sample in which these two refractive indices are different is said to be **circularly birefringent**.

To explain why the refractive indices depend on the handedness of the light, we must examine why the polarizabilities depend on the handedness. One interpretation is that, if a molecule is helical (such as a polypeptide α -helix described in Section 19.7) or a crystal has molecules in a helical arrangement (as in a cholesteric liquid crystal, as described in *Impact* I6.1), its polarizability depends on whether or not the electric field of the incident radiation rotates in the same sense as the helix.

Associated with the circular birefringence of the medium is a difference in absorption intensities for right- and left-circularly polarized radiation. This difference is known as **circular dichroism**, which is explored in Chapter 14.

Electrostatics

Electrostatics is the study of the interactions of stationary electric charges. The elementary charge, the magnitude of charge carried by a single electron or proton, is $e \approx 1.60 \times 10^{-19} \text{ C}$. The magnitude of the charge per mole is Faraday's constant: $F = N_A e = 9.65 \times 10^4 \text{ C mol}^{-1}$.

Fig. A3.7 Electromagnetic radiation consists of a wave of electric and magnetic fields perpendicular to the direction of propagation (in this case the x -direction), and mutually perpendicular to each other. This illustration shows a plane-polarized wave, with the electric and magnetic fields oscillating in the xy - and xz -planes, respectively.

* More values are given in the *Data section*.

Fig. A3.8 The superposition of left and right circularly polarized light as viewed from an observer facing the oncoming beam.

A3.11 The Coulomb interaction

If a point charge q_1 is at a distance r in a vacuum from another point charge q_2 , then their potential energy is

$$V = \frac{q_1 q_2}{4\pi\epsilon_0 r} \quad (\text{A3.30})$$

The constant ϵ_0 is the **vacuum permittivity**, a fundamental constant with the value $8.85 \times 10^{-12} \text{ C}^2 \text{ J}^{-1} \text{ m}^{-1}$. This very important relation is called the **Coulomb potential energy** and the interaction it describes is called the **Coulomb interaction** of two charges. The Coulomb potential energy is equal to the work that must be done to bring up a charge q_1 from infinity to a distance r from a charge q_2 .

It follows from eqns A3.5 and A3.30 that the electrical force, F , exerted by a charge q_1 on a second charge q_2 has magnitude

$$F = \frac{q_1 q_2}{4\pi\epsilon_0 r^2} \quad (\text{A3.31})$$

The force itself is a vector directed along the line joining the two charges. With charge in coulombs and distance in metres, the force is obtained in newtons.

In a medium other than a vacuum, the potential energy of interaction between two charges is reduced, and the vacuum permittivity is replaced by the **permittivity**, ϵ , of the medium (see Section 18.3).

A3.12 The Coulomb potential

The potential energy of a charge q_1 in the presence of another charge q_2 can be expressed in terms of the **Coulomb potential**, ϕ :

$$V = q_1 \phi \quad \phi = \frac{q_2}{4\pi\epsilon_0 r} \quad (\text{A3.32})$$

The units of potential are joules per coulomb, J C^{-1} , so, when ϕ is multiplied by a charge in coulombs, the result is in joules. The combination joules per coulomb occurs widely in electrostatics, and is called a *volt*, V:

$$1 \text{ V} = 1 \text{ J C}^{-1} \quad (\text{A3.33})$$

If there are several charges $q_2, q_3, \dots$ present in the system, the total potential experienced by the charge q_1 is the sum of the potential generated by each charge:

$$\phi = \phi_2 + \phi_3 + \dots \quad (\text{A3.34})$$

When the charge distribution is more complex than a single point-like object, the Coulomb potential is described in terms of a charge density, ρ . With charge in coulomb and length in metres, the charge density is expressed in coulombs per metre-cubed (C m^{-3}). The electric potential arising from a charge distribution with density ρ is the solution to **Poisson's equation**:

$$\nabla^2 \phi = -\rho / \epsilon_0 \quad (\text{A3.35})$$

where $\nabla^2 = (\partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2)$. If the distribution is spherically symmetrical, then so too is ϕ and eqn A3.35 reduces to the form used in *Further information* 5.1.

A3.13 The strength of the electric field

Just as the potential energy of a charge q_1 can be written $V = q_1 \phi$, so the magnitude of the force on q_1 can be written $F = q_1 \mathcal{E}$, where $\mathcal{E}$ is the magnitude of the electric field

strength arising from q_2 or from some more general charge distribution. The electric field strength (which, like the force, is actually a vector quantity) is the negative gradient of the electric potential:

$$\mathcal{E} = -\nabla\phi \quad (\text{A3.36})$$

A3.14 Electric current and power

The motion of charge gives rise to an electric **current**, I . Electric current is measured in *ampere*, A, where

$$1 \text{ A} = 1 \text{ C s}^{-1} \quad (\text{A3.37})$$

If the current flows from a region of potential ϕ_i to ϕ_f through a **potential difference** $\Delta\phi = \phi_f - \phi_i$, the rate of doing work is the current (the rate of transfer of charge) multiplied by the potential difference, $I\Delta\phi$. The rate of doing electrical work is the **electrical power**, P , so

$$P = I\Delta\phi \quad (\text{A3.38})$$

With current in amperes and the potential difference in volts, the power works out in watts. The total energy, E , supplied in an interval Δt is the power (the rate of energy supply) multiplied by the duration of the interval:

$$E = P\Delta t = I\Delta\phi\Delta t \quad (\text{A3.39})$$

The energy is obtained in joules with the current in amperes, the potential difference in volts, and the time in seconds.

Hexane	18.4
Mercury	472
Methanol	22.6
Water	72.75
	72.0 at 25°C
	58.0 at 100°C

Data: KL.

Table 19.1 Radius of gyration of some macromolecules

	$M/(\text{kg mol}^{-1})$	R_g/nm
Serum albumin	66	2.98
Myosin	493	46.8
Polystyrene	3.2×10^3	50 (in poor solvent)
DNA	4×10^3	117.0
Tobacco mosaic virus	3.9×10^4	92.4

Data: C. Tanford, *Physical chemistry of macromolecules*. Wiley, New York (1961).

Table 19.2 Diffusion coefficients of macromolecules in water at 20°C

	$M/(\text{kg mol}^{-1})$	$D/(10^{-10} \text{ m}^2 \text{ s}^{-1})$
Sucrose	0.342	4.586
Ribonuclease	13.7	1.19
Lysozyme	14.1	1.04
Serum albumin	65	0.594
Haemoglobin	68	0.69
Urease	480	0.346
Collagen	345	0.069
Myosin	493	0.116

Data: C. Tanford, *Physical chemistry of macromolecules*. Wiley, New York (1961).

Table 19.3 Frictional coefficients and molecular geometry

Major axis/Minor axis	Prolate	Oblate
2	1.04	1.04
3	1.11	1.10
4	1.18	1.17
5	1.25	1.22
6	1.31	1.28
7	1.38	1.33
8	1.43	1.37
9	1.49	1.42
10	1.54	1.46
50	2.95	2.38
100	4.07	2.97

Data: K.E. Van Holde, *Physical biochemistry*. Prentice-Hall, Englewood Cliffs (1971).

Sphere; radius a , $c = af_0$

Prolate ellipsoid; major axis $2a$, minor axis $2b$, $c = (ab^2)^{1/3}$

$$f = \left\{ \frac{(1 - b^2/a^2)^{1/2}}{(b/a)^{2/3} \ln\{[1 + (1 - b^2/a^2)^{1/2}]/(b/a)\}} \right\} f_0$$

Oblate ellipsoid; major axis $2a$, minor axis $2b$, $c = (a^2b)^{1/3}$

$$f = \left\{ \frac{(a^2/b^2 - 1)^{1/2}}{(a/b)^{2/3} \arctan[(a^2/b^2 - 1)^{1/2}]} \right\} f_0$$

Long rod; length l , radius a , $c = (3a^2/4)^{1/3}$

$$f = \left\{ \frac{(1/2a)^{2/3}}{(3/2)^{1/3} \{2 \ln(l/a) - 0.11\}} \right\} f_0$$

In each case $f_0 = 6\pi\eta c$ with the appropriate value of c .

Table 19.4 Intrinsic viscosity

Macromolecule	Solvent	$\theta/^\circ\text{C}$	$K/(10^{-3} \text{ cm}^3 \text{ g}^{-1})$	a
Polystyrene	Benzene	25	9.5	0.74
	Cyclohexane	34†	81	0.50
Polyisobutylene	Benzene	23†	83	0.50
	Cyclohexane	30	26	0.70
Amylose	0.33 M KCl(aq)	25†	113	0.50
Various proteins‡	Guanidine hydrochloride + HSCH ₂ CH ₂ OH		7.16	0.66

† The θ temperature.

‡ Use $[\eta] = KN^a$; N is the number of amino acid residues.

Data: K.E. Van Holde, *Physical biochemistry*. Prentice-Hall, Englewood Cliffs (1971).

Table 21.4 Viscosities of liquids at 298 K, $\eta/(10^{-3} \text{ kg m}^{-1} \text{ s}^{-1})$

Benzene	0.601
Carbon tetrachloride	0.880
Ethanol	1.06
Mercury	1.55
Methanol	0.553
Pentane	0.224
Sulfuric acid	27
Water†	0.891

† The viscosity of water over its entire liquid range is represented with less than 1 per cent error by the expression

$$\log(\eta_{20}/\eta) = A/B,$$

$$A = 1.370\,23(t - 20) + 8.36 \times 10^{-4}(t - 20)^2$$

$$B = 109 + t \quad t = \theta/^{\circ}\text{C}$$

Convert $\text{kg m}^{-1} \text{ s}^{-1}$ to centipoise (cP) by multiplying by 10^3 (so $\eta \approx 1$ cP for water).
Data: AIP, KL.

Table 21.5 Limiting ionic conductivities in water at 298 K, $\lambda/(\text{mS m}^2 \text{ mol}^{-1})$

Cations		Anions

8.13 $1.67 \times 10^{-16} \text{ J}$.

8.14 $\hbar$.

Chapter 9

9.1 (a) $2.14 \times 10^{-19} \text{ J}$, 1.34 eV , $1.08 \times 10^4 \text{ cm}^{-1}$, 129 kJ mol^{-1} ;

(b) $3.48 \times 10^{-19} \text{ J}$, 2.17 eV , $1.75 \times 10^4 \text{ cm}^{-1}$, 210 kJ mol^{-1} .

9.2 (a) $P = 0.031$; (b) $P = 0.029$.

9.3 $p = 0$, $p^2 = \frac{\hbar^2}{L^2}$.

9.4 $L = \left(\frac{3}{8}\right)^{1/2} \frac{\hbar}{mc} = \left(\frac{3}{8}\right)^{1/2} \lambda_c$.

9.5 $x = \frac{L}{10}, \frac{3L}{10}, \frac{L}{2}, \frac{7L}{10}, \frac{9L}{10}$.

9.6 6.

9.7 $n = 7.26 \times 10^{10}$, $\Delta E = 1.71 \times 10^{-31} \text{ J}$, $m = 27.5 \text{ pm}$, the particle behaves classically.

9.8 $E_0 = 3.92 \times 10^{-21} \text{ J}$.

9.9 $k = 260 \text{ N m}^{-1}$.

9.10 $\lambda = 13.2 \text{ }\mu\text{m}$.

9.11 $\lambda = 18.7 \text{ }\mu\text{m}$.

9.12 (a) $\Delta E = 2.2 \times 10^{-29} \text{ J}$; (b) $\Delta E = 3.14 \times 10^{-20} \text{ J}$.

9.14 $0, \pm 0.96\alpha$, or $\pm 2.02\alpha$.

9.15 $E_0 = 2.3421 \times 10^{-20} \text{ J}$.

9.17 Magnitude $= 2.58 \times 10^{-34} \text{ J s}$; possible projections $= 0, \pm 1.0546 \times 10^{-34} \text{ J s}$ and $\pm 2.1109 \times 10^{-34} \text{ J s}$.

Chapter 10

10.1 $I = 12.1 \text{ eV}$.

10.2 $r = 11.5a_0/Z$, $r = 3.53a_0/Z$, $r = 0$.

10.3 $r = 0$, $r = 1.382a_0$, $r = 3.618a_0$.

10.4 $N = \frac{1}{4\sqrt{2\pi a_0^3}}$.

10.5 $\langle V \rangle = -\frac{Z^2 e^2}{16\pi\epsilon_0 a_0}$, $\langle E_K \rangle = \frac{\hbar^2 Z^2}{8ma_0^2}$.

10.6 $P_{3s} = 4\pi r^2 \left(\frac{1}{4\pi}\right) \times \left(\frac{1}{243}\right) \times \left(\frac{Z}{a_0}\right)^3 \times (6 - 6\rho + \rho^2)^2 e^{-\rho}$,

$r = 0.74 a_0/Z$, $4.19 a_0/Z$ and $13.08 a_0/Z$.

10.7 $r = 1.76 a_0/Z$.

10.8 (a) angular momentum $= \frac{1}{2}\hbar = 2.45 \times 10^{-34} \text{ J s}$, angular nodes = 2, radial nodes = 1;

(b) angular momentum $= \frac{1}{2}\hbar = 1.49 \times 10^{-34} \text{ J s}$, angular nodes = 1, radial nodes = 0;

(c) angular momentum $= \frac{1}{2}\hbar = 1.49 \times 10^{-34} \text{ J s}$, angular nodes = 1, radial nodes = 1.

10.9 (a) $j = \frac{1}{2}, \frac{3}{2}$; (b) $j = \frac{9}{2}, \frac{11}{2}$.

10.10 $J = 8, 7, 6, 5, 4, 3, 2$.

10.11 (a) $g = 1$; (b) $g = 64$; (c) $g = 25$.

10.12 The letter F indicates that the total orbital angular momentum quantum number L is 3; the superscript 3 is the multiplicity of the term, $2S + 1$, related to the spin quantum number $S = 1$; and the subscript 4 indicates the total angular momentum quantum number J .

10.13 (a) $r = 110 \text{ pm}$, $r = 20.1 \text{ ppm}$; (b) $r = 86 \text{ pm}$, $r = 29.4 \text{ ppm}$.

10.14 (a) forbidden; (b) allowed; (c) forbidden.

10.15 (a) $[\text{Ar}]3d^3$; (b) For $S = \frac{3}{2}$, $M_s = \pm\frac{1}{2}$ and $\pm\frac{3}{2}$, for $S = \frac{1}{2}$, $M_s = \pm\frac{1}{2}$.

10.16 (a) $S = 2, 1, 0$; multiplicities = 5, 3, 1, respectively. (b) $S' = \frac{5}{2}, \frac{3}{2}, \frac{1}{2}$; multiplicities = 6, 4, 2 respectively.

10.17 $^1F_3$; $^3F_4$; $^3F_3$; $^3F_2$; $^1D_2$; $^3D_3$; $^3D_2$; $^3D_1$; $^1P_1$; $^3P_2$; $^3P_1$; $^3P_0$, the $^3F_2$ set of terms are the lower in energy.

10.18 (a) $J = 3, 2$ and 1, with 7, 5 and 3 states respectively;

(b) $J = \frac{7}{2}, \frac{5}{2}, \frac{3}{2}, \frac{1}{2}$, with 8, 6, 4 and 2 states respectively;

(c) $J = \frac{9}{2}, \frac{7}{2}$, with 10 and 8 states respectively.

10.19 (a) $^2D_{5/2}$ and $^2D_{3/2}$ (b) $^2P_{3/2}$ and $^2P_{1/2}$.

Chapter 11

11.1 (a) $1\sigma^2 2\sigma^{*1}$; (b) $1\sigma^2 2\sigma^{*2} 1\pi^4 3\sigma^2$; (c) $1\sigma^2 2\sigma^{*2} 3\sigma^2 1\pi^4 2\pi^{*2}$.

11.2 (a) $1\sigma^2 2\sigma^{*2} 3\sigma^2 1\pi^4 2\pi^{*4}$; (b) $1\sigma^2 2\sigma^{*2} 1\pi^4 3\sigma^2$;
(c) $1\sigma^2 2\sigma^{*2} 3\sigma^2 1\pi^4 2\pi^{*3}$.

11.3 (a) C_2 and CN ; (b) NO , O_2 and F_2 .

11.4 BrCl is likely to have a shorter bond length than BrCl^- ; it has a bond order of 1, while BrCl^- has a bond order of $1/2$.

11.5 The sequence O_2^+ , O_2 , O_2^- , O_2^{2-} has progressively longer bonds.

11.6 $N = \left(\frac{1}{1 + 2\lambda S + \lambda^2}\right)^{1/2}$.

11.7 $a = -\frac{0.145S + 0.844}{0.145 + 0.844S}b$, $N(0.844A - 0.145B)$.

11.8 Not appropriate.

11.9 $E_{\text{trial}} = \frac{-\mu e^4}{12\pi^3 \epsilon_0^2 \hbar^2}$.

11.10 $3.39 \times 10^{-16} \text{ J}$.

11.12 (a) $a_{2u}^2 e_{1g}^4 e_{2u}^1$, $E = 7\alpha + 7\beta$; (b) $a_{2u}^2 e_{1g}^3$, $E = 5\alpha + 7\beta$.

11.13 (a) 19.31368β ; (b) 19.44824β .

Chapter 12

12.1 CCl_4 has 4 C_3 axes (each C—Cl axis), 3 C_2 axes (bisecting Cl—C—Cl angles), 3 S_4 axes (the same as the C_2 axes), and 6 dihedral mirror planes (each Cl—C—Cl plane).

12.2 (a) CH_3Cl .

12.3 Yes, it is zero.

12.4 Forbidden.

12.6 T_d has S_4 axes and mirror planes ($= \text{S}_1$), T_h has a centre of inversion ($= \text{S}_2$).

12.8 (a) $\text{C}_{\infty\text{v}}$; (b) D_3 ; (c) $\text{C}_{4\text{v}}$, $\text{C}_{2\text{v}}$; (d) C_s .

12.9 (a) $\text{D}_{2\text{h}}$; (b) $\text{D}_{2\text{h}}$; (c) (i) $\text{C}_{2\text{v}}$; (ii) $\text{C}_{2\text{v}}$; (iii) $\text{D}_{2\text{h}}$.

12.10 (a) $\text{C}_{\infty\text{v}}$; (b) $\text{D}_{5\text{h}}$; (c) $\text{C}_{2\text{v}}$; (d) $\text{D}_{3\text{h}}$; (e) O_h ; (f) T_d .

12.11 (a) *ortho*-dichlorobenzene, *meta*-dichlorobenzene, HF and XeO_2F_2 ;
(b) none are chiral.

12.12 NO_3^- : p_x and p_y , SO_3 : all d orbitals except d_z^2 .

12.13 A_2 .

12.14 (a) $\text{B}_{3\text{U}}$ (x -polarized), $\text{B}_{2\text{U}}$ (y -polarized), $\text{B}_{1\text{U}}$ (z -polarized); (b) $\text{A}_{1\text{U}}$ or $\text{E}_{1\text{U}}$.

12.15 Yes, it is zero.

Chapter 13

13.1 (a) $7.73 \times 10^{-32} \text{ J m}^{-3} \text{ s}$; (b) $\nu = 6.2 \times 10^{-28} \text{ J m}^{-3} \text{ s}$.

 14.11 Stronger.

Chapter 15

- 15.1 $\nu = 649 \text{ MHz}$.
 15.2 $E_{m_f} = -2.35 \times 10^{-26} \text{ J}$, 0, $+2.35 \times 10^{-26} \text{ J}$.
 15.3 47.3 MHz.
 15.4 (a) $\Delta E = 2.88 \times 10^{-26} \text{ J}$; (b) $\Delta E = 5.77 \times 10^{-24} \text{ J}$.
 15.5 3.523 T.

B/T	^{14}N	^{19}F	^{31}P
g_I	0.40356	5.2567	2.2634
(a) 300 MHz	97.5	7.49	17.4
(b) 750 MHz	244	18.7	43.5

- 15.7 (a) 4.3×10^{-7} ; (b) 2.2×10^{-6} ; (c) 1.34×10^{-5} .
 15.8 (a) δ is independent of both B and ν . (b) $\frac{\nu - \nu^o(800 \text{ MHz})}{\nu - \nu^o(60 \text{ MHz})} = 13$.

- 15.9 (a) $4.2 \times 10^{-6} \text{ T}$; (b) $3.63 \times 10^{-5} \text{ T}$. Spectrum appears narrower at 650 MHz.
 15.11 $2.9 \times 10^3 \text{ s}^{-1}$.
 15.14 (a) The H and F nuclei are both chemically and magnetically equivalent. (b) The P and H nuclei chemically and magnetically equivalent in both the *cis*- and *trans*-forms.
 15.15 $B_1 = 9.40 \times 10^{-4} \text{ T}$, 6.25 μs .
 15.16 1.3 T.
 15.17 $g = 2.0022$.
 15.18 2.2 mT, $g = 1.992$.
 15.19 Eight equal parts at $\pm 1.445 \pm 1.435 \pm 1.055 \text{ mT}$ from the centre, namely: 328.865, 330.975, 331.735, 331.755, 333.845, 333.865, 334.625 and 336.735 mT.
 15.21 (a) 332.3 mT; (b) 1209 mT.
 15.22 $I = 1$.

Chapter 16

- 16.1 $T = 623 \text{ K}$.
 16.2 (a) 15.9 pm, 5.04 pm; (b) 2.47×10^{26} , 7.82×10^{27} .
 16.3 $\frac{q_{\text{Xe}}}{q_{\text{He}}} = 187.9$.
 16.4 $q = 4.006$.
 16.5 $E = 7.605 \text{ kJ mol}^{-1}$.
 16.6 213 K.
 16.7 (a) 0.997, 0.994; (b) 0.999 99, 0.999 98.
 16.8 (a) (i) $\frac{n_2}{n_1} = 1.39 \times 10^{-11}$, $\frac{n_3}{n_1} = 1.93 \times 10^{-22}$;
 (ii) $\frac{n_2}{n_1} = 0.368$, $\frac{n_3}{n_1} = 0.135$;
 (iii) $\frac{n_2}{n_1} = 0.779$, $\frac{n_3}{n_1} = 0.607$;
 (b) $q = 1.503$; (c) $U_m = 88.3 \text{ J mol}^{-1}$;
 (d) $C_v = 3.53 \text{ J K}^{-1} \text{ mol}^{-1}$; (e) $S_m = 6.92 \text{ J K}^{-1} \text{ mol}^{-1}$.
 16.9 7.26 K.
 16.10 (a) $147 \text{ J K}^{-1} \text{ mol}^{-1}$; (b) $169.6 \text{ J K}^{-1} \text{ mol}^{-1}$.
 16.11 $10.7 \text{ J K}^{-1} \text{ mol}^{-1}$.
 16.12 (a)

Chapter 17

- 17.1 (a) $\text{O}_3 : 3R$ [experimental = 3.7R]
 (b) $\text{C}_2\text{H}_6 : 4R$ [experimental = 6.3R]
 (c) $\text{CO}_2 : \frac{5}{2}R$ [experimental = 4.5R]
 17.2 With vibrations: 115, Without vibrations: 140, Experimental: 1.29.
 17.3 (a) 143; (b) 251.
 17.4 (a) 2; (b) 2; (c) 6; (d) 24; (e) 4.
 17.5 $q^K = 5837$, $\theta_R = 0.8479 \text{ K}$, $T = 0.3335 \text{ K}$.
 17.6 $S_m^R = 84.57 \text{ J K}^{-1} \text{ mol}^{-1}$.
 17.7 (a) At 298 K, $q^R = 2.50 \times 10^3$. At 500 K, $q^R = 5.43 \times 10^3$;
 (b) At 298 K, $q = 2.50 \times 10^3$. At 500 K, $q = 5.43 \times 10^3$.
 17.8 (a) At 25°C, $q^R = 7.97 \times 10^3$; (b) At 100°C, $q^R = 1.12 \times 10^4$.
 17.9 (a) At 298 K, $S_m = 5.88 \text{ J mol}^{-1} \text{ K}^{-1}$.
 (b) At 500 K, $S_m = 16.48 \text{ J mol}^{-1} \text{ K}^{-1}$.
 17.10 $G_m^R - G_m^V(0) = -20.1 \text{ kJ mol}^{-1}$, $G_m^V - G_m^V(0) = -0.110 \text{ kJ mol}^{-1}$.
 17.11 $-3.65 \text{ kJ mol}^{-1}$.
 17.12 $S_m = 14.9 \text{ J mol}^{-1} \text{ K}^{-1}$.
 17.14 $K = 0.25$.

Chapter 18

- 18.1 SF_4 .
 18.2 $\mu = 1.4 \text{ D}$.
 18.3 $\mu = 9.45 \times 10^{-29} \text{ C m}$, $\theta = 194.0^\circ$.
 18.4 $\mu = 3.23 \times 10^{-30} \text{ C m}$, $\alpha = 2.55 \times 10^{-39} \text{ C}^2 \text{ m}^2 \text{ J}^{-1}$.
 18.5 $\epsilon_r = 8.97$.
 18.6 $\mu^* = 3.71 \times 10^{-36} \text{ C m}$.
 18.7 $\alpha = 3.40 \times 10^{-40} \text{ C}^2 \text{ m}^2 \text{ J}^{-1}$.
 18.8 $n_r = 1.10$.
 18.9 $\epsilon_r = 16$.
 18.10 $p = 5.92 \text{ kPa}$.
 18.11 $\gamma = 7.12 \times 10^{-2} \text{ N m}^{-1}$.
 18.12 $p_{\text{in}} - p_{\text{out}} = 2.04 \times 10^5 \text{ Pa}$.

Chapter 19

- 19.1 $\bar{M}_n = 68 \text{ kg mol}^{-1}$, $\bar{M}_w = 69 \text{ kg mol}^{-1}$.
 19.2 $R_g = 1.06 \times 10^4$.
 19.3 (a) $\bar{M}_n = 8.8 \text{ kg mol}^{-1}$; (b) $\bar{M}_w = 11 \text{ kg mol}^{-1}$.
 19.4 $\tau = 9.4 \times 10^{-8} \text{ s}$.
 19.5 71.
 19.6 $\bar{M}_n = 120 \text{ kg mol}^{-1}$.
 19.7 $s = 1.47 \times 10^{-4} \text{ m s}^{-1}$.
 19.8 $\bar{M} = 56 \text{ kg mol}^{-1}$.
 19.9 $\bar{M}_w = 3.1 \times 10^3 \text{ kg mol}^{-1}$.
 19.10 $al/g = 3.86 \times 10^5$.
 19.11 $R_{\text{rms}} = 38.97 \text{ nm}$.
 19.12 $R_c = 1.26 \times 10^{-6} \text{ m}$, $R_{\text{rms}} = 1.97 \times 10^{-8} \text{ m}$.

Chapter 20

- 20.1 $(\frac{1}{2}, \frac{1}{2}, 0)$ and $(0, \frac{1}{2}, \frac{1}{2})$.
 20.2 $(3 \ 1 \ 3)$ and $(6 \ 4 \ 3)$.
 20.3 $d_{121} = 214 \text{ pm}$, $d_{221} = 174 \text{ pm}$, $d_{244} = 87.2 \text{ pm}$.
 20.4 $\lambda = 86.7 \text{ pm}$.

20.5	hkl	$\sin \theta$	$\theta/^\circ$	$2\theta/^\circ$
	111	0.327	19.1	38.2
	200	0.378	22.2	44.4
	220	0.535	32.3	64.6

- 20.6 $D = 0.054 \text{ cm}$.
 20.7 $V = 1.2582 \text{ nm}^3$.
 20.8 $d = 5$, $d = 2.90 \text{ g cm}^{-3}$.
 20.9 $d_{322} = 182 \text{ pm}$.
 20.10 (100) , (110) , (111) , and (200) .

20.11	hkl	d_{hkl}/pm	$\theta_{hkl}/^\circ$
	100	574.1	4.166
	010	796.8	3.000
	111	339.5	7.057

- 20.12 body-centred cubic.
 20.13 $F_{hkl} = 2f$ for $h + k + l$ even; 0 for $h + k + l$ odd.

- 20.14 $\frac{2}{3}$.
 20.15 $\frac{r}{R} = 0.732$.
 20.16 (a) 57 pm; (b) 111 pm.
 20.17 $\frac{2V_{\text{atom}}}{V_{\text{cell}}} = 0.370$.
 20.18 contraction.
 20.20 $\lambda = 252 \text{ pm}$.
 20.21 $\Delta_L H^\circ(\text{MgBr}_2, \text{s}) = 2421 \text{ kJ mol}^{-1}$.
 20.23 strain $= 5.8 \times 10^{-2}$.
 20.24 $\Delta V = 0.003 \text{ dm}^3$.
 20.25 p-type.
 20.26 $2.71 \times 10^4 \text{ H}$.
 20.27 5.
 20.28 $-8.2 \times 10^{-4} \text{ cm}^3 \text{ mol}^{-1}$.
 20.29 $\chi_m = 1.58 \times 10^{-8} \text{ m}^3 \text{ mol}^{-1}$, dimerization occurs.
 20.30 2.52 = effective unpaired spins, theoretical number = 2.
 20.31 $\chi_m = 1.85 \times 10^{-7} \text{ m}^3 \text{ mol}^{-1}$.
 20.32 $r = 0.935$.

Chapter 21

- 21.1 (a) 7.079; (b) 1.
 21.2 (a) $c = 4.75 \times 10^2 \text{ m s}^{-1}$; (b) $\lambda = 4 \times 10^4 \text{ m}$; (c) $z = 0.01 \text{ s}^{-1}$.
 21.3 $p = 2.4 \times 10^7 \text{ Pa}$.
 21.4 $\lambda = 4.1 \times 10^{-7} \text{ m}$.
 21.5 $z = 9.9 \times 10^8 \text{ s}^{-1}$.
 21.6 (a) $\lambda = 3.7 \times 10^{-9} \text{ m}$; (b) $\lambda = 5.5 \times 10^{-8} \text{ m}$; (c) $\lambda = 4.1 \times 10^{-5} \text{ m}$.
 21.7 $F \approx 9.6 \times 10^{-2}$.
 21.8 $N = 5.3 \times 10^{21}$.
 21.9 $\Delta m = 4.98 \times 10^{-4} \text{ kg}$.
 21.10 $M_{\text{fluorocarbon}} = 554 \text{ g mol}^{-1}$.
 21.11 $t = 1.5 \times 10^4 \text{ s}$.
 21.12 $0.17 \text{ J m}^{-2} \text{ s}^{-1}$.
 21.13 $1.61 \times 10^{-19} \text{ m}^2$.
 21.14 22 J s^{-1} .
 21.15 $3.00 \times 10^{-19} \text{ m}^2$.
 21.16 $1.00 \times 10^5 \text{ Pa}$.
 21.17 (a) At 273 K: $\eta = 0.95 \times 10^{-5} \text{ kg m}^{-1} \text{ s}^{-1}$;
 (b) At 298 K: $\eta = 0.99 \times 10^{-5} \text{ kg m}^{-1} \text{ s}^{-1}$;
 (c) At 1000 K: $\eta = 1.81 \times 10^{-5} \text{ kg m}^{-1} \text{ s}^{-1}$.
 21.18 (a) $\kappa = 0.0114 \text{ J m}^{-1} \text{ s}^{-1} \text{ K}^{-1}$, 0.017 J s^{-1} ;
 (b) $\kappa = 9.0 \times 10^{-3} \text{ J m}^{-1} \text{ s}^{-1} \text{ K}^{-1}$, 0.014 J s^{-1} .
 21.19 $52.0 \times 10^{-7} \text{ kg m}^{-1} \text{ s}^{-1}$, $d = 923 \text{ pm}$.
 21.20 $\kappa = 9.0 \times 10^{-3} \text{ J m}^{-1} \text{ s}^{-1} \text{ K}^{-1}$.
 21.21 (a) $D = 0.107 \text{ m}^2 \text{ s}^{-1}$, $J = 0.87 \text{ mol m}^{-2} \text{ s}^{-1}$;
 (b) $D = 1.07 \times 10^{-5} \text{ m}^2 \text{ s}^{-1}$, $J = 8.7 \times 10^{-5} \text{ mol m}^{-2} \text{ s}^{-1}$;
 (c) $D = 7.13 \times 10^{-8} \text{ m}^2 \text{ s}^{-1}$, $J = 5.8 \times 10^{-7} \text{ mol m}^{-2} \text{ s}^{-1}$.
 21.22 $4.09 \times 10^{-3} \text{ S m}^2 \text{ mol}^{-1}$.
 21.23 $4.81 \times 10^{-5} \text{ m V}^{-1} \text{ s}^{-1}$.
 21.24 0.604.
 21.25 $\Lambda_m^\circ(\text{MgI}_2) = 25.96 \text{ mS m}^2 \text{ mol}^{-1}$.
 21.26 F^- : $u = 5.74 \times 10^{-8} \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$;

Chapter 11

$$11.3 \quad R = 2.1a_0.$$

$$11.7 \quad (a) P = 8.6 \times 10^{-7} / P = 2.0 \times 10^{-6};$$

$$(b) P = 8.6 \times 10^{-7} / P = 2.0 \times 10^{-6};$$

$$(c) P = 3.7 \times 10^{-7} / P = 0;$$

$$(d) P = 4.9 \times 10^{-7} / P = 5.5 \times 10^{-7}.$$

$$11.13 \quad \text{Delocalization energy} = 2\{E_{\text{with resonance}} - E_{\text{without resonance}}\}$$

$$= \{(\alpha_O - \alpha_N)^2 + 12\beta^2\}^{1/2} - \{(\alpha_O - \alpha_N)^2 + 4\beta^2\}^{1/2}$$

$$11.15 \quad (a) \text{C}_2\text{H}_4: -3.813, \text{C}_4\text{H}_6: -4.623, \text{C}_6\text{H}_8: -5.538, \text{C}_8\text{H}_{10}: -5.873;$$

$$(b) 8.913 \text{ eV}.$$

$$11.29 \quad (a) \text{linear relationship}; (b) E^* = -0.122 \text{ V}; (c) E^* = -0.174 \text{ V},$$

$$\text{ubiquinone a better oxidizing agent than plastoquinone}.$$

Chapter 12

$$12.1 \quad (a) D_{3d}; (b) \text{chair: } D_{3d}, \text{boat: } C_{2v}; (c) D_{2h}; (d) D_3; (e) D_{4d}; (i) \text{Polar:}$$

$$\text{Boat } C_6\text{H}_{12}; (ii) \text{Chiral: } [\text{Co(en)}_3]^{3+}.$$

$$12.3 \quad C_2\sigma_h = i.$$

	1	σ_x	σ_y	σ_z
1	1	σ_x	σ_y	σ_z
σ_x	σ_x	1	$i\sigma_x$	$-i\sigma_y$
σ_y	σ_y	—	1	$i\sigma_x$
		$i\sigma_z$		
σ_z	σ_z	$i\sigma_y$	—	1
			$i\sigma_z$	

The matrices do not form a group since the products $i\sigma_z, i\sigma_y, i\sigma_x$ and their negatives are not among the four given matrices.

$$12.9 \quad \text{All five } d \text{ orbitals may contribute to bonding. (b) All except } A_2(d_{xy})$$

$$\text{may participate in bonding}.$$
