Preface

We have taken the opportunity to refresh both the content and presentation of this text while—as for all its editions—keeping it flexible to use, accessible to students, broad in scope, and authoritative. The bulk of textbooks is a perennial concern: we have sought to tighten the presentation in this edition. However, it should always be borne in mind that much of the bulk arises from the numerous pedagogical features that we include (such as *Worked examples* and the *Data section*), not necessarily from density of information.

The most striking change in presentation is the use of colour. We have made every effort to use colour systematically and pedagogically, not gratuitously, seeing as a medium for making the text more attractive but using it to convey concepts and data more clearly. The text is still divided into three parts, but material has been moved between chapters and the chapters have been reorganized. We have responded to the shift in emphasis away from classical thermodynamics by combining several chapters in Part 1 (Equilibrium), bearing in mind that some of the material will already have been covered in earlier courses. We no longer make a distinction between ‘concepts’ and ‘machinery’, and as a result have provided a more compact presentation of thermodynamics with less artificial divisions between the approaches. Similarly, equilibrium electrochemistry now finds a home within the chapter on chemical equilibrium, where space has been made by reducing the discussion of acids and bases.

In Part 2 (Structure) the principal changes are within the chapters, where we have sought to bring into the discussion contemporary techniques of spectroscopy and approaches to computational chemistry. In recognition of the major role that physical chemistry plays in materials science, we have a short sequence of chapters on materials, which deal respectively with hard and soft matter. Moreover, we have introduced concepts of nanoscience throughout much of Part 2.

Part 3 has lost its chapter on dynamic electrochemistry, but not the material. We regard this material as highly important in a contemporary context, but as a final chapter it rarely received the attention it deserves. To make it more readily accessible within the context of courses and to acknowledge that the material it covers is at home intellectually with other material in the book, the description of electron transfer reactions is now a part of the sequence on chemical kinetics and the description of processes at electrodes is now a part of the general discussion of solid surfaces.

We have discarded the Boxes of earlier editions. They have been replaced by more fully integrated and extensive *Impact* sections, which show how physical chemistry is applied to biology, materials, and the environment. By liberating these topics from their boxes, we believe they are more likely to be used and read; there are end-of-chapter problems on most of the material in these sections.

In the preface to the seventh edition we wrote that there was vigorous discussion in the physical chemistry community about the choice of a ‘quantum first’ or a ‘thermodynamics first’ approach. That discussion continues. In response we have paid particular attention to making the organization flexible. The strategic aim of this revision is to make it possible to work through the text in a variety of orders and at the end of this Preface we once again include two suggested road maps.

The concern expressed in the seventh edition about the level of mathematical ability has not evaporated, of course, and we have developed further our strategies for showing the absolute centrality of mathematics to physical chemistry and to make it accessible. Thus, we give more help with the development of equations, motivate

them, justify them, and comment on the steps. We have kept in mind the struggling student, and have tried to provide help at every turn.

We are, of course, alert to the developments in electronic resources and have made a special effort in this edition to encourage the use of the resources on our Web site (at www.whfreeman.com/pchem8) where you can also access the eBook. In particular, we think it important to encourage students to use the *Living graphs* and their considerable extension as *Explorations in Physical Chemistry*. To do so, wherever we call out a *Living graph* (by an icon attached to a graph in the text), we include an *Exploration* in the figure legend, suggesting how to explore the consequences of changing parameters.

Overall, we have taken this opportunity to refresh the text thoroughly, to integrate applications, to encourage the use of electronic resources, and to make the text even more flexible and up to date.

Traditional approach

Molecular approach

About the book

There are numerous features in this edition that are designed to make learning physical chemistry more effective and more enjoyable. One of the problems that make the subject daunting is the sheer amount of information: we have introduced several devices for organizing the material: see **Organizing the information**. We appreciate that mathematics is often troublesome, and therefore have taken care to give help with this enormously important aspect of physical chemistry: see **Mathematics and Physics support**. Problem solving—especially, ‘where do I start?’—is often a challenge, and we have done our best to help overcome this first hurdle: see **Problem solving**. Finally, the web is an extraordinary resource, but it is necessary to know where to start, or where to go for a particular piece of information; we have tried to indicate the right direction: see **About the Web site**. The following paragraphs explain the features in more detail.

Organizing the information

Checklist of key ideas

☐ 1. A gas is a form of matter that fills any container it occupies.	☐ 12. The partial pressure of any gas i is $x_i p$, where $x_i = n_i/n$ is its mole fraction in a mixture of gases at pressure p .
☐ 2. An equation of state interrelates pressure, volume, temperature, and amount of substance: $p = f(T, V, n)$.	☐ 13. In real gases, molecular interactions are important; the true equation of state is $p = p(T, V, n)$, with coefficients $B, C, \dots$: $pV_m = RT(1 + B/V_m + C/V_m^2 + \dots)$.
☐ 3. The pressure is the force divided by the area to which the force is applied. The standard pressure is $p^\circ = 1 \text{ bar}$ (10^5 Pa).	☐ 14. The vapour pressure is the pressure of a gas in equilibrium with its condensed phase.
☐ 4. Mechanical equilibrium is the condition of equality of pressure on either side of a movable wall.	☐ 15. The critical point is the point at the end of the horizontal part of the p - V isotherm. The critical constants are p_c, V_c, T_c .
☐ 5. Temperature is the property that indicates the direction of the flow of energy through a thermally conducting, rigid wall.	☐ 16. A supercritical fluid is a dense fluid above its critical temperature and pressure.
☐ 6. A diathermic boundary is a boundary that permits the passage of energy as heat. An adiabatic boundary is a boundary that prevents the passage of energy as heat.	☐ 17. The van der Waals equation of state is $p = nRT/(V - nb) - a(n/V)^2$, where a and b are parameters.
☐ 7. Thermal equilibrium is a condition in which no change of state occurs when two objects A and B are in contact through a diathermic boundary.	☐ 18. A reduced variable is the actual variable divided by its corresponding critical constant.
☐ 8. The Zeroth Law of thermodynamics states that, if A is in thermal equilibrium with B, and B is in thermal equilibrium with C, then C is also in thermal equilibrium with A.	
☐ 9. The Celsius and thermodynamic temperature scales are related by $T/K = \theta/^\circ\text{C} + 273.15$.	
☐ 10. A perfect gas obeys the perfect gas equation, $pV = nRT$, exactly.	

Checklist of key ideas

Here we collect together the major concepts introduced in the chapter. We suggest checking off the box that precedes each entry when you feel confident about the topic.

IMPACT ON NANOSCIENCE 120.2 Nanowires

We have already remarked (Impacts 19.1, 19.2, and 119.3) that research on nanometre-sized materials is motivated by the possibility that they will form the basis for cheaper and smaller electronic devices. The synthesis of *nanowires*, nanometre-sized atomic assemblies that conduct electricity, is a major step in the fabrication of nanodevices. An important type of nanowire is based on carbon nanotubes, which, like graphite, can conduct electrons through delocalized π molecular orbitals that form from unhybridized $2p$ orbitals on carbon. Recent studies have shown a correlation between structure and conductivity in single-walled nanotubes (SWNTs) that does not occur in graphite. The SWNT in Fig. 20.45 is a semiconductor. If the hexagons are rotated by 60° about their sixfold axis, the resulting SWNT is a metallic conductor.

Carbon nanotubes are promising building blocks not only because they have useful electrical properties but also because they have unusual mechanical properties. For example, an SWNT has a Young's modulus that is approximately five times larger and a tensile strength that is approximately 375 times larger than that of steel.

Silicon nanowires can be made by focusing a pulsed laser beam on to a solid target composed of silicon and iron. The laser ejects Fe and Si atoms from the surface of the

Impact sections

Where appropriate, we have separated the principles from their applications: the principles are constant and straightforward; the applications come and go as the subject progresses. The *Impact* sections show how the principles developed in the chapter are currently being applied in a variety of modern contexts.

A note on good practice We write $T = 0$, not $T = 0\text{ K}$ for the zero temperature on the thermodynamic temperature scale. This scale is absolute, and the lowest temperature is 0 regardless of the size of the divisions on the scale (just as we write $p = 0$ for zero pressure, regardless of the size of the units we adopt, such as bar or pascal). However, we write 0°C because the Celsius scale is not absolute.

5.8 The activities of regular solutions

The material on regular solutions presented in Section 5.4 gives further insight into the origin of deviations from Raoult's law and its relation to activity coefficients. The starting point is the expression for the Gibbs energy of mixing for a regular solution (eqn 5.31). We show in the following *Justification* that eqn 5.31 implies that the activity coefficients are given by expressions of the form

$$\ln \gamma_A = \beta x_B^2 \quad \ln \gamma_B = \beta x_A^2 \quad (5.57)$$

These relations are called the **Margules equations**.

Justification 5.4 The Margules equations

The Gibbs energy of mixing to form a nonideal solution is

$$\Delta_{\text{mix}}G = nRT\{x_A \ln a_A + x_B \ln a_B\}$$

This relation follows from the derivation of eqn 5.31 with activities in place of mole fractions. If each activity is replaced by γx , this expression becomes

$$\Delta_{\text{mix}}G = nRT\{x_A \ln x_A + x_B \ln x_B + x_A \ln \gamma_A + x_B \ln \gamma_B\}$$

Now we introduce the two expressions in eqn 5.57, and use $x_A + x_B = 1$, which gives

$$\begin{aligned} \Delta_{\text{mix}}G &= nRT\{x_A \ln x_A + x_B \ln x_B + \beta x_A x_B^2 + \beta x_B x_A^2\} \\ &= nRT\{x_A \ln x_A + x_B \ln x_B + \beta x_A x_B (x_A + x_B)\} \\ &= nRT\{x_A \ln x_A + x_B \ln x_B + \beta x_A x_B\} \end{aligned}$$

as required by eqn 5.31. Note, moreover, that the activity coefficients behave correctly for dilute solutions: $\gamma_A \rightarrow 1$ as $x_B \rightarrow 0$ and $\gamma_B \rightarrow 1$ as $x_A \rightarrow 0$.

Notes on good practice

Science is a precise activity and its language should be used accurately. We have used this feature to help encourage the use of the language and procedures of science in conformity to international practice and to help avoid common mistakes.

Justifications

On first reading it might be sufficient to appreciate the 'bottom line' rather than work through detailed development of a mathematical expression. However, mathematical development is an intrinsic part of physical chemistry, and it is important to see how a particular expression is obtained. The *Justifications* let you adjust the level of detail that you require to your current needs, and make it easier to review material.

Molecular interpretation 5.2 The lowering of vapour pressure of a solvent in a mixture

The molecular origin of the lowering of the chemical potential is not the energy of interaction of the solute and solvent particles, because the lowering occurs even in an ideal solution (for which the enthalpy of mixing is zero). If it is not an enthalpy effect, it must be an entropy effect.

The pure liquid solvent has an entropy that reflects the number of microstates available to its molecules. Its vapour pressure reflects the tendency of the solution towards greater entropy, which can be achieved if the liquid vaporizes to form a gas. When a solute is present, there is an additional contribution to the entropy of the liquid, even in an ideal solution. Because the entropy of the liquid is already higher than that of the pure liquid, there is a weaker tendency to form the gas (Fig. 5.22). The effect of the solute appears as a lowered vapour pressure, and hence a higher boiling point.

Similarly, the enhanced molecular randomness of the solution opposes the tendency to freeze. Consequently, a lower temperature must be reached before equilibrium between solid and solution is achieved. Hence, the freezing point is lowered.

Molecular interpretation sections

Historically, much of the material in the first part of the text was developed before the emergence of detailed models of atoms, molecules, and molecular assemblies. The *Molecular interpretation* sections enhance and enrich coverage of that material by explaining how it can be understood in terms of the behaviour of atoms and molecules.

Further information

Further information 5.1 *The Debye–Hückel theory of ionic solutions*

Imagine a solution in which all the ions have their actual positions, but in which their Coulombic interactions have been turned off. The difference in molar Gibbs energy between the ideal and real solutions is equal to w_c , the electrical work of charging the system in this arrangement. For a salt M_pX_q , we write

$$w_c = \overbrace{(p\mu_+ + q\mu_-)}^{G_m} - \overbrace{(p\mu_+^{\text{ideal}} + q\mu_-^{\text{ideal}})}^{G_m^{\text{ideal}}} \\ = p(\mu_+ - \mu_+^{\text{ideal}}) + q(\mu_- - \mu_-^{\text{ideal}})$$

From eqn 5.64 we write

$$\mu_+ - \mu_+^{\text{ideal}} = \mu_- - \mu_-^{\text{ideal}} = RT \ln \gamma_{\pm}$$

So it follows that

$$\ln \gamma_{\pm} = \frac{w_c}{sRT} \quad s = p + q \tag{5.73}$$

This equation tells us that we must first find the final distribution of the ions and then the work of charging them in that distribution.

The Coulomb potential at a distance r from an isolated ion of charge $z_i e$ in a medium of permittivity ϵ is

$$\phi_i = \frac{Z_i}{r} \quad Z_i = \frac{z_i e}{4\pi\epsilon} \tag{5.74}$$

The ionic atmosphere causes the potential to decay with distance more sharply than this expression implies. Such shielding is a familiar problem in electrostatics, and its effect is taken into account by replacing the Coulomb potential by the **shielded Coulomb potential**, an expression of the form

$$\phi_i = \frac{Z_i}{r} e^{-r/r_D} \tag{5.75}$$

where r_D is called the **Debye length**. When the Debye length is small, the shielded potential is much smaller than the unshielded potential, even for short distances (Fig. 5.36).

Fig. 5.36 The variation of the shielded Coulomb potential with distance for different values of the Debye length, r_D . The more sharply the potential decays, the smaller r_D is. a is an arbitrary unit of length.

Exploration Write an expression for the unshielded and shielded Coulomb potentials. Then plot this expression against r_D and interpret the shape of the plot.

A2.6 Partial derivatives

A **partial derivative** of a function of more than one variable with respect to one of the variables, all the other variables being held constant (see Fig. 2.4). Although a partial derivative shows how one variable changes, it may be used to determine how more than one variable changes by an infinitesimal amount of x and y , then when x and y change by dx and dy , respectively,

$$df = \left(\frac{\partial f}{\partial x} \right)_y dx + \left(\frac{\partial f}{\partial y} \right)_x dy$$

where the symbol ∂ is used (instead of d) to denote a partial derivative. df is also called the **differential** of f . For example, if $f = ax^3 + by^2$,

$$\left(\frac{\partial f}{\partial x} \right)_y = 3ax^2y \quad \left(\frac{\partial f}{\partial y} \right)_x = 2by$$

Further information

In some cases, we have judged that a derivation is too long, too detailed, or too different in level for it to be included in the text. In these cases, the derivations will be found less obtrusively at the end of the chapter.

Appendices

Physical chemistry draws on a lot of background material, especially in mathematics and physics. We have included a set of *Appendices* to provide a quick survey of some of the information relating to units, physics, and mathematics that we draw on in the text.

Table 2.8 Expansion coefficients, α , and isothermal compressibilities, κ_T

	$\alpha / (10^{-4} \text{ K}^{-1})$	$\kappa_T / (10^{-6} \text{ atm}^{-1})$
Liquids

s: sublimates.
Data: AIP, JL, and M.W. Zemansky, *Heat and Thermodynamics*, 1967.

Synoptic tables and the Data section

Long tables of data are helpful for assembling and solving exercises and problems, but can break up the flow of the text. We provide a lot of data in the *Data section* at the end of the text and short extracts in the *Synoptic tables* in the text itself to give an idea of the typical values of the physical quantities we are introducing.

Mathematics and Physics support

Comment 1.2

A hyperbola is a curve obtained by plotting y against x with $xy = \text{constant}$.

Comment 2.5

The partial-differential operation $(\partial z / \partial x)_y$, consists of taking the first derivative of $z(x, y)$ with respect to x , treating y as a constant. For example, if $z(x, y) = x^2 y$, then

$$\left(\frac{\partial z}{\partial x} \right)_y = \left(\frac{\partial [x^2 y]}{\partial x} \right)_y = y \frac{dx^2}{dx} = 2yx$$

Partial derivatives are reviewed in [Appendix 2](#).

Comments

A topic often needs to draw on a mathematical procedure or a concept of physics; a *Comment* is a quick reminder of the procedure or concept.

Appendices

There is further information on mathematics and physics in Appendices 2 and 3, respectively. These appendices do not go into great detail, but should be enough to act as reminders of topics learned in other courses.

Classical mechanics

Classical mechanics describes the behaviour of objects in terms of forces. It expresses the fact that the total energy is constant in the absence of external forces. It also expresses the response of particles to the forces acting on them.

A3.3 The trajectory in terms of the energy

The **velocity**, v , of a particle is the rate of change of its position with time.

$$v = \frac{dr}{dt}$$

The velocity is a vector, with both direction and magnitude. The speed is the magnitude of the velocity. The **linear momentum**, p , of a particle is the product of its mass, m , and its velocity, v , by

$$p = mv$$

Like the velocity vector, the linear momentum vector points in the same direction as the velocity vector (Fig. A3.1). In terms of the linear momentum, the kinetic energy of a particle is

A3.1 The linear momentum of a particle is a vector property and points in the direction of motion.

Problem solving

Illustration 5.2 Using Henry's law

To estimate the molar solubility of oxygen in water at 25°C and a partial pressure of 21 kPa, its partial pressure in the atmosphere at sea level, we write

$$b_{\text{O}_2} = \frac{p_{\text{O}_2}}{K_{\text{O}_2}} = \frac{21 \text{ kPa}}{7.9 \times 10^4 \text{ kPa kg mol}^{-1}} = 2.9 \times 10^{-4} \text{ mol kg}^{-1}$$

The molality of the saturated solution is therefore 0.29 mmol kg⁻¹. To convert this quantity to a molar concentration, we assume that the mass density of this dilute solution is essentially that of pure water at 25°C, or $\rho_{\text{H}_2\text{O}} = 0.99709 \text{ kg dm}^{-3}$. It follows that the molar concentration of oxygen is

$$[\text{O}_2] = b_{\text{O}_2} \times \rho_{\text{H}_2\text{O}} = 0.29 \text{ mmol kg}^{-1} \times 0.99709 \text{ kg dm}^{-3} = 0.29 \text{ mmol dm}^{-3}$$

A note on good practice The number of significant figures in the result of a calculation should not exceed the number in the data (only two in this case).

Self-test 5.5 Calculate the molar solubility of nitrogen in water exposed to air at 25°C; partial pressures were calculated in [Example 1.3](#). [0.51 mmol dm⁻³]

Illustrations

An *Illustration* (don't confuse this with a diagram!) is a short example of how to use an equation that has just been introduced in the text. In particular, we show how to use data and how to manipulate units correctly.

Example 8.1 Calculating the number of photons

Calculate the number of photons emitted by a 100 W yellow lamp in 1.0 s. Take the wavelength of yellow light as 560 nm and assume 100 per cent efficiency.

Method Each photon has an energy $h\nu$, so the total number of photons needed to produce an energy E is $E/h\nu$. To use this equation, we need to know the frequency of the radiation (from $\nu = c/\lambda$) and the total energy emitted by the lamp. The latter is given by the product of the power (P , in watts) and the time interval for which the lamp is turned on ($E = P\Delta t$).

Answer The number of photons is

$$N = \frac{E}{h\nu} = \frac{P\Delta t}{h(c/\lambda)} = \frac{\lambda P\Delta t}{hc}$$

Substitution of the data gives

$$N = \frac{(5.60 \times 10^{-7} \text{ m}) \times (100 \text{ J s}^{-1}) \times (1.0 \text{ s})}{(6.626 \times 10^{-34} \text{ J s}) \times (2.998 \times 10^8 \text{ m s}^{-1})} = 2.8 \times 10^{20}$$

Note that it would take nearly 40 min to produce 1 mol of these photons.

A note on good practice To avoid rounding and other numerical errors, it is best to carry out algebraic manipulations first, and to substitute numerical values into a single, final formula. Moreover, an analytical result may be used for other data without having to repeat the entire calculation.

Self-test 8.1 How many photons does a monochromatic (single frequency) infrared rangefinder of power 1 mW and wavelength 1000 nm emit in 0.1 s?
[5×10^{14}]

Self-test 3.12 Calculate the change in G_m for ice at -10°C , with density 917 kg m^{-3} , when the pressure is increased from 1.0 bar to 2.0 bar.
[$+2.0 \text{ J mol}^{-1}$]

Discussion questions

1.1 Explain how the perfect gas equation of state arises by combination of Boyle's law, Charles's law, and Avogadro's principle. 1.2 Explain the term 'partial pressure' and explain why Dalton's law is a limiting law. 1.3 Explain how the compression factor varies with pressure and temperature and describe how it reveals information about intermolecular interactions in real gases.	1.4 What is the significance of the critical temperature and pressure? 1.5 Describe the formulation of the van der Waals equation of state and the rationale for one other equation of state in terms of intermolecular interactions. 1.6 Explain how the van der Waals equation of state can be used to predict the behaviour of real gases.

Worked examples

A *Worked example* is a much more structured form of *Illustration*, often involving a more elaborate procedure. Every *Worked example* has a Method section to suggest how to set up the problem (another way might seem more natural: setting up problems is a highly personal business). Then there is the worked-out Answer.

Self-tests

Each *Worked example*, and many of the *Illustrations*, has a *Self-test*, with the answer provided as a check that the procedure has been mastered. There are also free-standing *Self-tests* where we thought it a good idea to provide a question to check understanding. Think of *Self-tests* as in-chapter *Exercises* designed to help monitor your progress.

Discussion questions

The end-of-chapter material starts with a short set of questions that are intended to encourage reflection on the material and to view it in a broader context than is obtained by solving numerical problems.

Exercises

14.1a The term symbol for the ground state of N_2^+ is $^2\Sigma_g^+$. What is the total spin and total orbital angular momentum of the molecule? Show that the term symbol agrees with the electron configuration that would be predicted using the building-up principle.

14.1b One of the excited states of the C_2 molecule has the valence electron configuration $1\sigma_g^2 1\sigma_g^2 1\pi_u^2 1\pi_u^1$. Give the multiplicity and parity of the term.

14.2a The molar absorption coefficient of a substance dissolved in hexane is known to be $855 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$ at 270 nm. Calculate the percentage reduction in intensity when light of that wavelength passes through 2.5 mm of a solution of concentration $3.25 \text{ mmol dm}^{-3}$.

14.2b The molar absorption coefficient of a substance dissolved in hexane is known to be $327 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$ at 300 nm. Calculate the percentage reduction in intensity when light of that wavelength passes through 1.50 mm of a solution of concentration $2.22 \text{ mmol dm}^{-3}$.

14.3a A solution of an unknown component of a biological sample when placed in an absorption cell of path length 1.00 cm transmits 20.1 per cent of light of 340 nm incident upon it. If the concentration of the component is $0.111 \text{ mmol dm}^{-3}$, what is the molar absorption coefficient?

14.3b When light of wavelength 400 nm passes through 3.5 mm of a solution of an absorbing substance at a concentration $0.667 \text{ mmol dm}^{-3}$, the transmission is 65.5 per cent. Calculate the molar absorption coefficient of the solute at this wavelength and express the answer in $\text{cm}^2 \text{ mol}^{-1}$.

Fig. 14.49

14.7b The following data were obtained for the molar absorption coefficient of a dye in methylbenzene using a 2.50 mm cell. Calculate the molar absorption coefficient of the dye at the wavelength employed.

[dye]/(mol dm ⁻³)	0.0010	0.0050	0.0100
<i>T</i> /(per cent)	73	21	4.1

Problems

Assume all gases are perfect unless stated otherwise. Note that 1 atm = 1.013 25 bar. Unless otherwise stated, thermochemical data are for 298.15 K.

Numerical problems

2.1 A sample consisting of 1 mol of perfect gas atoms (for which $C_{V,m} = \frac{5}{2}R$) is taken through the cycle shown in Fig. 2.34. (a) Determine the temperature at the points 1, 2, and 3. (b) Calculate q , w , ΔU , and ΔH for each step and for the overall cycle. If a numerical answer cannot be obtained from the information given, then write in +, -, 0, or ? as appropriate.

Fig. 2.34

2.2 A sample consisting of 1.0 mol $\text{CaCO}_3(\text{s})$ was heated to 800°C , when it decomposed. The heating was carried out in a container fitted with a piston that was initially resting on the solid. Calculate the work done during complete decomposition at 1.0 atm. What work would be done if instead of having a piston the container was open to the atmosphere?

Table 2.2. Calculate the standard enthalpy of formation of $\text{C}_2\text{H}_5\text{OH}(\text{l})$ from its value at 298 K.

2.8 A sample of the sugar D-ribose ($\text{C}_5\text{H}_{10}\text{O}_5$) in a calorimeter and then ignited in the presence of oxygen. The temperature rose by 0.910 K . In a separate experiment the combustion of 0.825 g of benzoic acid, for which the combustion is $-3251 \text{ kJ mol}^{-1}$, gave a temperature rise of 0.891 K . Calculate the internal energy of combustion of D-ribose.

2.9 The standard enthalpy of formation of bis(benzene)chromium was measured in a calorimeter. The reaction $\text{Cr}(\text{C}_6\text{H}_6)_2(\text{s}) \rightarrow \text{Cr}(\text{s}) + 2 \text{C}_6\text{H}_6(\text{g})$ was studied. Find the corresponding reaction enthalpy and the standard enthalpy of formation of the compound at 583 K . The heat capacity of benzene is $136.1 \text{ J K}^{-1} \text{ mol}^{-1}$ at 298 K and $81.67 \text{ J K}^{-1} \text{ mol}^{-1}$ as a gas.

2.10† From the enthalpy of combustion data for alkanes from methane through octane, test the expression $\Delta_c H^\circ = k[(M/(\text{g mol}^{-1}))^a]$ holds and find the value of k . Predict $\Delta_c H^\circ$ for decane and compare to the experimental value.

2.11 It is possible to investigate the thermodynamic properties of hydrocarbons with molecular modelling methods. Use software to predict $\Delta_c H^\circ$ values for the alkanes from methane through octane. Calculate $\Delta_c H^\circ$ values, estimate the standard enthalpy of formation of $\text{C}_n\text{H}_{2n+2}(\text{g})$ by performing semi-empirical calculations (or PM3 methods) and use experimental standard values for $\text{CO}_2(\text{g})$ and $\text{H}_2\text{O}(\text{l})$. (b) Compare experimental values of $\Delta_c H^\circ$ (Table 2.5) and the molecular modelling method. (c) Test the expression $\Delta_c H^\circ = k[(M/(\text{g mol}^{-1}))^a]$ holds and find the value of k .

Exercises and Problems

The real core of testing understanding is the collection of end-of-chapter *Exercises* and *Problems*. The *Exercises* are straightforward numerical tests that give practice with manipulating numerical data. The *Problems* are more searching. They are divided into 'numerical', where the emphasis is on the manipulation of data, and 'theoretical', where the emphasis is on the manipulation of equations before (in some cases) using numerical data. At the end of the *Problems* are collections of problems that focus on practical applications of various kinds, including the material covered in the *Impact* sections.

About the Web site

The Web site to accompany *Physical Chemistry* is available at:

www.whfreeman.com/pchem8

It includes the following features:

Living graphs

A *Living graph* is indicated in the text by the icon  attached to a graph. This feature can be used to explore how a property changes as a variety of parameters are changed. To encourage the use of this resource (and the more extensive *Explorations in Physical Chemistry*) we have added a question to each figure where a *Living graph* is called out.

Artwork

An instructor may wish to use the illustrations from this text in a lecture. Almost all the illustrations are available and can be used for lectures without charge (but not for commercial purposes without specific permission). This edition is in full colour: we have aimed to use colour systematically and helpfully, not just to make the page prettier.

Tables of data

All the tables of data that appear in the chapter text are available and may be used under the same conditions as the figures.

Web links

There is a huge network of information available about physical chemistry, and it can be bewildering to find your way to it. Also, a piece of information may be needed that we have not included in the text. The web site might suggest where to find the specific data or indicate where additional data can be found.

Tools

Interactive calculators, plotters and a periodic table for the study of chemistry.

Group theory tables

Comprehensive group theory tables are available for downloading.

Explorations in Physical Chemistry

Now from W.H. Freeman & Company, the new edition of the popular *Explorations in Physical Chemistry* is available on-line at www.whfreeman.com/explorations, using the activation code card included with *Physical Chemistry* 8e. The new edition consists of interactive Mathcad® worksheets and, for the first time, interactive Excel® workbooks. They motivate students to simulate physical, chemical, and biochemical phenomena with their personal computers. Harnessing the computational power of Mathcad® by Mathsoft, Inc. and Excel® by Microsoft Corporation, students can manipulate over 75 graphics, alter simulation parameters, and solve equations to gain deeper insight into physical chemistry. Complete with thought-stimulating exercises, *Explorations in Physical Chemistry* is a perfect addition to any physical chemistry course, using any physical chemistry text book.

The Physical Chemistry, Eighth Edition eBook

A complete online version of the textbook. The eBook offers students substantial savings and provides a rich learning experience by taking full advantage of the electronic medium

integrating all student media resources and adds features unique to the eBook. The eBook also offers instructors unparalleled flexibility and customization options not previously possible with any printed textbook. Access to the eBook is included with purchase of the special package of the text (0-7167-8586-2), through use of an activation code card. Individual eBook copies can be purchased on-line at www.whfreeman.com.

Key features of the eBook include:

- Easy access from any Internet-connected computer via a standard Web browser.
- Quick, intuitive navigation to any section or subsection, as well as any printed book page number.
- Integration of all Living Graph animations.
- Text **highlighting**, down to the level of individual phrases.
- A **book marking** feature that allows for quick reference to any page.
- A powerful **Notes** feature that allows students or instructors to add notes to any page.
- A full **index**.
- **Full-text search**, including an option to also search the glossary and index.
- Automatic saving of all notes, highlighting, and bookmarks.

Additional features for lecturers:

- Custom chapter selection: Lecturers can choose the chapters that correspond with their syllabus, and students will get a custom version of the eBook with the selected chapters only.
- Instructor notes: Lecturers can choose to create an annotated version of the eBook with their notes on any page. When students in their course log in, they will see the lecturer's version.
- Custom content: Lecturer notes can include text, web links, and even images, allowing lecturers to place any content they choose exactly where they want it.

Physical Chemistry is now available in two volumes!

For maximum flexibility in your physical chemistry course, this text is now offered as a traditional, full text or in two volumes. The chapters from *Physical Chemistry*, 8e that appear in each volume are as follows:

Volume 1: Thermodynamics and Kinetics (0-7167-8567-6)

1. The properties of gases
2. The first law

3. The second law
4. Physical transformations of pure substances
5. Simple mixtures
6. Phase diagrams
7. Chemical equilibrium

21. Molecules in motion
22. The rates of chemical reactions
23. The kinetics of complex reactions
24. Molecular reaction dynamics

Data section

Answers to problems

Index

Volume 2: Quantum Chemistry, Spectroscopy, and Statistical Thermodynamics (0-7167-8569-2)

8. Quantum theory: introduction and principles
9. Quantum theory: techniques and applications

10. Atomic structure and atomic spectra
11. Molecular structure
12. Molecular symmetry
13. Spectroscopy 1: rotational and vibrational spectra
14. Spectroscopy 2: electronic transitions
15. Spectroscopy 3: magnetic resonance
16. Statistical thermodynamics: the concepts
17. Statistical thermodynamics: the machinery

Solutions manuals

As with previous editions Charles Trapp, Carmen Giunta, and Marshall Cady have produced the solutions manuals to accompany this book. A *Student's Solutions Manual* (0-7167-6206-4) provides full solutions to the 'a' exercises and the odd-numbered problems. An *Instructor's Solutions Manual* (0-7167-2566-5) provides full solutions to the 'b' exercises and the even-numbered problems.

About the authors

Julio de Paula is Professor of Chemistry and Dean of the College of Arts & Sciences at Lewis & Clark College. A native of Brazil, Professor de Paula received a B.A. degree in chemistry from Rutgers, The State University of New Jersey, and a Ph.D. in biophysical chemistry from Yale University. His research activities encompass the areas of molecular spectroscopy, biophysical chemistry, and nanoscience. He has taught courses in general chemistry, physical chemistry, biophysical chemistry, instrumental analysis, and writing.

Peter Atkins is Professor of Chemistry at Oxford University, a fellow of Lincoln College, and the author of more than fifty books for students and a general audience. His texts are market leaders around the globe. A frequent lecturer in the United States and throughout the world, he has held visiting professorships in France, Israel, Japan, China, and New Zealand. He was the founding chairman of the Committee on Chemistry Education of the International Union of Pure and Applied Chemistry and a member of IUPAC's Physical and Biophysical Chemistry Division.

Acknowledgements

A book as extensive as this could not have been written without significant input from many individuals. We would like to reiterate our thanks to the hundreds of people who contributed to the first seven editions. Our warm thanks go Charles Trapp, Carmen Giunta, and Marshall Cady who have produced the *Solutions manuals* that accompany this book.

Many people gave their advice based on the seventh edition, and others reviewed the draft chapters for the eighth edition as they emerged. We therefore wish to thank the following colleagues most warmly:

Joe Addison, Governors State University
Joseph Alia, University of Minnesota Morris
David Andrews, University of East Anglia
Mike Ashfold, University of Bristol
Daniel E. Autrey, Fayetteville State University
Jeffrey Bartz, Kalamazoo College
Martin Bates, University of Southampton
Roger Bickley, University of Bradford
E.M. Blokhuis, Leiden University
Jim Bowers, University of Exeter
Mark S. Braiman, Syracuse University
Alex Brown, University of Alberta
David E. Budil, Northeastern University
Dave Cook, University of Sheffield
Ian Cooper, University of Newcastle-upon-Tyne
T. Michael Duncan, Cornell University
Christer Elvingson, Uppsala University
Cherice M. Evans, Queens College—CUNY
Stephen Fletcher, Loughborough University
Alyx S. Frantzen, Stephen F. Austin State University
David Gardner, Lander University
Roberto A. Garza-López, Pomona College
Robert J. Gordon, University of Illinois at Chicago
Pete Griffiths, Cardiff University
Robert Haines, University of Prince Edward Island
Ron Haines, University of New South Wales
Arthur M. Halpern, Indiana State University
Tom Halstead, University of York
Todd M. Hamilton, Adrian College
Gerard S. Harbison, University Nebraska at Lincoln
Ulf Henriksson, Royal Institute of Technology, Sweden
Mike Hey, University of Nottingham
Paul Hodgkinson, University of Durham
Robert E. Howard, University of Tulsa
Mike Jezercak, University of Central Oklahoma
Clarence Josefson, Millikin University
Pramesh N. Kapoor, University of Delhi
Peter Karadakov, University of York

Miklos Kertesz, Georgetown University
Neil R. Kestner, Louisiana State University

Terence E. Warner, University of Southern Denmark

Richard Wells, University of Aberdeen
Ben Whitaker, University of Leeds
Christopher Whitehead, University of Manchester
Mark Wilson, University College London
Kazushige Yokoyama, State University of New York at Geneseo
Nigel Young, University of Hull
Sidney H. Young, University of South Alabama

We also thank Fabienne Meyers (of the IUPAC Secretariat) for helping us to bring colour to most of the illustrations and doing so on a very short timescale. We would also like to thank our two publishers, Oxford University Press and W.H. Freeman & Co., for their constant encouragement, advice, and assistance, and in particular our editors Jonathan Crowe, Jessica Fiorillo, and Ruth Hughes. Authors could not wish for a more congenial publishing environment.

PART 1 Equilibrium

Part 1 of the text develops the concepts that are needed for the discussion of equilibria in chemistry. Equilibria include physical change, such as fusion and vaporization, and chemical change, including electrochemistry. The discussion is in terms of thermodynamics, and particularly in terms of enthalpy and entropy. We see that we can obtain a unified view of equilibrium and the direction of spontaneous change in terms of the chemical potentials of substances. The chapters in Part 1 deal with the bulk properties of matter; those of Part 2 will show how these properties stem from the behaviour of individual atoms.

The properties of gases

1

This chapter establishes the properties of gases that will be used throughout the text. It begins with an account of an idealized version of a gas, a perfect gas, and shows how its equation of state may be assembled experimentally. We then see how the properties of real gases differ from those of a perfect gas, and construct an equation of state that describes their properties.

The simplest state of matter is a **gas**, a form of matter that fills any container it occupies. Initially we consider only pure gases, but later in the chapter we see that the same ideas and equations apply to mixtures of gases too.

The perfect gas

We shall find it helpful to picture a gas as a collection of molecules (or atoms) in continuous random motion, with average speeds that increase as the temperature is raised. A gas differs from a liquid in that, except during collisions, the molecules of a gas are widely separated from one another and move in paths that are largely unaffected by intermolecular forces.

1.1 The states of gases

The **physical state** of a sample of a substance, its physical condition, is defined by its physical properties. Two samples of a substance that have the same physical properties are in the same state. The state of a pure gas, for example, is specified by giving its volume, V , amount of substance (number of moles), n , pressure, p , and temperature, T . However, it has been established experimentally that it is sufficient to specify only three of these variables, for then the fourth variable is fixed. That is, it is an experimental fact that each substance is described by an **equation of state**, an equation that interrelates these four variables.

The general form of an equation of state is

$$p = f(T, V, n) \quad (1.1)$$

This equation tells us that, if we know the values of T , V , and n for a particular substance, then the pressure has a fixed value. Each substance is described by its own equation of state, but we know the explicit form of the equation in only a few special cases. One very important example is the equation of state of a ‘perfect gas’, which has the form $p = nRT/V$, where R is a constant. Much of the rest of this chapter will examine the origin of this equation of state and its applications.

Table 1.1 Pressure units

Name	Symbol	Value
pascal	1 Pa	1 N m^{-2} , $1 \text{ kg m}^{-1} \text{ s}^{-2}$
bar	1 bar	10^5 Pa
atmosphere	1 atm	101.325 kPa
torr	1 Torr	$(101\,325/760) \text{ Pa} = 133.32 \dots \text{ Pa}$
millimetres of mercury	1 mmHg	$133.322 \dots \text{ Pa}$
pound per square inch	1 psi	$6.894\,757 \dots \text{ kPa}$

Comment 1.1

The International System of units (SI, from the French *Système International d'Unités*) is discussed in Appendix 1.

Fig. 1.1 When a region of high pressure is separated from a region of low pressure by a movable wall, the wall will be pushed into one region or the other, as in (a) and (c). However, if the two pressures are identical, the wall will not move (b). The latter condition is one of mechanical equilibrium between the two regions.

(a) Pressure

Pressure is defined as force divided by the area to which the force is applied. The greater the force acting on a given area, the greater the pressure. The origin of the force exerted by a gas is the incessant battering of the molecules on the walls of its container. The collisions are so numerous that they exert an effectively steady force, which is experienced as a steady pressure.

The SI unit of pressure, the *pascal* (Pa), is defined as 1 newton per metre-squared:

$$1 \text{ Pa} = 1 \text{ N m}^{-2} \quad [1.2a]$$

In terms of base units,

$$1 \text{ Pa} = 1 \text{ kg m}^{-1} \text{ s}^{-2} \quad [1.2b]$$

Several other units are still widely used (Table 1.1); of these units, the most commonly used are atmosphere ($1 \text{ atm} = 1.013\,25 \times 10^5 \text{ Pa}$ exactly) and bar ($1 \text{ bar} = 10^5 \text{ Pa}$). A pressure of 1 bar is the **standard pressure** for reporting data; we denote it $p^\ominus$.

Self-test 1.1 Calculate the pressure (in pascals and atmospheres) exerted by a mass of 1.0 kg pressing through the point of a pin of area $1.0 \times 10^{-2} \text{ mm}^2$ at the surface of the Earth. *Hint.* The force exerted by a mass m due to gravity at the surface of the Earth is mg , where g is the acceleration of free fall (see endpaper 2 for its standard value). [0.98 GPa, $9.7 \times 10^3 \text{ atm}$]

If two gases are in separate containers that share a common movable wall (Fig. 1.1), the gas that has the higher pressure will tend to compress (reduce the volume of) the gas that has lower pressure. The pressure of the high-pressure gas will fall as it expands and that of the low-pressure gas will rise as it is compressed. There will come a stage when the two pressures are equal and the wall has no further tendency to move. This condition of equality of pressure on either side of a movable wall (a 'piston') is a state of **mechanical equilibrium** between the two gases. The pressure of a gas is therefore an indication of whether a container that contains the gas will be in mechanical equilibrium with another gas with which it shares a movable wall.

(b) The measurement of pressure

The pressure exerted by the atmosphere is measured with a **barometer**. The original version of a barometer (which was invented by Torricelli, a student of Galileo) was an inverted tube of mercury sealed at the upper end. When the column of mercury is in mechanical equilibrium with the atmosphere, the pressure at its base is equal to that

exerted by the atmosphere. It follows that the height of the mercury column is proportional to the external pressure.

Example 1.1 Calculating the pressure exerted by a column of liquid

Derive an equation for the pressure at the base of a column of liquid of mass density ρ (rho) and height h at the surface of the Earth.

Method Pressure is defined as $p = F/A$ where F is the force applied to the area A , and $F = mg$. To calculate F we need to know the mass m of the column of liquid, which is its mass density, ρ , multiplied by its volume, V : $m = \rho V$. The first step, therefore, is to calculate the volume of a cylindrical column of liquid.

Answer Let the column have cross-sectional area A ; then its volume is Ah and its mass is $m = \rho Ah$. The force the column of this mass exerts at its base is

$$F = mg = \rho Ahg$$

The pressure at the base of the column is therefore

$$p = \frac{F}{A} = \frac{\rho Ahg}{A} = \rho gh \quad (1.3)$$

Note that the pressure is independent of the shape and cross-sectional area of the column. The mass of the column of a given height increases as the area, but so does the area on which the force acts, so the two cancel.

Self-test 1.2 Derive an expression for the pressure at the base of a column of liquid of length l held at an angle θ (theta) to the vertical (1). $[p = \rho gl \cos \theta]$

The pressure of a sample of gas inside a container is measured by using a pressure gauge, which is a device with electrical properties that depend on the pressure. For instance, a *Bayard–Alpert pressure gauge* is based on the ionization of the molecules present in the gas and the resulting current of ions is interpreted in terms of the pressure. In a *capacitance manometer*, the deflection of a diaphragm relative to a fixed electrode is monitored through its effect on the capacitance of the arrangement. Certain semiconductors also respond to pressure and are used as transducers in solid-state pressure gauges.

(c) Temperature

The concept of temperature springs from the observation that a change in physical state (for example, a change of volume) can occur when two objects are in contact with one another, as when a red-hot metal is plunged into water. Later (Section 2.1) we shall see that the change in state can be interpreted as arising from a flow of energy as heat from one object to another. The **temperature**, T , is the property that indicates the direction of the flow of energy through a thermally conducting, rigid wall. If energy flows from A to B when they are in contact, then we say that A has a higher temperature than B (Fig. 1.2).

It will prove useful to distinguish between two types of boundary that can separate the objects. A boundary is **diathermic** (thermally conducting) if a change of state is observed when two objects at different temperatures are brought into contact.¹ A

¹ The word dia is from the Greek for ‘through’.

Fig. 1.2 Energy flows as heat from a region at a higher temperature to one at a lower temperature if the two are in contact through a diathermic wall, as in (a) and (c). However, if the two regions have identical temperatures, there is no net transfer of energy as heat even though the two regions are separated by a diathermic wall (b). The latter condition corresponds to the two regions being at thermal equilibrium.

Fig. 1.3 The experience summarized by the Zeroth Law of thermodynamics is that, if an object A is in thermal equilibrium with B and B is in thermal equilibrium with C, then C is in thermal equilibrium with A.

metal container has diathermic walls. A boundary is **adiabatic** (thermally insulating) if no change occurs even though the two objects have different temperatures. A vacuum flask is an approximation to an adiabatic container.

The temperature is a property that indicates whether two objects would be in ‘thermal equilibrium’ if they were in contact through a diathermic boundary. **Thermal equilibrium** is established if no change of state occurs when two objects A to B are in contact through a diathermic boundary. Suppose an object A (which we can think of as a block of iron) is in thermal equilibrium with an object B (a block of copper), and that B is also in thermal equilibrium with another object C (a flask of water). Then it has been found experimentally that A and C will also be in thermal equilibrium when they are put in contact (Fig. 1.3). This observation is summarized by the **Zeroth Law of thermodynamics**:

If A is in thermal equilibrium with B, and B is in thermal equilibrium with C, then C is also in thermal equilibrium with A.

The Zeroth Law justifies the concept of temperature and the use of a **thermometer**, a device for measuring the temperature. Thus, suppose that B is a glass capillary containing a liquid, such as mercury, that expands significantly as the temperature increases. Then, when A is in contact with B, the mercury column in the latter has a certain length. According to the Zeroth Law, if the mercury column in B has the same length when it is placed in thermal contact with another object C, then we can predict that no change of state of A and C will occur when they are in thermal contact. Moreover, we can use the length of the mercury column as a measure of the temperatures of A and C.

In the early days of thermometry (and still in laboratory practice today), temperatures were related to the length of a column of liquid, and the difference in lengths shown when the thermometer was first in contact with melting ice and then with boiling water was divided into 100 steps called ‘degrees’, the lower point being labelled 0. This procedure led to the **Celsius scale** of temperature. In this text, temperatures on the Celsius scale are denoted θ and expressed in *degrees Celsius* ($^{\circ}\text{C}$). However, because different liquids expand to different extents, and do not always expand uniformly over a given range, thermometers constructed from different materials showed different numerical values of the temperature between their fixed points. The pressure of a gas, however, can be used to construct a **perfect-gas temperature scale** that is independent of the identity of the gas. The perfect-gas scale turns out to be identical to the **thermodynamic temperature scale** to be introduced in Section 3.2c, so we shall use the latter term from now on to avoid a proliferation of names. On the thermodynamic temperature scale, temperatures are denoted T and are normally reported in kelvins, K (not $^{\circ}\text{K}$). Thermodynamic and Celsius temperatures are related by the exact expression

$$T/\text{K} = \theta/^{\circ}\text{C} + 273.15 \quad (1.4)$$

This relation, in the form $\theta/^{\circ}\text{C} = T/\text{K} - 273.15$, is the current definition of the Celsius scale in terms of the more fundamental **Kelvin scale**. It implies that a difference in temperature of 1°C is equivalent to a difference of 1 K.

A note on good practice We write $T = 0$, not $T = 0 \text{ K}$ for the zero temperature on the thermodynamic temperature scale. This scale is absolute, and the lowest temperature is 0 regardless of the size of the divisions on the scale (just as we write $p = 0$ for zero pressure, regardless of the size of the units we adopt, such as bar or pascal). However, we write 0°C because the Celsius scale is not absolute.

Illustration 1.1 Converting temperatures

To express 25.00°C as a temperature in kelvins, we use eqn 1.4 to write

$$T/\text{K} = (25.00^\circ\text{C})/^\circ\text{C} + 273.15 = 25.00 + 273.15 = 298.15$$

Note how the units (in this case, °C) are cancelled like numbers. This is the procedure called ‘quantity calculus’ in which a physical quantity (such as the temperature) is the product of a numerical value (25.00) and a unit (1°C). Multiplication of both sides by the unit K then gives $T = 298.15 \text{ K}$.

A note on good practice When the units need to be specified in an equation, the approved procedure, which avoids any ambiguity, is to write (physical quantity)/units, which is a dimensionless number, just as $(25.00^\circ\text{C})/^\circ\text{C} = 25.00$ in this *Illustration*. Units may be multiplied and cancelled just like numbers.

1.2 The gas laws

The equation of state of a gas at low pressure was established by combining a series of empirical laws.

(a) The perfect gas law

We assume that the following individual gas laws are familiar:

Boyle’s law: $pV = \text{constant}$, at constant n , T (1.5)^o

Charles’s law: $V = \text{constant} \times T$, at constant n , p (1.6a)^o

$p = \text{constant} \times T$, at constant n , V (1.6b)^o

Avogadro’s principle:² $V = \text{constant} \times n$ at constant p , T (1.7)^o

Boyle’s and Charles’s laws are examples of a **limiting law**, a law that is strictly true only in a certain limit, in this case $p \rightarrow 0$. Equations valid in this limiting sense will be signalled by a ^o on the equation number, as in these expressions. Avogadro’s principle is commonly expressed in the form ‘equal volumes of gases at the same temperature and pressure contain the same numbers of molecules’. In this form, it is increasingly true as $p \rightarrow 0$. Although these relations are strictly true only at $p = 0$, they are reasonably reliable at normal pressures ($p \approx 1 \text{ bar}$) and are used widely throughout chemistry.

Figure 1.4 depicts the variation of the pressure of a sample of gas as the volume is changed. Each of the curves in the graph corresponds to a single temperature and hence is called an **isotherm**. According to Boyle’s law, the isotherms of gases are hyperbolas. An alternative depiction, a plot of pressure against $1/\text{volume}$, is shown in Fig. 1.5. The linear variation of volume with temperature summarized by Charles’s law is illustrated in Fig. 1.6. The lines in this illustration are examples of **isobars**, or lines showing the variation of properties at constant pressure. Figure 1.7 illustrates the linear variation of pressure with temperature. The lines in this diagram are **isochores**, or lines showing the variation of properties at constant volume.

Fig. 1.4 The pressure–volume dependence of a fixed amount of perfect gas at different temperatures. Each curve is a hyperbola ($pV = \text{constant}$) and is called an *isotherm*.

Exploration³ Explore how the pressure of 1.5 mol $\text{CO}_2(\text{g})$ varies with volume as it is compressed at (a) 273 K, (b) 373 K from 30 dm^3 to 15 dm^3 .

Comment 1.2

A hyperbola is a curve obtained by plotting y against x with $xy = \text{constant}$.

² Avogadro’s principle is a principle rather than a law (a summary of experience) because it depends on the validity of a model, in this case the existence of molecules. Despite there now being no doubt about the existence of molecules, it is still a model-based principle rather than a law.

³ To solve this and other *Explorations*, use either mathematical software or the *Living graphs* from the text’s web site.

Fig. 1.5 Straight lines are obtained when the pressure is plotted against $1/V$ at constant temperature.

 **Exploration** Repeat *Exploration 1.4*, but plot the data as p against $1/V$.

Fig. 1.6 The variation of the volume of a fixed amount of gas with the temperature at constant pressure. Note that in each case the isobars extrapolate to zero volume at $T = 0$, or $\theta = -273^\circ\text{C}$.

 **Exploration** Explore how the volume of 1.5 mol $\text{CO}_2(\text{g})$ in a container maintained at (a) 1.00 bar, (b) 0.50 bar varies with temperature as it is cooled from 373 K to 273 K.

Fig. 1.7 The pressure also varies linearly with the temperature at constant volume, and extrapolates to zero at $T = 0$ (-273°C).

 **Exploration** Explore how the pressure of 1.5 mol $\text{CO}_2(\text{g})$ in a container of volume (a) 30 dm^3 , (b) 15 dm^3 varies with temperature as it is cooled from 373 K to 273 K.

A note on good practice To test the validity of a relation between two quantities, it is best to plot them in such a way that they should give a straight line, for deviations from a straight line are much easier to detect than deviations from a curve.

The empirical observations summarized by eqns 1.5–7 can be combined into a single expression:

$$pV = \text{constant} \times nT$$

This expression is consistent with Boyle's law ($pV = \text{constant}$) when n and T are constant, with both forms of Charles's law ($p \propto T$, $V \propto T$) when n and either V or p are held constant, and with Avogadro's principle ($V \propto n$) when p and T are constant. The constant of proportionality, which is found experimentally to be the same for all gases, is denoted R and called the **gas constant**. The resulting expression

$$pV = nRT \quad (1.8)^\circ$$

is the **perfect gas equation**. It is the approximate equation of state of any gas, and becomes increasingly exact as the pressure of the gas approaches zero. A gas that obeys eqn 1.8 exactly under all conditions is called a **perfect gas** (or *ideal gas*). A **real gas**, an actual gas, behaves more like a perfect gas the lower the pressure, and is described exactly by eqn 1.8 in the limit of $p \rightarrow 0$. The gas constant R can be determined by evaluating $R = pV/nT$ for a gas in the limit of zero pressure (to guarantee that it is

behaving perfectly). However, a more accurate value can be obtained by measuring the speed of sound in a low-pressure gas (argon is used in practice) and extrapolating its value to zero pressure. Table 1.2 lists the values of R in a variety of units.

Table 1.2 The gas constant

R	
8.314 47	$\text{J K}^{-1} \text{mol}^{-1}$

Molecular interpretation 1.1 *The kinetic model of gases*

The molecular explanation of Boyle's law is that, if a sample of gas is compressed to half its volume, then twice as many molecules strike the walls in a given period of time than before it was compressed. As a result, the average force exerted on the walls is doubled. Hence, when the volume is halved the pressure of the gas is doubled, and $p \times V$ is a constant. Boyle's law applies to all gases regardless of their chemical identity (provided the pressure is low) because at low pressures the average separation of molecules is so great that they exert no influence on one another and hence travel independently. The molecular explanation of Charles's law lies in the fact that raising the temperature of a gas increases the average speed of its molecules. The molecules collide with the walls more frequently and with greater impact. Therefore they exert a greater pressure on the walls of the container.

These qualitative concepts are expressed quantitatively in terms of the kinetic model of gases, which is described more fully in Chapter 21. Briefly, the kinetic model is based on three assumptions:

1. The gas consists of molecules of mass m in ceaseless random motion.
2. The size of the molecules is negligible, in the sense that their diameters are much smaller than the average distance travelled between collisions.
3. The molecules interact only through brief, infrequent, and elastic collisions.

An *elastic collision* is a collision in which the total translational kinetic energy of the molecules is conserved. From the very economical assumptions of the kinetic model, it can be deduced (as we shall show in detail in Chapter 21) that the pressure and volume of the gas are related by

$$pV = \frac{1}{3}nMc^2 \quad (1.9)^\circ$$

where $M = mN_A$, the molar mass of the molecules, and c is the *root mean square speed* of the molecules, the square root of the mean of the squares of the speeds, v , of the molecules:

$$c = \langle v^2 \rangle^{1/2} \quad (1.10)$$

We see that, if the root mean square speed of the molecules depends only on the temperature, then at constant temperature

$$pV = \text{constant}$$

which is the content of Boyle's law. Moreover, for eqn 1.9 to be the equation of state of a perfect gas, its right-hand side must be equal to nRT . It follows that the root mean square speed of the molecules in a gas at a temperature T must be

$$c = \left(\frac{3RT}{M} \right)^{1/2} \quad (1.11)^\circ$$

We can conclude that *the root mean square speed of the molecules of a gas is proportional to the square root of the temperature and inversely proportional to the square root of the molar mass*. That is, the higher the temperature, the higher the root mean square speed of the molecules, and, at a given temperature, heavy molecules travel more slowly than light molecules. The root mean square speed of N_2 molecules, for instance, is found from eqn 1.11 to be 515 m s^{-1} at 298 K .

Comment 1.3

For an object of mass m moving at a speed v , the kinetic energy is $E_K = \frac{1}{2}mv^2$. The potential energy, E_P or V , of an object is the energy arising from its position (not speed). No universal expression for the potential energy can be given because it depends on the type of interaction the object experiences.

Fig. 1.8 A region of the p, V, T surface of a fixed amount of perfect gas. The points forming the surface represent the only states of the gas that can exist.

Fig. 1.9 Sections through the surface shown in Fig. 1.8 at constant temperature give the isotherms shown in Fig. 1.4 and the isobars shown in Fig. 1.6.

The surface in Fig. 1.8 is a plot of the pressure of a fixed amount of perfect gas against its volume and thermodynamic temperature as given by eqn 1.8. The surface depicts the only possible states of a perfect gas: the gas cannot exist in states that do not correspond to points on the surface. The graphs in Figs. 1.4 and 1.6 correspond to the sections through the surface (Fig. 1.9).

Example 1.2 Using the perfect gas equation

In an industrial process, nitrogen is heated to 500 K in a vessel of constant volume. If it enters the vessel at 100 atm and 300 K, what pressure would it exert at the working temperature if it behaved as a perfect gas?

Method We expect the pressure to be greater on account of the increase in temperature. The perfect gas law in the form $PV/nT = R$ implies that, if the conditions are changed from one set of values to another, then because PV/nT is equal to a constant, the two sets of values are related by the ‘combined gas law’:

$$\frac{p_1 V_1}{n_1 T_1} = \frac{p_2 V_2}{n_2 T_2} \quad (1.12)^\circ$$

The known and unknown data are summarized in (2).

Answer Cancellation of the volumes (because $V_1 = V_2$) and amounts (because $n_1 = n_2$) on each side of the combined gas law results in

$$\frac{p_1}{T_1} = \frac{p_2}{T_2}$$

which can be rearranged into

$$p_2 = \frac{T_2}{T_1} \times p_1$$

	n	p	V	T
Initial	Same	100	Same	300
Final	Same	?	Same	500

2

Substitution of the data then gives

$$p_2 = \frac{500 \text{ K}}{300 \text{ K}} \times (100 \text{ atm}) = 167 \text{ atm}$$

Experiment shows that the pressure is actually 183 atm under these conditions, so the assumption that the gas is perfect leads to a 10 per cent error.

Self-test 1.3 What temperature would result in the same sample exerting a pressure of 300 atm? [900 K]

The perfect gas equation is of the greatest importance in physical chemistry because it is used to derive a wide range of relations that are used throughout thermodynamics. However, it is also of considerable practical utility for calculating the properties of a gas under a variety of conditions. For instance, the molar volume, $V_m = V/n$, of a perfect gas under the conditions called **standard ambient temperature and pressure** (SATP), which means 298.15 K and 1 bar (that is, exactly 10^5 Pa), is easily calculated from $V_m = RT/p$ to be $24.789 \text{ dm}^3 \text{ mol}^{-1}$. An earlier definition, **standard temperature and pressure** (STP), was 0°C and 1 atm; at STP, the molar volume of a perfect gas is $22.414 \text{ dm}^3 \text{ mol}^{-1}$. Among other applications, eqn 1.8 can be used to discuss processes in the atmosphere that give rise to the weather.

IMPACT ON ENVIRONMENTAL SCIENCE

11.1 The gas laws and the weather

The biggest sample of gas readily accessible to us is the atmosphere, a mixture of gases with the composition summarized in Table 1.3. The composition is maintained moderately constant by diffusion and convection (winds, particularly the local turbulence called *eddies*) but the pressure and temperature vary with altitude and with the local conditions, particularly in the troposphere (the ‘sphere of change’), the layer extending up to about 11 km.

Table 1.3 The composition of dry air at sea level

Component	Percentage	
	By volume	By mass
Nitrogen, N_2	78.08	75.53
Oxygen, O_2	20.95	23.14
Argon, Ar	0.93	1.28
Carbon dioxide, CO_2	0.031	0.047
Hydrogen, H_2	5.0×10^{-3}	2.0×10^{-4}
Neon, Ne	1.8×10^{-3}	1.3×10^{-3}
Helium, He	5.2×10^{-4}	7.2×10^{-5}
Methane, CH_4	2.0×10^{-4}	1.1×10^{-4}
Krypton, Kr	1.1×10^{-4}	3.2×10^{-4}
Nitric oxide, NO	5.0×10^{-5}	1.7×10^{-6}
Xenon, Xe	8.7×10^{-6}	1.2×10^{-5}
Ozone, O_3 : summer	7.0×10^{-6}	1.2×10^{-5}
winter	2.0×10^{-6}	3.3×10^{-6}

Fig. 1.10 The variation of atmospheric pressure with altitude, as predicted by the barometric formula and as suggested by the ‘US Standard Atmosphere’, which takes into account the variation of temperature with altitude.

Exploration How would the graph shown in the illustration change if the temperature variation with altitude were taken into account? Construct a graph allowing for a linear decrease in temperature with altitude.

Fig. 1.11 A typical weather map; in this case, for the United States on 1 January 2000.

Fig. 1.12 The flow of air (‘wind’) around regions of high and low pressure in the Northern and Southern hemispheres.

In the troposphere the average temperature is 15°C at sea level, falling to -57°C at the bottom of the tropopause at 11 km. This variation is much less pronounced when expressed on the Kelvin scale, ranging from 288 K to 216 K, an average of 268 K. If we suppose that the temperature has its average value all the way up to the tropopause, then the pressure varies with altitude, h , according to the *barometric formula*:

$$p = p_0 e^{-h/H}$$

where p_0 is the pressure at sea level and H is a constant approximately equal to 8 km. More specifically, $H = RT/Mg$, where M is the average molar mass of air and T is the temperature. The barometric formula fits the observed pressure distribution quite well even for regions well above the troposphere (see Fig. 1.10). It implies that the pressure of the air and its density fall to half their sea-level value at $h = H \ln 2$, or 6 km.

Local variations of pressure, temperature, and composition in the troposphere are manifest as ‘weather’. A small region of air is termed a *parcel*. First, we note that a parcel of warm air is less dense than the same parcel of cool air. As a parcel rises, it expands adiabatically (that is, without transfer of heat from its surroundings), so it cools. Cool air can absorb lower concentrations of water vapour than warm air, so the moisture forms clouds. Cloudy skies can therefore be associated with rising air and clear skies are often associated with descending air.

The motion of air in the upper altitudes may lead to an accumulation in some regions and a loss of molecules from other regions. The former result in the formation of regions of high pressure (‘highs’ or anticyclones) and the latter result in regions of low pressure (‘lows’, depressions, or cyclones). These regions are shown as H and L on the accompanying weather map (Fig. 1.11). The lines of constant pressure—differing by 4 mbar (400 Pa, about 3 Torr)—marked on it are called *isobars*. The elongated regions of high and low pressure are known, respectively, as *ridges* and *troughs*.

In meteorology, large-scale vertical movement is called *convection*. Horizontal pressure differentials result in the flow of air that we call *wind* (see Fig. 1.12). Winds coming from the north in the Northern hemisphere and from the south in the Southern hemisphere are deflected towards the west as they migrate from a region where the Earth is rotating slowly (at the poles) to where it is rotating most rapidly (at the equator). Winds travel nearly parallel to the isobars, with low pressure to their left in the Northern hemisphere and to the right in the Southern hemisphere. At the surface, where wind speeds are lower, the winds tend to travel perpendicular to the isobars from high to low pressure. This differential motion results in a spiral outward flow of air clockwise in the Northern hemisphere around a high and an inward counter-clockwise flow around a low.

The air lost from regions of high pressure is restored as an influx of air converges into the region and descends. As we have seen, descending air is associated with clear skies. It also becomes warmer by compression as it descends, so regions of high pressure are associated with high surface temperatures. In winter, the cold surface air may prevent the complete fall of air, and result in a temperature *inversion*, with a layer of warm air over a layer of cold air. Geographical conditions may also trap cool air, as in Los Angeles, and the photochemical pollutants we know as *smog* may be trapped under the warm layer.

(b) Mixtures of gases

When dealing with gaseous mixtures, we often need to know the contribution that each component makes to the total pressure of the sample. The **partial pressure**, p_j , of a gas J in a mixture (any gas, not just a perfect gas), is defined as

$$p_j = x_j p \quad [1.13]$$

where x_J is the **mole fraction** of the component J, the amount of J expressed as a fraction of the total amount of molecules, n , in the sample:

$$x_J = \frac{n_J}{n} \quad n = n_A + n_B + \dots \quad [1.14]$$

When no J molecules are present, $x_J = 0$; when only J molecules are present, $x_J = 1$. It follows from the definition of x_J that, whatever the composition of the mixture, $x_A + x_B + \dots = 1$ and therefore that the sum of the partial pressures is equal to the total pressure:

$$p_A + p_B + \dots = (x_A + x_B + \dots)p = p \quad (1.15)$$

This relation is true for both real and perfect gases.

When all the gases are perfect, the partial pressure as defined in eqn 1.13 is also the pressure that each gas would occupy if it occupied the same container alone at the same temperature. The latter is the original meaning of ‘partial pressure’. That identification was the basis of the original formulation of **Dalton’s law**:

The pressure exerted by a mixture of gases is the sum of the pressures that each one would exist if it occupied the container alone.

Now, however, the relation between partial pressure (as defined in eqn 1.13) and total pressure (as given by eqn 1.15) is true for all gases and the identification of partial pressure with the pressure that the gas would exert on its own is valid only for a perfect gas.

Example 1.3 Calculating partial pressures

The mass percentage composition of dry air at sea level is approximately N₂: 75.5; O₂: 23.2; Ar: 1.3. What is the partial pressure of each component when the total pressure is 1.00 atm?

Method We expect species with a high mole fraction to have a proportionally high partial pressure. Partial pressures are defined by eqn 1.13. To use the equation, we need the mole fractions of the components. To calculate mole fractions, which are defined by eqn 1.14, we use the fact that the amount of molecules J of molar mass M_J in a sample of mass m_J is $n_J = m_J/M_J$. The mole fractions are independent of the total mass of the sample, so we can choose the latter to be 100 g (which makes the conversion from mass percentages very easy). Thus, the mass of N₂ present is 75.5 per cent of 100 g, which is 75.5 g.

Answer The amounts of each type of molecule present in 100 g of air, in which the masses of N₂, O₂, and Ar are 75.5 g, 23.2 g, and 1.3 g, respectively, are

$$n(\text{N}_2) = \frac{75.5 \text{ g}}{28.02 \text{ g mol}^{-1}} = \frac{75.5}{28.02} \text{ mol}$$

$$n(\text{O}_2) = \frac{23.2 \text{ g}}{32.00 \text{ g mol}^{-1}} = \frac{23.2}{32.00} \text{ mol}$$

$$n(\text{Ar}) = \frac{1.3 \text{ g}}{39.95 \text{ g mol}^{-1}} = \frac{1.3}{39.95} \text{ mol}$$

These three amounts work out as 2.69 mol, 0.725 mol, and 0.033 mol, respectively, for a total of 3.45 mol. The mole fractions are obtained by dividing each of the

above amounts by 3.45 mol and the partial pressures are then obtained by multiplying the mole fraction by the total pressure (1.00 atm):

	N ₂	O ₂	Ar
Mole fraction:	0.780	0.210	0.0096
Partial pressure/atm:	0.780	0.210	0.0096

We have not had to assume that the gases are perfect: partial pressures are defined as $p_j = x_j p$ for any kind of gas.

Self-test 1.4 When carbon dioxide is taken into account, the mass percentages are 75.52 (N₂), 23.15 (O₂), 1.28 (Ar), and 0.046 (CO₂). What are the partial pressures when the total pressure is 0.900 atm? [0.703, 0.189, 0.0084, 0.00027 atm]

Real gases

Real gases do not obey the perfect gas law exactly. Deviations from the law are particularly important at high pressures and low temperatures, especially when a gas is on the point of condensing to liquid.

1.3 Molecular interactions

Real gases show deviations from the perfect gas law because molecules interact with one another. Repulsive forces between molecules assist expansion and attractive forces assist compression.

Repulsive forces are significant only when molecules are almost in contact: they are short-range interactions, even on a scale measured in molecular diameters (Fig. 1.13). Because they are short-range interactions, repulsions can be expected to be important only when the average separation of the molecules is small. This is the case at high pressure, when many molecules occupy a small volume. On the other hand, attractive intermolecular forces have a relatively long range and are effective over several molecular diameters. They are important when the molecules are fairly close together but not necessarily touching (at the intermediate separations in Fig. 1.13). Attractive forces are ineffective when the molecules are far apart (well to the right in Fig. 1.13). Intermolecular forces are also important when the temperature is so low that the molecules travel with such low mean speeds that they can be captured by one another.

At low pressures, when the sample occupies a large volume, the molecules are so far apart for most of the time that the intermolecular forces play no significant role, and the gas behaves virtually perfectly. At moderate pressures, when the average separation of the molecules is only a few molecular diameters, the attractive forces dominate the repulsive forces. In this case, the gas can be expected to be more compressible than a perfect gas because the forces help to draw the molecules together. At high pressures, when the average separation of the molecules is small, the repulsive forces dominate and the gas can be expected to be less compressible because now the forces help to drive the molecules apart.

(a) The compression factor

The **compression factor**, Z , of a gas is the ratio of its measured molar volume, $V_m = V/n$, to the molar volume of a perfect gas, V_m° , at the same pressure and temperature:

Fig. 1.13 The variation of the potential energy of two molecules on their separation. High positive potential energy (at very small separations) indicates that the interactions between them are strongly repulsive at these distances. At intermediate separations, where the potential energy is negative, the attractive interactions dominate. At large separations (on the right) the potential energy is zero and there is no interaction between the molecules.

$$Z = \frac{V_m}{V_m^o} \quad [1.16]$$

Because the molar volume of a perfect gas is equal to RT/p , an equivalent expression is $Z = RT/pV_m^o$, which we can write as

$$pV_m = RTZ \quad (1.17)$$

Because for a perfect gas $Z = 1$ under all conditions, deviation of Z from 1 is a measure of departure from perfect behaviour.

Some experimental values of Z are plotted in Fig. 1.14. At very low pressures, all the gases shown have $Z \approx 1$ and behave nearly perfectly. At high pressures, all the gases have $Z > 1$, signifying that they have a larger molar volume than a perfect gas. Repulsive forces are now dominant. At intermediate pressures, most gases have $Z < 1$, indicating that the attractive forces are reducing the molar volume relative to that of a perfect gas.

(b) Virial coefficients

Figure 1.15 shows the experimental isotherms for carbon dioxide. At large molar volumes and high temperatures the real-gas isotherms do not differ greatly from perfect-gas isotherms. The small differences suggest that the perfect gas law is in fact the first term in an expression of the form

$$pV_m = RT(1 + B'p + C'p^2 + \dots) \quad (1.18)$$

This expression is an example of a common procedure in physical chemistry, in which a simple law that is known to be a good first approximation (in this case $pV = nRT$) is

Fig. 1.14 The variation of the compression factor, Z , with pressure for several gases at 0°C . A perfect gas has $Z = 1$ at all pressures. Notice that, although the curves approach 1 as $p \rightarrow 0$, they do so with different slopes.

Fig. 1.15 Experimental isotherms of carbon dioxide at several temperatures. The 'critical isotherm', the isotherm at the critical temperature, is at 31.04°C . The critical point is marked with a star.

Comment 1.4

Series expansions are discussed in Appendix 2.

treated as the first term in a series in powers of a variable (in this case p). A more convenient expansion for many applications is

$$pV_m = RT \left(1 + \frac{B}{V_m} + \frac{C}{V_m^2} + \cdots \right) \quad (1.19)$$

These two expressions are two versions of the **virial equation of state**.⁴ By comparing the expression with eqn 1.17 we see that the term in parentheses can be identified with the compression factor, Z .

The coefficients $B, C, \dots$, which depend on the temperature, are the second, third, $\dots$ **virial coefficients** (Table 1.4); the first virial coefficient is 1. The third virial coefficient, C , is usually less important than the second coefficient, B , in the sense that at typical molar volumes $C/V_m^2 \ll B/V_m$.

We can use the virial equation to demonstrate the important point that, although the equation of state of a real gas may coincide with the perfect gas law as $p \rightarrow 0$, not all its properties necessarily coincide with those of a perfect gas in that limit. Consider, for example, the value of dZ/dp , the slope of the graph of compression factor against pressure. For a perfect gas $dZ/dp = 0$ (because $Z = 1$ at all pressures), but for a real gas from eqn 1.18 we obtain

$$\frac{dZ}{dp} = B' + 2pC' + \cdots \rightarrow B' \quad \text{as} \quad p \rightarrow 0 \quad (1.20a)$$

However, B' is not necessarily zero, so the slope of Z with respect to p does not necessarily approach 0 (the perfect gas value), as we can see in Fig. 1.14. Because several physical properties of gases depend on derivatives, the properties of real gases do not always coincide with the perfect gas values at low pressures. By a similar argument,

$$\frac{dZ}{d(1/V_m)} \rightarrow B \text{ as } V_m \rightarrow \infty, \quad \text{corresponding to } p \rightarrow 0 \quad (1.20b)$$

Because the virial coefficients depend on the temperature, there may be a temperature at which $Z \rightarrow 1$ with zero slope at low pressure or high molar volume (Fig. 1.16). At this temperature, which is called the **Boyle temperature**, T_B , the properties of the real gas do coincide with those of a perfect gas as $p \rightarrow 0$. According to eqn 1.20b, Z has zero slope as $p \rightarrow 0$ if $B = 0$, so we can conclude that $B = 0$ at the Boyle temperature. It then follows from eqn 1.19 that $pV_m \approx RT_B$ over a more extended range of pressures than at other temperatures because the first term after 1 (that is, B/V_m) in the virial equation is zero and C/V_m^2 and higher terms are negligibly small. For helium $T_B = 22.64 \text{ K}$; for air $T_B = 346.8 \text{ K}$; more values are given in Table 1.5.

Fig. 1.16 The compression factor, Z , approaches 1 at low pressures, but does so with different slopes. For a perfect gas, the slope is zero, but real gases may have either positive or negative slopes, and the slope may vary with temperature. At the Boyle temperature, the slope is zero and the gas behaves perfectly over a wider range of conditions than at other temperatures.

Synoptic Table 1.5* Critical constants of gases

	p_c/atm	$V_c/(\text{cm}^3 \text{ mol}^{-1})$	T_c/K	Z_c	T_B/K
Ar	48.0	75.3	150.7	0.292	411.5
CO ₂	72.9	94.0	304.2	0.274	714.8
He	2.26	57.8	5.2	0.305	22.64
O ₂	50.14	78.0	154.8	0.308	405.9

* More values are given in the Data section.

⁴ The name comes from the Latin word for force. The coefficients are sometimes denoted $B_2, B_3, \dots$.

(c) Condensation

Now consider what happens when we compress a sample of gas initially in the state marked A in Fig. 1.15 at constant temperature (by pushing in a piston). Near A, the pressure of the gas rises in approximate agreement with Boyle's law. Serious deviations from that law begin to appear when the volume has been reduced to B.

At C (which corresponds to about 60 atm for carbon dioxide), all similarity to perfect behaviour is lost, for suddenly the piston slides in without any further rise in pressure: this stage is represented by the horizontal line CDE. Examination of the contents of the vessel shows that just to the left of C a liquid appears, and there are two phases separated by a sharply defined surface. As the volume is decreased from C through D to E, the amount of liquid increases. There is no additional resistance to the piston because the gas can respond by condensing. The pressure corresponding to the line CDE, when both liquid and vapour are present in equilibrium, is called the **vapour pressure** of the liquid at the temperature of the experiment.

At E, the sample is entirely liquid and the piston rests on its surface. Any further reduction of volume requires the exertion of considerable pressure, as is indicated by the sharply rising line to the left of E. Even a small reduction of volume from E to F requires a great increase in pressure.

(d) Critical constants

The isotherm at the temperature T_c (304.19 K, or 31.04°C for CO_2) plays a special role in the theory of the states of matter. An isotherm slightly below T_c behaves as we have already described: at a certain pressure, a liquid condenses from the gas and is distinguishable from it by the presence of a visible surface. If, however, the compression takes place at T_c itself, then a surface separating two phases does not appear and the volumes at each end of the horizontal part of the isotherm have merged to a single point, the **critical point** of the gas. The temperature, pressure, and molar volume at the critical point are called the **critical temperature**, T_c , **critical pressure**, p_c , and **critical molar volume**, V_c , of the substance. Collectively, p_c , V_c , and T_c are the **critical constants** of a substance (Table 1.5).

At and above T_c , the sample has a single phase that occupies the entire volume of the container. Such a phase is, by definition, a gas. Hence, the liquid phase of a substance does not form above the critical temperature. The critical temperature of oxygen, for instance, signifies that it is impossible to produce liquid oxygen by compression alone if its temperature is greater than 155 K: to liquefy oxygen—to obtain a fluid phase that does not occupy the entire volume—the temperature must first be lowered to below 155 K, and then the gas compressed isothermally. The single phase that fills the entire volume when $T > T_c$ may be much denser than we normally consider typical of gases, and the name **supercritical fluid** is preferred.

Comment 1.5

The web site contains links to online databases of properties of gases.

1.4 The van der Waals equation

We can draw conclusions from the virial equations of state only by inserting specific values of the coefficients. It is often useful to have a broader, if less precise, view of all gases. Therefore, we introduce the approximate equation of state suggested by J.D. van der Waals in 1873. This equation is an excellent example of an expression that can be obtained by thinking scientifically about a mathematically complicated but physically simple problem, that is, it is a good example of 'model building'.

The **van der Waals equation** is

$$p = \frac{nRT}{V - nb} - a \left(\frac{n}{V} \right)^2 \quad (1.21a)$$

Synoptic Table 1.6* van der Waals coefficients

	$a/(\text{atm dm}^6 \text{ mol}^{-2})$	$b/(10^{-2} \text{ dm}^3 \text{ mol}^{-1})$
Ar	1.337	3.20
CO ₂	3.610	4.29
He	0.0341	2.38
Xe	4.137	5.16

* More values are given in the Data section.

and a derivation is given in *Justification 1.1*. The equation is often written in terms of the molar volume $V_m = V/n$ as

$$p = \frac{RT}{V_m - b} - \frac{a}{V_m^2} \quad (1.21b)$$

The constants a and b are called the **van der Waals coefficients**. They are characteristic of each gas but independent of the temperature (Table 1.6).

Justification 1.1 The van der Waals equation of state

The repulsive interactions between molecules are taken into account by supposing that they cause the molecules to behave as small but impenetrable spheres. The non-zero volume of the molecules implies that instead of moving in a volume V they are restricted to a smaller volume $V - nb$, where nb is approximately the total volume taken up by the molecules themselves. This argument suggests that the perfect gas law $p = nRT/V$ should be replaced by

$$p = \frac{nRT}{V - nb}$$

when repulsions are significant. The closest distance of two hard-sphere molecules of radius r , and volume $V_{\text{molecule}} = \frac{4}{3}\pi r^3$, is $2r$, so the volume excluded is $\frac{4}{3}\pi(2r)^3$, or $8V_{\text{molecule}}$. The volume excluded per molecule is one-half this volume, or $4V_{\text{molecule}}$, so $b \approx 4V_{\text{molecule}}N_A$.

The pressure depends on both the frequency of collisions with the walls and the force of each collision. Both the frequency of the collisions and their force are reduced by the attractive forces, which act with a strength proportional to the molar concentration, n/V , of molecules in the sample. Therefore, because both the frequency and the force of the collisions are reduced by the attractive forces, the pressure is reduced in proportion to the square of this concentration. If the reduction of pressure is written as $-a(n/V)^2$, where a is a positive constant characteristic of each gas, the combined effect of the repulsive and attractive forces is the van der Waals equation of state as expressed in eqn 1.21.

In this *Justification* we have built the van der Waals equation using vague arguments about the volumes of molecules and the effects of forces. The equation can be derived in other ways, but the present method has the advantage that it shows how to derive the form of an equation out of general ideas. The derivation also has the advantage of keeping imprecise the significance of the coefficients a and b : they are much better regarded as empirical parameters than as precisely defined molecular properties.

Example 1.4 Using the van der Waals equation to estimate a molar volume

Estimate the molar volume of CO₂ at 500 K and 100 atm by treating it as a van der Waals gas.

Method To express eqn 1.21b as an equation for the molar volume, we multiply both sides by $(V_m - b)V_m^2$, to obtain

$$(V_m - b)V_m^2 p = RTV_m^2 - (V_m - b)a$$

and, after division by p , collect powers of V_m to obtain

$$V_m^3 - \left(b + \frac{RT}{p}\right)V_m^2 + \left(\frac{a}{p}\right)V_m - \frac{ab}{p} = 0$$

Although closed expressions for the roots of a cubic equation can be given, they are very complicated. Unless analytical solutions are essential, it is usually more expedient to solve such equations with commercial software.

Answer According to Table 1.6, $a = 3.592 \text{ dm}^6 \text{ atm mol}^{-2}$ and $b = 4.267 \times 10^{-2} \text{ dm}^3 \text{ mol}^{-1}$. Under the stated conditions, $RT/p = 0.410 \text{ dm}^3 \text{ mol}^{-1}$. The coefficients in the equation for V_m are therefore

$$b + RT/p = 0.453 \text{ dm}^3 \text{ mol}^{-1}$$

$$a/p = 3.61 \times 10^{-2} (\text{dm}^3 \text{ mol}^{-1})^2$$

$$ab/p = 1.55 \times 10^{-3} (\text{dm}^3 \text{ mol}^{-1})^3$$

Therefore, on writing $x = V_m/(\text{dm}^3 \text{ mol}^{-1})$, the equation to solve is

$$x^3 - 0.453x^2 + (3.61 \times 10^{-2})x - (1.55 \times 10^{-3}) = 0$$

The acceptable root is $x = 0.366$, which implies that $V_m = 0.366 \text{ dm}^3 \text{ mol}^{-1}$. For a perfect gas under these conditions, the molar volume is $0.410 \text{ dm}^3 \text{ mol}^{-1}$.

Self-test 1.5 Calculate the molar volume of argon at 100°C and 100 atm on the assumption that it is a van der Waals gas. $[0.298 \text{ dm}^3 \text{ mol}^{-1}]$

(a) The reliability of the equation

We now examine to what extent the van der Waals equation predicts the behaviour of real gases. It is too optimistic to expect a single, simple expression to be the true equation of state of all substances, and accurate work on gases must resort to the virial equation, use tabulated values of the coefficients at various temperatures, and analyse the systems numerically. The advantage of the van der Waals equation, however, is that it is analytical (that is, expressed symbolically) and allows us to draw some general conclusions about real gases. When the equation fails we must use one of the other equations of state that have been proposed (some are listed in Table 1.7), invent a new one, or go back to the virial equation.

That having been said, we can begin to judge the reliability of the equation by comparing the isotherms it predicts with the experimental isotherms in Fig. 1.15. Some

Table 1.7 Selected equations of state

	Equation	Reduced form*	Critical constants		
			p_c	V_c	T_c
Perfect gas	$p = \frac{RT}{V_m}$				
van der Waals	$p = \frac{RT}{V_m - b} - \frac{a}{V_m^2}$	$p = \frac{8T_r}{3V_r - 1} - \frac{3}{V_r^2}$	$\frac{a}{27b^2}$	$3b$	$\frac{8a}{27bR}$
Berthelot	$p = \frac{RT}{V_m - b} - \frac{a}{TV_m^2}$	$p = \frac{8T_r}{3V_r - 1} - \frac{3}{T_r V_r^2}$	$\frac{1}{12} \left(\frac{2aR}{3b^3} \right)^{1/2}$	$3b$	$\frac{2}{3} \left(\frac{2a}{3bR} \right)^{1/2}$
Dieterici	$p = \frac{RTe^{-a/RTV_m}}{V_m - b}$	$p = \frac{e^2 T_r e^{-2/T_r V_r}}{2V_r - 1}$	$\frac{a}{4e^2 b^2}$	$2b$	$\frac{a}{4bR}$
Virial	$p = \frac{RT}{V_m} \left\{ 1 + \frac{B(T)}{V_m} + \frac{C(T)}{V_m^2} + \dots \right\}$				

* Reduced variables are defined in Section 1.5.

Fig. 1.17 The surface of possible states allowed by the van der Waals equation. Compare this surface with that shown in Fig. 1.8.

Fig. 1.18 Van der Waals isotherms at several values of T/T_c . Compare these curves with those in Fig. 1.15. The van der Waals loops are normally replaced by horizontal straight lines. The critical isotherm is the isotherm for $T/T_c = 1$.

Exploration Calculate the molar volume of chlorine gas on the basis of the van der Waals equation of state at 250 K and 150 kPa and calculate the percentage difference from the value predicted by the perfect gas equation.

calculated isotherms are shown in Figs. 1.17 and 1.18. Apart from the oscillations below the critical temperature, they do resemble experimental isotherms quite well. The oscillations, the **van der Waals loops**, are unrealistic because they suggest that under some conditions an increase of pressure results in an increase of volume. Therefore they are replaced by horizontal lines drawn so the loops define equal areas above and below the lines: this procedure is called the **Maxwell construction** (3). The van der Waals coefficients, such as those in Table 1.7, are found by fitting the calculated curves to the experimental curves.

(b) The features of the equation

The principal features of the van der Waals equation can be summarized as follows.

- (1) Perfect gas isotherms are obtained at high temperatures and large molar volumes.

When the temperature is high, RT may be so large that the first term in eqn 1.21b greatly exceeds the second. Furthermore, if the molar volume is large in the sense $V_m \gg b$, then the denominator $V_m - b \approx V_m$. Under these conditions, the equation reduces to $p = RT/V_m$, the perfect gas equation.

- (2) Liquids and gases coexist when cohesive and dispersing effects are in balance.

The van der Waals loops occur when both terms in eqn 1.21b have similar magnitudes. The first term arises from the kinetic energy of the molecules and their repulsive interactions; the second represents the effect of the attractive interactions.

- (3) The critical constants are related to the van der Waals coefficients.

For $T < T_c$, the calculated isotherms oscillate, and each one passes through a minimum followed by a maximum. These extrema converge as $T \rightarrow T_c$ and coincide at $T = T_c$; at the critical point the curve has a flat inflexion (4). From the properties of curves, we know that an inflexion of this type occurs when both the first and second derivatives are zero. Hence, we can find the critical constants by calculating these derivatives and setting them equal to zero:

$$\begin{aligned}\frac{dp}{dV_m} &= -\frac{RT}{(V_m - b)^2} + \frac{2a}{V_m^3} = 0 \\ \frac{d^2p}{dV_m^2} &= \frac{2RT}{(V_m - b)^3} - \frac{6a}{V_m^4} = 0\end{aligned}$$

at the critical point. The solutions of these two equations (and using eqn 1.21b to calculate p_c from V_c and T_c) are

$$V_c = 3b \quad p_c = \frac{a}{27b^2} \quad T_c = \frac{8a}{27Rb} \quad (1.22)$$

These relations provide an alternative route to the determination of a and b from the values of the critical constants. They can be tested by noting that the **critical compression factor**, Z_c , is predicted to be equal to

$$Z_c = \frac{p_c V_c}{RT_c} = \frac{3}{8} \quad (1.23)$$

for all gases. We see from Table 1.5 that, although $Z_c < \frac{3}{8} = 0.375$, it is approximately constant (at 0.3) and the discrepancy is reasonably small.

1.5 The principle of corresponding states

An important general technique in science for comparing the properties of objects is to choose a related fundamental property of the same kind and to set up a relative scale on that basis. We have seen that the critical constants are characteristic properties of gases, so it may be that a scale can be set up by using them as yardsticks. We therefore introduce the dimensionless **reduced variables** of a gas by dividing the actual variable by the corresponding critical constant:

$$p_r = \frac{p}{p_c} \quad V_r = \frac{V_m}{V_c} \quad T_r = \frac{T}{T_c} \quad [1.24]$$

If the reduced pressure of a gas is given, we can easily calculate its actual pressure by using $p = p_r p_c$, and likewise for the volume and temperature. Van der Waals, who first tried this procedure, hoped that gases confined to the same reduced volume, V_r , at the same reduced temperature, T_r , would exert the same reduced pressure, p_r . The hope was largely fulfilled (Fig. 1.19). The illustration shows the dependence of the compression factor on the reduced pressure for a variety of gases at various reduced temperatures. The success of the procedure is strikingly clear: compare this graph with Fig. 1.14, where similar data are plotted without using reduced variables. The observation that real gases at the same reduced volume and reduced temperature exert the same reduced pressure is called the **principle of corresponding states**. The principle is only an approximation. It works best for gases composed of spherical molecules; it fails, sometimes badly, when the molecules are non-spherical or polar.

The van der Waals equation sheds some light on the principle. First, we express eqn 1.21b in terms of the reduced variables, which gives

$$p_r p_c = \frac{RT_r T_c}{V_r V_c - b} - \frac{a}{V_r^2 V_c^2}$$

Fig. 1.19 The compression factors of four of the gases shown in Fig. 1.14 plotted using reduced variables. The curves are labelled with the reduced temperature $T_r = T/T_c$. The use of reduced variables organizes the data on to single curves.

Exploration Is there a set of conditions at which the compression factor of a van der Waals gas passes through a minimum? If so, how does the location and value of the minimum value of Z depend on the coefficients a and b ?

Then we express the critical constants in terms of a and b by using eqn 1.22:

$$\frac{ap_r}{27b^2} = \frac{8aT_r}{27b(3bV_r - b)} - \frac{a}{9b^2V_r^2}$$

which can be reorganized into

$$p_r = \frac{8T_r}{3V_r - 1} - \frac{3}{V_r^2} \quad (1.25)$$

This equation has the same form as the original, but the coefficients a and b , which differ from gas to gas, have disappeared. It follows that if the isotherms are plotted in terms of the reduced variables (as we did in fact in Fig. 1.18 without drawing attention to the fact), then the same curves are obtained whatever the gas. This is precisely the content of the principle of corresponding states, so the van der Waals equation is compatible with it.

Looking for too much significance in this apparent triumph is mistaken, because other equations of state also accommodate the principle (Table 1.7). In fact, all we need are two parameters playing the roles of a and b , for then the equation can always be manipulated into reduced form. The observation that real gases obey the principle approximately amounts to saying that the effects of the attractive and repulsive interactions can each be approximated in terms of a single parameter. The importance of the principle is then not so much its theoretical interpretation but the way that it enables the properties of a range of gases to be coordinated on to a single diagram (for example, Fig. 1.19 instead of Fig. 1.14).

Checklist of key ideas

- ☐ 1. A gas is a form of matter that fills any container it occupies.
- ☐ 2. An equation of state interrelates pressure, volume, temperature, and amount of substance: $p = f(T, V, n)$.
- ☐ 3. The pressure is the force divided by the area to which the force is applied. The standard pressure is $p^\circ = 1 \text{ bar}$ (10^5 Pa).
- ☐ 4. Mechanical equilibrium is the condition of equality of pressure on either side of a movable wall.
- ☐ 5. Temperature is the property that indicates the direction of the flow of energy through a thermally conducting, rigid wall.
- ☐ 6. A diathermic boundary is a boundary that permits the passage of energy as heat. An adiabatic boundary is a boundary that prevents the passage of energy as heat.
- ☐ 7. Thermal equilibrium is a condition in which no change of state occurs when two objects A and B are in contact through a diathermic boundary.
- ☐ 8. The Zeroth Law of thermodynamics states that, if A is in thermal equilibrium with B, and B is in thermal equilibrium with C, then C is also in thermal equilibrium with A.
- ☐ 9. The Celsius and thermodynamic temperature scales are related by $T/\text{K} = \theta/^\circ\text{C} + 273.15$.
- ☐ 10. A perfect gas obeys the perfect gas equation, $pV = nRT$, exactly under all conditions.
- ☐ 11. Dalton's law states that the pressure exerted by a mixture of gases is the sum of the partial pressures of the gases.
- ☐ 12. The partial pressure of any gas is defined as $p_i = x_i p$, where $x_i = n_i/n$ is its mole fraction in a mixture and p is the total pressure.
- ☐ 13. In real gases, molecular interactions affect the equation of state; the true equation of state is expressed in terms of virial coefficients $B, C, \dots$: $pV_m = RT(1 + B/V_m + C/V_m^2 + \dots)$.
- ☐ 14. The vapour pressure is the pressure of a vapour in equilibrium with its condensed phase.
- ☐ 15. The critical point is the point at which the volumes at each end of the horizontal part of the isotherm have merged to a single point. The critical constants p_c , V_c , and T_c are the pressure, molar volume, and temperature, respectively, at the critical point.
- ☐ 16. A supercritical fluid is a dense fluid phase above its critical temperature and pressure.
- ☐ 17. The van der Waals equation of state is an approximation to the true equation of state in which attractions are represented by a parameter a and repulsions are represented by a parameter b : $p = nRT/(V - nb) - a(n/V)^2$.
- ☐ 18. A reduced variable is the actual variable divided by the corresponding critical constant.
- ☐ 19. According to the principle of corresponding states, real gases at the same reduced volume and reduced temperature exert the same reduced pressure.

Discussion questions

- 1.1** Explain how the perfect gas equation of state arises by combination of Boyle's law, Charles's law, and Avogadro's principle.
- 1.2** Explain the term 'partial pressure' and explain why Dalton's law is a limiting law.
- 1.3** Explain how the compression factor varies with pressure and temperature and describe how it reveals information about intermolecular interactions in real gases.
- 1.4** What is the significance of the critical constants?
- 1.5** Describe the formulation of the van der Waals equation and suggest a rationale for one other equation of state in Table 1.7.
- 1.6** Explain how the van der Waals equation accounts for critical behaviour.

Exercises

1.1(a) (a) Could 131 g of xenon gas in a vessel of volume 1.0 dm^3 exert a pressure of 20 atm at 25°C if it behaved as a perfect gas? If not, what pressure would it exert? (b) What pressure would it exert if it behaved as a van der Waals gas?

1.1(b) (a) Could 25 g of argon gas in a vessel of volume 1.5 dm^3 exert a pressure of 2.0 bar at 30°C if it behaved as a perfect gas? If not, what pressure would it exert? (b) What pressure would it exert if it behaved as a van der Waals gas?

1.2(a) A perfect gas undergoes isothermal compression, which reduces its volume by 2.20 dm^3 . The final pressure and volume of the gas are 5.04 bar and 4.65 dm^3 , respectively. Calculate the original pressure of the gas in (a) bar, (b) atm.

1.2(b) A perfect gas undergoes isothermal compression, which reduces its volume by 1.80 dm^3 . The final pressure and volume of the gas are 1.97 bar and 2.14 dm^3 , respectively. Calculate the original pressure of the gas in (a) bar, (b) Torr.

1.3(a) A car tyre (i.e. an automobile tire) was inflated to a pressure of 24 lb in^{-2} ($1.00 \text{ atm} = 14.7 \text{ lb in}^{-2}$) on a winter's day when the temperature was -5°C . What pressure will be found, assuming no leaks have occurred and that the volume is constant, on a subsequent summer's day when the temperature is 35°C ? What complications should be taken into account in practice?

1.3(b) A sample of hydrogen gas was found to have a pressure of 125 kPa when the temperature was 23°C . What can its pressure be expected to be when the temperature is 11°C ?

1.4(a) A sample of 255 mg of neon occupies 3.00 dm^3 at 122 K. Use the perfect gas law to calculate the pressure of the gas.

1.4(b) A homeowner uses $4.00 \times 10^3 \text{ m}^3$ of natural gas in a year to heat a home. Assume that natural gas is all methane, CH_4 , and that methane is a perfect gas for the conditions of this problem, which are 1.00 atm and 20°C . What is the mass of gas used?

1.5(a) A diving bell has an air space of 3.0 m^3 when on the deck of a boat. What is the volume of the air space when the bell has been lowered to a depth of 50 m? Take the mean density of sea water to be 1.025 g cm^{-3} and assume that the temperature is the same as on the surface.

1.5(b) What pressure difference must be generated across the length of a 15 cm vertical drinking straw in order to drink a water-like liquid of density 1.0 g cm^{-3} ?

1.6(a) A manometer consists of a U-shaped tube containing a liquid. One side is connected to the apparatus and the other is open to the atmosphere. The pressure inside the apparatus is then determined from the difference in heights of the liquid. Suppose the liquid is water, the external pressure is 770 Torr, and the open side is 10.0 cm lower than the side connected to the apparatus. What is the pressure in the apparatus? (The density of water at 25°C is $0.99707 \text{ g cm}^{-3}$.)

1.6(b) A manometer like that described in Exercise 1.6a contained mercury in place of water. Suppose the external pressure is 760 Torr, and the open side is 10.0 cm higher than the side connected to the apparatus. What is the pressure in the apparatus? (The density of mercury at 25°C is 13.55 g cm^{-3} .)

1.7(a) In an attempt to determine an accurate value of the gas constant, R , a student heated a container of volume 20.000 dm^3 filled with 0.25132 g of helium gas to 500°C and measured the pressure as 206.402 cm of water in a manometer at 25°C . Calculate the value of R from these data. (The density of water at 25°C is $0.99707 \text{ g cm}^{-3}$; the construction of a manometer is described in Exercise 1.6a.)

1.7(b) The following data have been obtained for oxygen gas at 273.15 K . Calculate the best value of the gas constant R from them and the best value of the molar mass of O_2 .

p/atm	0.750 000	0.500 000	0.250 000
$V_m/(\text{dm}^3 \text{ mol}^{-1})$	29.9649	44.8090	89.6384
$\rho/(\text{g dm}^{-3})$	1.07144	0.714110	0.356975

1.8(a) At 500°C and 93.2 kPa, the mass density of sulfur vapour is 3.710 kg m^{-3} . What is the molecular formula of sulfur under these conditions?

1.8(b) At 100°C and 1.60 kPa, the mass density of phosphorus vapour is 0.6388 kg m^{-3} . What is the molecular formula of phosphorus under these conditions?

1.9(a) Calculate the mass of water vapour present in a room of volume 400 m^3 that contains air at 27°C on a day when the relative humidity is 60 per cent.

1.9(b) Calculate the mass of water vapour present in a room of volume 250 m^3 that contains air at 23°C on a day when the relative humidity is 53 per cent.

1.10(a) Given that the density of air at 0.987 bar and 27°C is 1.146 kg m^{-3} , calculate the mole fraction and partial pressure of nitrogen and oxygen assuming that (a) air consists only of these two gases, (b) air also contains 1.0 mole per cent Ar.

1.10(b) A gas mixture consists of 320 mg of methane, 175 mg of argon, and 225 mg of neon. The partial pressure of neon at 300 K is 8.87 kPa. Calculate (a) the volume and (b) the total pressure of the mixture.

1.11(a) The density of a gaseous compound was found to be 1.23 kg m^{-3} at 330 K and 20 kPa. What is the molar mass of the compound?

1.11(b) In an experiment to measure the molar mass of a gas, 250 cm^3 of the gas was confined in a glass vessel. The pressure was 152 Torr at 298 K and, after correcting for buoyancy effects, the mass of the gas was 33.5 mg. What is the molar mass of the gas?

1.12(a) The densities of air at -85°C , 0°C , and 100°C are 1.877 g dm^{-3} , 1.294 g dm^{-3} , and 0.946 g dm^{-3} , respectively. From these data, and assuming that air obeys Charles's law, determine a value for the absolute zero of temperature in degrees Celsius.

1.12(b) A certain sample of a gas has a volume of 20.00 dm^3 at 0°C and 1.000 atm. A plot of the experimental data of its volume against the Celsius temperature, θ , at constant p , gives a straight line of slope $0.0741 \text{ dm}^3 (^\circ\text{C})^{-1}$. From these data alone (without making use of the perfect gas law), determine the absolute zero of temperature in degrees Celsius.

1.13(a) Calculate the pressure exerted by 1.0 mol C_2H_6 behaving as (a) a perfect gas, (b) a van der Waals gas when it is confined under the following conditions: (i) at 273.15 K in 22.414 dm^3 , (ii) at 1000 K in 100 cm^3 . Use the data in Table 1.6.

1.13(b) Calculate the pressure exerted by 1.0 mol H_2S behaving as (a) a perfect gas, (b) a van der Waals gas when it is confined under the following conditions: (i) at 273.15 K in 22.414 dm^3 , (ii) at 500 K in 150 cm^3 . Use the data in Table 1.6.

1.14(a) Express the van der Waals parameters $a = 0.751 \text{ atm dm}^6 \text{ mol}^{-2}$ and $b = 0.0226 \text{ dm}^3 \text{ mol}^{-1}$ in SI base units.

1.14(b) Express the van der Waals parameters $a = 1.32 \text{ atm dm}^6 \text{ mol}^{-2}$ and $b = 0.0436 \text{ dm}^3 \text{ mol}^{-1}$ in SI base units.

1.15(a) A gas at 250 K and 15 atm has a molar volume 12 per cent smaller than that calculated from the perfect gas law. Calculate (a) the compression factor under these conditions and (b) the molar volume of the gas. Which are dominating in the sample, the attractive or the repulsive forces?

1.15(b) A gas at 350 K and 12 atm has a molar volume 12 per cent larger than that calculated from the perfect gas law. Calculate (a) the compression factor under these conditions and (b) the molar volume of the gas. Which are dominating in the sample, the attractive or the repulsive forces?

1.16(a) In an industrial process, nitrogen is heated to 500 K at a constant volume of 1.000 m³. The gas enters the container at 300 K and 100 atm. The mass of the gas is 92.4 kg. Use the van der Waals equation to determine the approximate pressure of the gas at its working temperature of 500 K. For nitrogen, $a = 1.352 \text{ dm}^6 \text{ atm mol}^{-2}$, $b = 0.0387 \text{ dm}^3 \text{ mol}^{-1}$.

1.16(b) Cylinders of compressed gas are typically filled to a pressure of 200 bar. For oxygen, what would be the molar volume at this pressure and 25°C based on (a) the perfect gas equation, (b) the van der Waals equation. For oxygen, $a = 1.364 \text{ dm}^6 \text{ atm mol}^{-2}$, $b = 3.19 \times 10^{-2} \text{ dm}^3 \text{ mol}^{-1}$.

1.17(a) Suppose that 10.0 mol C₂H₆(g) is confined to 4.860 dm³ at 27°C. Predict the pressure exerted by the ethane from (a) the perfect gas and (b) the van der Waals equations of state. Calculate the compression factor based on these calculations. For ethane, $a = 5.507 \text{ dm}^6 \text{ atm mol}^{-2}$, $b = 0.0651 \text{ dm}^3 \text{ mol}^{-1}$.

1.17(b) At 300 K and 20 atm, the compression factor of a gas is 0.86. Calculate (a) the volume occupied by 8.2 mmol of the gas under these conditions and (b) an approximate value of the second virial coefficient B at 300 K.

1.18(a) A vessel of volume 22.4 dm³ contains 2.0 mol H₂ and 1.0 mol N₂ at 273.15 K. Calculate (a) the mole fractions of each component, (b) their partial pressures, and (c) their total pressure.

1.18(b) A vessel of volume 22.4 dm³ contains 1.5 mol H₂ and 2.5 mol N₂ at 273.15 K. Calculate (a) the mole fractions of each component, (b) their partial pressures, and (c) their total pressure.

1.19(a) The critical constants of methane are $p_c = 45.6 \text{ atm}$, $V_c = 98.7 \text{ cm}^3 \text{ mol}^{-1}$, and $T_c = 190.6 \text{ K}$. Calculate the van der Waals parameters of the gas and estimate the radius of the molecules.

1.19(b) The critical constants of ethane are $p_c = 48.20 \text{ atm}$, $V_c = 148 \text{ cm}^3 \text{ mol}^{-1}$, and $T_c = 305.4 \text{ K}$. Calculate the van der Waals parameters of the gas and estimate the radius of the molecules.

1.20(a) Use the van der Waals parameters for chlorine to calculate approximate values of (a) the Boyle temperature of chlorine and (b) the radius of a Cl₂ molecule regarded as a sphere.

1.20(b) Use the van der Waals parameters for hydrogen sulfide to calculate approximate values of (a) the Boyle temperature of the gas and (b) the radius of a H₂S molecule regarded as a sphere ($a = 4.484 \text{ dm}^6 \text{ atm mol}^{-2}$, $b = 0.0434 \text{ dm}^3 \text{ mol}^{-1}$).

1.21(a) Suggest the pressure and temperature at which 1.0 mol of (a) NH₃, (b) Xe, (c) He will be in states that correspond to 1.0 mol H₂ at 1.0 atm and 25°C.

1.21(b) Suggest the pressure and temperature at which 1.0 mol of (a) H₂S, (b) CO₂, (c) Ar will be in states that correspond to 1.0 mol N₂ at 1.0 atm and 25°C.

1.22(a) A certain gas obeys the van der Waals equation with $a = 0.50 \text{ m}^6 \text{ Pa mol}^{-2}$. Its volume is found to be $5.00 \times 10^{-4} \text{ m}^3 \text{ mol}^{-1}$ at 273 K and 3.0 MPa. From this information calculate the van der Waals constant b . What is the compression factor for this gas at the prevailing temperature and pressure?

1.22(b) A certain gas obeys the van der Waals equation with $a = 0.76 \text{ m}^6 \text{ Pa mol}^{-2}$. Its volume is found to be $4.00 \times 10^{-4} \text{ m}^3 \text{ mol}^{-1}$ at 288 K and 4.0 MPa. From this information calculate the van der Waals constant b . What is the compression factor for this gas at the prevailing temperature and pressure?

Problems*

Numerical problems

1.1 Recent communication with the inhabitants of Neptune have revealed that they have a Celsius-type temperature scale, but based on the melting point (0°N) and boiling point (100°N) of their most common substance, hydrogen. Further communications have revealed that the Neptunians know about perfect gas behaviour and they find that, in the limit of zero pressure, the value of pV is 28 dm³ atm at 0°N and 40 dm³ atm at 100°N. What is the value of the absolute zero of temperature on their temperature scale?

1.2 Deduce the relation between the pressure and mass density, ρ , of a perfect gas of molar mass M . Confirm graphically, using the following data on dimethyl ether at 25°C, that perfect behaviour is reached at low pressures and find the molar mass of the gas.

p/kPa	12.223	25.20	36.97	60.37	85.23	101.3
$\rho/(\text{kg m}^{-3})$	0.225	0.456	0.664	1.062	1.468	1.734

1.3 Charles's law is sometimes expressed in the form $V = V_0(1 + \alpha\theta)$, where θ is the Celsius temperature, α is a constant, and V_0 is the volume of the sample at 0°C. The following values for α have been reported for nitrogen at 0°C:

p/Torr	749.7	599.6	333.1	98.6
$10^3\alpha/(\text{°C})^{-1}$	3.6717	3.6697	3.6665	3.6643

For these data calculate the best value for the absolute zero of temperature on the Celsius scale.

1.4 The molar mass of a newly synthesized fluorocarbon was measured in a gas microbalance. This device consists of a glass bulb forming one end of a beam, the whole surrounded by a closed container. The beam is pivoted, and the balance point is attained by raising the pressure of gas in the container, so increasing the buoyancy of the enclosed bulb. In one experiment, the balance point was reached when the fluorocarbon pressure was 327.10 Torr; for the same setting of the pivot, a balance was reached when CHF₃ ($M = 70.014 \text{ g mol}^{-1}$) was introduced at 423.22 Torr. A repeat of the experiment with a different setting of the pivot required a pressure of 293.22 Torr of the fluorocarbon and 427.22 Torr of the CHF₃. What is the molar mass of the fluorocarbon? Suggest a molecular formula.

1.5 A constant-volume perfect gas thermometer indicates a pressure of 6.69 kPa at the triple point temperature of water (273.16 K). (a) What change of pressure indicates a change of 1.00 K at this temperature? (b) What pressure indicates a temperature of 100.00°C? (c) What change of pressure indicates a change of 1.00 K at the latter temperature?

1.6 A vessel of volume 22.4 dm³ contains 2.0 mol H₂ and 1.0 mol N₂ at 273.15 K initially. All the H₂ reacted with sufficient N₂ to form NH₃. Calculate the partial pressures and the total pressure of the final mixture.

1.7 Calculate the molar volume of chlorine gas at 350 K and 2.30 atm using (a) the perfect gas law and (b) the van der Waals equation. Use the answer to (a) to calculate a first approximation to the correction term for attraction and then use successive approximations to obtain a numerical answer for part (b).

* Problems denoted with the symbol ‡ were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

1.8 At 273 K measurements on argon gave $B = -21.7 \text{ cm}^3 \text{ mol}^{-1}$ and $C = 1200 \text{ cm}^6 \text{ mol}^{-2}$, where B and C are the second and third virial coefficients in the expansion of Z in powers of $1/V_m$. Assuming that the perfect gas law holds sufficiently well for the estimation of the second and third terms of the expansion, calculate the compression factor of argon at 100 atm and 273 K. From your result, estimate the molar volume of argon under these conditions.

1.9 Calculate the volume occupied by 1.00 mol N_2 using the van der Waals equation in the form of a virial expansion at (a) its critical temperature, (b) its Boyle temperature, and (c) its inversion temperature. Assume that the pressure is 10 atm throughout. At what temperature is the gas most perfect? Use the following data: $T_c = 126.3 \text{ K}$, $a = 1.352 \text{ dm}^6 \text{ atm mol}^{-2}$, $b = 0.0387 \text{ dm}^3 \text{ mol}^{-1}$.

1.10† The second virial coefficient of methane can be approximated by the empirical equation $B'(T) = a + be^{-c/T^2}$, where $a = -0.1993 \text{ bar}^{-1}$, $b = 0.2002 \text{ bar}^{-1}$, and $c = 1131 \text{ K}^2$ with $300 \text{ K} < T < 600 \text{ K}$. What is the Boyle temperature of methane?

1.11 The mass density of water vapour at 327.6 atm and 776.4 K is 133.2 kg m^{-3} . Given that for water $T_c = 647.4 \text{ K}$, $p_c = 218.3 \text{ atm}$, $a = 5.464 \text{ dm}^6 \text{ atm mol}^{-2}$, $b = 0.03049 \text{ dm}^3 \text{ mol}^{-1}$, and $M = 18.02 \text{ g mol}^{-1}$, calculate (a) the molar volume. Then calculate the compression factor (b) from the data, (c) from the virial expansion of the van der Waals equation.

1.12 The critical volume and critical pressure of a certain gas are $160 \text{ cm}^3 \text{ mol}^{-1}$ and 40 atm, respectively. Estimate the critical temperature by assuming that the gas obeys the Berthelot equation of state. Estimate the radii of the gas molecules on the assumption that they are spheres.

1.13 Estimate the coefficients a and b in the Dieterici equation of state from the critical constants of xenon. Calculate the pressure exerted by 1.0 mol Xe when it is confined to 1.0 dm^3 at 25°C .

Theoretical problems

1.14 Show that the van der Waals equation leads to values of $Z < 1$ and $Z > 1$, and identify the conditions for which these values are obtained.

1.15 Express the van der Waals equation of state as a virial expansion in powers of $1/V_m$ and obtain expressions for B and C in terms of the parameters a and b . The expansion you will need is $(1-x)^{-1} = 1 + x + x^2 + \dots$. Measurements on argon gave $B = -21.7 \text{ cm}^3 \text{ mol}^{-1}$ and $C = 1200 \text{ cm}^6 \text{ mol}^{-2}$ for the virial coefficients at 273 K. What are the values of a and b in the corresponding van der Waals equation of state?

1.16† Derive the relation between the critical constants and the Dieterici equation parameters. Show that $Z_c = 2e^{-2}$ and derive the reduced form of the Dieterici equation of state. Compare the van der Waals and Dieterici predictions of the critical compression factor. Which is closer to typical experimental values?

1.17 A scientist proposed the following equation of state:

$$p = \frac{RT}{V_m} - \frac{B}{V_m^2} + \frac{C}{V_m^3}$$

Show that the equation leads to critical behaviour. Find the critical constants of the gas in terms of B and C and an expression for the critical compression factor.

1.18 Equations 1.18 and 1.19 are expansions in p and $1/V_m$, respectively. Find the relation between B , C and B' , C' .

1.19 The second virial coefficient B' can be obtained from measurements of the density ρ of a gas at a series of pressures. Show that the graph of p/ρ against p should be a straight line with slope proportional to B' . Use the data on dimethyl ether in Problem 1.2 to find the values of B' and B at 25°C .

1.20 The equation of state of a certain gas is given by $p = RT/V_m + (a + bT)/V_m^2$, where a and b are constants. Find $(\partial V/\partial T)_p$.

1.21 The following equations of state are occasionally used for approximate calculations on gases: (gas A) $pV_m = RT(1 + b/V_m)$, (gas B) $p(V_m - b) = RT$. Assuming that there were gases that actually obeyed these equations of state, would it be possible to liquefy either gas A or B? Would they have a critical temperature? Explain your answer.

1.22 Derive an expression for the compression factor of a gas that obeys the equation of state $p(V - nb) = nRT$, where b and R are constants. If the pressure and temperature are such that $V_m = 10b$, what is the numerical value of the compression factor?

1.23† The discovery of the element argon by Lord Rayleigh and Sir William Ramsay had its origins in Rayleigh's measurements of the density of nitrogen with an eye toward accurate determination of its molar mass. Rayleigh prepared some samples of nitrogen by chemical reaction of nitrogen-containing compounds; under his standard conditions, a glass globe filled with this 'chemical nitrogen' had a mass of 2.2990 g. He prepared other samples by removing oxygen, carbon dioxide, and water vapour from atmospheric air; under the same conditions, this 'atmospheric nitrogen' had a mass of 2.3102 g (Lord Rayleigh, *Royal Institution Proceedings* **14**, 524 (1895)). With the hindsight of knowing accurate values for the molar masses of nitrogen and argon, compute the mole fraction of argon in the latter sample on the assumption that the former was pure nitrogen and the latter a mixture of nitrogen and argon.

1.24† A substance as elementary and well known as argon still receives research attention. Stewart and Jacobsen have published a review of thermodynamic properties of argon (R.B. Stewart and R.T. Jacobsen, *J. Phys. Chem. Ref. Data* **18**, 639 (1989)) that included the following 300 K isotherm.

p/MPa	0.4000	0.5000	0.6000	0.8000	1.000
$V_m/(\text{dm}^3 \text{ mol}^{-1})$	6.2208	4.9736	4.1423	3.1031	2.4795
p/MPa	1.500	2.000	2.500	3.000	4.000
$V_m/(\text{dm}^3 \text{ mol}^{-1})$	1.6483	1.2328	0.98357	0.81746	0.60998

(a) Compute the second virial coefficient, B , at this temperature. (b) Use non-linear curve-fitting software to compute the third virial coefficient, C , at this temperature.

Applications: to environmental science

1.25 Atmospheric pollution is a problem that has received much attention. Not all pollution, however, is from industrial sources. Volcanic eruptions can be a significant source of air pollution. The Kilauea volcano in Hawaii emits 200–300 t of SO_2 per day. If this gas is emitted at 800°C and 1.0 atm, what volume of gas is emitted?

1.26 Ozone is a trace atmospheric gas that plays an important role in screening the Earth from harmful ultraviolet radiation, and the abundance of ozone is commonly reported in *Dobson units*. One Dobson unit is the thickness, in thousandths of a centimetre, of a column of gas if it were collected as a pure gas at 1.00 atm and 0°C . What amount of O_3 (in moles) is found in a column of atmosphere with a cross-sectional area of 1.00 dm^2 if the abundance is 250 Dobson units (a typical mid-latitude value)? In the seasonal Antarctic ozone hole, the column abundance drops below 100 Dobson units; how many moles of ozone are found in such a column of air above a 1.00 dm^2 area? Most atmospheric ozone is found between 10 and 50 km above the surface of the earth. If that ozone is spread uniformly through this portion of the atmosphere, what is the average molar concentration corresponding to (a) 250 Dobson units, (b) 100 Dobson units?

1.27 The barometric formula relates the pressure of a gas of molar mass M at an altitude h to its pressure p_0 at sea level. Derive this relation by showing that

the change in pressure dp for an infinitesimal change in altitude dh where the density is ρ is $dp = -\rho g dh$. Remember that ρ depends on the pressure. Evaluate (a) the pressure difference between the top and bottom of a laboratory vessel of height 15 cm, and (b) the external atmospheric pressure at a typical cruising altitude of an aircraft (11 km) when the pressure at ground level is 1.0 atm.

1.28 Balloons are still used to deploy sensors that monitor meteorological phenomena and the chemistry of the atmosphere. It is possible to investigate some of the technicalities of ballooning by using the perfect gas law. Suppose your balloon has a radius of 3.0 m and that it is spherical. (a) What amount of H_2 (in moles) is needed to inflate it to 1.0 atm in an ambient temperature of 25°C at sea level? (b) What mass can the balloon lift at sea level, where the density of air is 1.22 kg m^{-3} ? (c) What would be the payload if He were used instead of H_2 ?

1.29† The preceding problem is most readily solved (see the *Solutions manual*) with the use of the Archimedes principle, which states that the lifting force is equal to the difference between the weight of the displaced air and the weight of the balloon. Prove the Archimedes principle for the atmosphere from the barometric formula. *Hint.* Assume a simple shape for the balloon, perhaps a right circular cylinder of cross-sectional area A and height h .

1.30 ‡ Chlorofluorocarbons such as CCl_3F and CCl_2F_2 have been linked to ozone depletion in Antarctica. As of 1994, these gases were found in quantities of 261 and 509 parts per trillion (10^{12}) by volume (World Resources Institute, *World resources* 1996–97). Compute the molar concentration of these gases under conditions typical of (a) the mid-latitude troposphere (10°C and 1.0 atm) and (b) the Antarctic stratosphere (200 K and 0.050 atm).

Problems

This chapter introduces some of the basic concepts of thermodynamics. It concentrates on the conservation of energy—the experimental observation that energy can be neither created nor destroyed—and shows how the principle of the conservation of energy can be used to assess the energy changes that accompany physical and chemical processes. Much of this chapter examines the means by which a system can exchange energy with its surroundings in terms of the work it may do or the heat that it may produce. The target concept of the chapter is enthalpy, which is a very useful book-keeping property for keeping track of the heat output (or requirements) of physical processes and chemical reactions at constant pressure. We also begin to unfold some of the power of thermodynamics by showing how to establish relations between different properties of a system. We shall see that one very useful aspect of thermodynamics is that a property can be measured indirectly by measuring others and then combining their values. The relations we derive also enable us to discuss the liquefaction of gases and to establish the relation between the heat capacities of a substance under different conditions.

The release of energy can be used to provide heat when a fuel burns in a furnace, to produce mechanical work when a fuel burns in an engine, and to generate electrical work when a chemical reaction pumps electrons through a circuit. In chemistry, we encounter reactions that can be harnessed to provide heat and work, reactions that liberate energy which is squandered (often to the detriment of the environment) but which give products we require, and reactions that constitute the processes of life. **Thermodynamics**, the study of the transformations of energy, enables us to discuss all these matters quantitatively and to make useful predictions.

The basic concepts

For the purposes of physical chemistry, the universe is divided into two parts, the system and its surroundings. The **system** is the part of the world in which we have a special interest. It may be a reaction vessel, an engine, an electrochemical cell, a biological cell, and so on. The **surroundings** comprise the region outside the system and are where we make our measurements. The type of system depends on the characteristics of the boundary that divides it from the surroundings (Fig. 2.1). If matter can be transferred through the boundary between the system and its surroundings the system is classified as **open**. If matter cannot pass through the boundary the system is classified as **closed**. Both open and closed systems can exchange energy with their surroundings. For example, a closed system can expand and thereby raise a weight in the surroundings; it may also transfer energy to them if they are at a lower temperature.

An **isolated system** is a closed system that has neither mechanical nor thermal contact with its surroundings.

2.1 Work, heat, and energy

The fundamental physical property in thermodynamics is work: **work** is motion against an opposing force. Doing work is equivalent to raising a weight somewhere in the surroundings. An example of doing work is the expansion of a gas that pushes out a piston and raises a weight. A chemical reaction that drives an electric current through a resistance also does work, because the same current could be driven through a motor and used to raise a weight.

The **energy** of a system is its capacity to do work. When work is done on an otherwise isolated system (for instance, by compressing a gas or winding a spring), the capacity of the system to do work is increased; in other words, the energy of the system is increased. When the system does work (when the piston moves out or the spring unwinds), the energy of the system is reduced and it can do less work than before.

Experiments have shown that the energy of a system may be changed by means other than work itself. When the energy of a system changes as a result of a temperature difference between the system and its surroundings we say that energy has been transferred as **heat**. When a heater is immersed in a beaker of water (the system), the capacity of the system to do work increases because hot water can be used to do more work than the same amount of cold water. Not all boundaries permit the transfer of energy even though there is a temperature difference between the system and its surroundings.

An **exothermic process** is a process that releases energy as heat into its surroundings. All combustion reactions are exothermic. An **endothermic process** is a process in which energy is acquired from its surroundings as heat. An example of an endothermic process is the vaporization of water. To avoid a lot of awkward circumlocution, we say that in an exothermic process energy is transferred ‘as heat’ to the surroundings and in an endothermic process energy is transferred ‘as heat’ from the surroundings into the system. However, it must never be forgotten that heat is a process (the transfer of energy as a result of a temperature difference), not an entity. An endothermic process in a diathermic container results in energy flowing into the system as heat. An exothermic process in a similar diathermic container results in a release of energy as heat into the surroundings. When an endothermic process takes place in an adiabatic container, it results in a lowering of temperature of the system; an exothermic process results in a rise of temperature. These features are summarized in Fig. 2.2.

(a) Open

(b) Closed

(c) Isolated

Fig. 2.1 (a) An open system can exchange matter and energy with its surroundings. (b) A closed system can exchange energy with its surroundings, but it cannot exchange matter. (c) An isolated system can exchange neither energy nor matter with its surroundings.

Molecular interpretation 2.1 Heat and work

In molecular terms, heating is the transfer of energy that makes use of *disorderly molecular motion*. The disorderly motion of molecules is called **thermal motion**. The thermal motion of the molecules in the hot surroundings stimulates the molecules in the cooler system to move more vigorously and, as a result, the energy of the system is increased. When a system heats its surroundings, molecules of the system stimulate the thermal motion of the molecules in the surroundings (Fig. 2.3).

In contrast, *work is the transfer of energy that makes use of organized motion* (Fig. 2.4). When a weight is raised or lowered, its atoms move in an organized way (up or down). The atoms in a spring move in an orderly way when it is wound; the

Fig. 2.2 (a) When an endothermic process occurs in an adiabatic system, the temperature falls; (b) if the process is exothermic, then the temperature rises. (c) When an endothermic process occurs in a diathermic container, energy enters as heat from the surroundings, and the system remains at the same temperature. (d) If the process is exothermic, then energy leaves as heat, and the process is isothermal.

Fig. 2.3 When energy is transferred to the surroundings as heat, the transfer stimulates random motion of the atoms in the surroundings. Transfer of energy from the surroundings to the system makes use of random motion (thermal motion) in the surroundings.

Fig. 2.4 When a system does work, it stimulates orderly motion in the surroundings. For instance, the atoms shown here may be part of a weight that is being raised. The ordered motion of the atoms in a falling weight does work on the system.

electrons in an electric current move in an orderly direction when it flows. When a system does work it causes atoms or electrons in its surroundings to move in an organized way. Likewise, when work is done on a system, molecules in the surroundings are used to transfer energy to it in an organized way, as the atoms in a weight are lowered or a current of electrons is passed.

The distinction between work and heat is made in the surroundings. The fact that a falling weight may stimulate thermal motion in the system is irrelevant to the distinction between heat and work: work is identified as energy transfer making use of the organized motion of atoms in the surroundings, and heat is identified as energy transfer making use of thermal motion in the surroundings. In the compression of a gas, for instance, work is done as the atoms of the compressing weight descend in an orderly way, but the effect of the incoming piston is to accelerate the gas molecules to higher average speeds. Because collisions between molecules quickly randomize their directions, the orderly motion of the atoms of the weight is in effect stimulating thermal motion in the gas. We observe the falling weight, the orderly descent of its atoms, and report that work is being done even though it is stimulating thermal motion.

2.2 The internal energy

In thermodynamics, the total energy of a system is called its **internal energy**, U . The internal energy is the total kinetic and potential energy of the molecules in the system (see *Comment 1.3* for the definitions of kinetic and potential energy).¹ We denote by ΔU the change in internal energy when a system changes from an initial state i with internal energy U_i to a final state f of internal energy U_f :

$$\Delta U = U_f - U_i \quad [2.1]$$

¹ The internal energy does not include the kinetic energy arising from the motion of the system as a whole, such as its kinetic energy as it accompanies the Earth on its orbit round the Sun.

The internal energy is a **state function** in the sense that its value depends only on the current state of the system and is independent of how that state has been prepared. In other words, it is a function of the properties that determine the current state of the system. Changing any one of the state variables, such as the pressure, results in a change in internal energy. The internal energy is an extensive property. That the internal energy is a state function has consequences of the greatest importance, as we start to unfold in Section 2.10.

Internal energy, heat, and work are all measured in the same units, the joule (J). The joule, which is named after the nineteenth-century scientist J.P. Joule, is defined as

$$1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$$

A joule is quite a small unit of energy: for instance, each beat of the human heart consumes about 1 J. Changes in molar internal energy, ΔU_{m} , are typically expressed in kilojoules per mole (kJ mol^{-1}). Certain other energy units are also used, but are more common in fields other than thermodynamics. Thus, 1 electronvolt (1 eV) is defined as the kinetic energy acquired when an electron is accelerated from rest through a potential difference of 1 V; the relation between electronvolts and joules is $1 \text{ eV} \approx 0.16 \text{ aJ}$ (where $1 \text{ aJ} = 10^{-18} \text{ J}$). Many processes in chemistry have an energy of several electronvolts. Thus, the energy to remove an electron from a sodium atom is close to 5 eV. Calories (cal) and kilocalories (kcal) are still encountered. The current definition of the calorie in terms of joules is

$$1 \text{ cal} = 4.184 \text{ J exactly}$$

An energy of 1 cal is enough to raise the temperature of 1 g of water by 1°C.

Comment 2.1

An extensive property is a property that depends on the amount of substance in the sample. An intensive property is a property that is independent of the amount of substance in the sample. Two examples of extensive properties are mass and volume. Examples of intensive properties are temperature, mass density (mass divided by volume), and pressure.

Molecular interpretation 2.2 *The internal energy of a gas*

A molecule has a certain number of degrees of freedom, such as the ability to translate (the motion of its centre of mass through space), rotate around its centre of mass, or vibrate (as its bond lengths and angles change). Many physical and chemical properties depend on the energy associated with each of these modes of motion. For example, a chemical bond might break if a lot of energy becomes concentrated in it.

The *equipartition theorem* of classical mechanics is a useful guide to the average energy associated with each degree of freedom when the sample is at a temperature T . First, we need to know that a ‘quadratic contribution’ to the energy means a contribution that can be expressed as the square of a variable, such as the position or the velocity. For example, the kinetic energy an atom of mass m as it moves through space is

$$E_{\text{K}} = \frac{1}{2}mv_x^2 + \frac{1}{2}mv_y^2 + \frac{1}{2}mv_z^2$$

and there are three quadratic contributions to its energy. The equipartition theorem then states that, for a collection of particles at thermal equilibrium at a temperature T , the average value of each quadratic contribution to the energy is the same and equal to $\frac{1}{2}kT$, where k is Boltzmann’s constant ($k = 1.381 \times 10^{-23} \text{ J K}^{-1}$).

The equipartition theorem is a conclusion from classical mechanics and is applicable only when the effects of quantization can be ignored (see Chapters 16 and 17). In practice, it can be used for molecular translation and rotation but not vibration. At 25°C, $\frac{1}{2}kT = 2 \text{ zJ}$ (where $1 \text{ zJ} = 10^{-21} \text{ J}$), or about 13 meV.

According to the equipartition theorem, the average energy of each term in the expression above is $\frac{1}{2}kT$. Therefore, the mean energy of the atoms is $\frac{3}{2}kT$ and the

Fig. 2.5 The rotational modes of molecules and the corresponding average energies at a temperature T . (a) A linear molecule can rotate about two axes perpendicular to the line of the atoms. (b) A nonlinear molecule can rotate about three perpendicular axes.

total energy of the gas (there being no potential energy contribution) is $\frac{3}{2}NkT$, or $\frac{3}{2}nRT$ (because $N = nN_A$ and $R = N_A k$). We can therefore write

$$U_m = U_m(0) + \frac{3}{2}RT$$

where $U_m(0)$ is the molar internal energy at $T = 0$, when all translational motion has ceased and the sole contribution to the internal energy arises from the internal structure of the atoms. This equation shows that the internal energy of a perfect gas increases linearly with temperature. At 25°C , $\frac{3}{2}RT = 3.7 \text{ kJ mol}^{-1}$, so translational motion contributes about 4 kJ mol^{-1} to the molar internal energy of a gaseous sample of atoms or molecules (the remaining contribution arises from the internal structure of the atoms and molecules).

When the gas consists of polyatomic molecules, we need to take into account the effect of rotation and vibration. A linear molecule, such as N_2 and CO_2 , can rotate around two axes perpendicular to the line of the atoms (Fig. 2.5), so it has two rotational modes of motion, each contributing a term $\frac{1}{2}kT$ to the internal energy. Therefore, the mean rotational energy is kT and the rotational contribution to the molar internal energy is RT . By adding the translational and rotational contributions, we obtain

$$U_m = U_m(0) + \frac{5}{2}RT \quad (\text{linear molecule, translation and rotation only})$$

A nonlinear molecule, such as CH_4 or water, can rotate around three axes and, again, each mode of motion contributes a term $\frac{1}{2}kT$ to the internal energy. Therefore, the mean rotational energy is $\frac{3}{2}kT$ and there is a rotational contribution of $\frac{3}{2}RT$ to the molar internal energy of the molecule. That is,

$$U_m = U_m(0) + 3RT \quad (\text{nonlinear molecule, translation and rotation only})$$

The internal energy now increases twice as rapidly with temperature compared with the monatomic gas.

The internal energy of interacting molecules in condensed phases also has a contribution from the potential energy of their interaction. However, no simple expressions can be written down in general. Nevertheless, the crucial molecular point is that, as the temperature of a system is raised, the internal energy increases as the various modes of motion become more highly excited.

It has been found experimentally that the internal energy of a system may be changed either by doing work on the system or by heating it. Whereas we may know how the energy transfer has occurred (because we can see if a weight has been raised or lowered in the surroundings, indicating transfer of energy by doing work, or if ice has melted in the surroundings, indicating transfer of energy as heat), the system is blind to the mode employed. *Heat and work are equivalent ways of changing a system's internal energy.* A system is like a bank: it accepts deposits in either currency, but stores its reserves as internal energy. It is also found experimentally that, if a system is isolated from its surroundings, then no change in internal energy takes place. This summary of observations is now known as the **First Law of thermodynamics** and expressed as follows:

The internal energy of an isolated system is constant.

We cannot use a system to do work, leave it isolated for a month, and then come back expecting to find it restored to its original state and ready to do the same work again. The evidence for this property is that no 'perpetual motion machine' (a machine that

does work without consuming fuel or some other source of energy) has ever been built.

These remarks may be summarized as follows. If we write w for the work done on a system, q for the energy transferred as heat to a system, and ΔU for the resulting change in internal energy, then it follows that

$$\Delta U = q + w \quad (2.2)$$

Equation 2.2 is the mathematical statement of the First Law, for it summarizes the equivalence of heat and work and the fact that the internal energy is constant in an isolated system (for which $q = 0$ and $w = 0$). The equation states that the change in internal energy of a closed system is equal to the energy that passes through its boundary as heat or work. It employs the ‘acquisitive convention’, in which $w > 0$ or $q > 0$ if energy is transferred to the system as work or heat and $w < 0$ or $q < 0$ if energy is lost from the system as work or heat. In other words, we view the flow of energy as work or heat from the system’s perspective.

Illustration 2.1 *The sign convention in thermodynamics*

If an electric motor produced 15 kJ of energy each second as mechanical work and lost 2 kJ as heat to the surroundings, then the change in the internal energy of the motor each second is

$$\Delta U = -2 \text{ kJ} - 15 \text{ kJ} = -17 \text{ kJ}$$

Suppose that, when a spring was wound, 100 J of work was done on it but 15 J escaped to the surroundings as heat. The change in internal energy of the spring is

$$\Delta U = +100 \text{ kJ} - 15 \text{ kJ} = +85 \text{ kJ}$$

2.3 Expansion work

The way can now be opened to powerful methods of calculation by switching attention to infinitesimal changes of state (such as infinitesimal change in temperature) and infinitesimal changes in the internal energy dU . Then, if the work done on a system is dw and the energy supplied to it as heat is dq , in place of eqn 2.2 we have

$$dU = dq + dw \quad (2.3)$$

To use this expression we must be able to relate dq and dw to events taking place in the surroundings.

We begin by discussing **expansion work**, the work arising from a change in volume. This type of work includes the work done by a gas as it expands and drives back the atmosphere. Many chemical reactions result in the generation or consumption of gases (for instance, the thermal decomposition of calcium carbonate or the combustion of octane), and the thermodynamic characteristics of a reaction depend on the work it can do. The term ‘expansion work’ also includes work associated with negative changes of volume, that is, compression.

(a) The general expression for work

The calculation of expansion work starts from the definition used in physics, which states that the work required to move an object a distance dz against an opposing force of magnitude F is

$$dw = -Fdz \quad [2.4]$$

Fig. 2.6 When a piston of area A moves out through a distance dz , it sweeps out a volume $dV = Adz$. The external pressure p_{ex} is equivalent to a weight pressing on the piston, and the force opposing expansion is $F = p_{\text{ex}}A$.

The negative sign tells us that, when the system moves an object against an opposing force, the internal energy of the system doing the work will decrease. Now consider the arrangement shown in Fig. 2.6, in which one wall of a system is a massless, frictionless, rigid, perfectly fitting piston of area A . If the external pressure is p_{ex} , the magnitude of the force acting on the outer face of the piston is $F = p_{\text{ex}}A$. When the system expands through a distance dz against an external pressure p_{ex} , it follows that the work done is $dw = -p_{\text{ex}}Adz$. But Adz is the change in volume, dV , in the course of the expansion. Therefore, the work done when the system expands by dV against a pressure p_{ex} is

$$dw = -p_{\text{ex}}dV \quad (2.5)$$

To obtain the total work done when the volume changes from V_i to V_f we integrate this expression between the initial and final volumes:

$$w = - \int_{V_i}^{V_f} p_{\text{ex}} dV \quad (2.6)$$

The force acting on the piston, $p_{\text{ex}}A$, is equivalent to a weight that is raised as the system expands.

If the system is compressed instead, then the same weight is lowered in the surroundings and eqn 2.6 can still be used, but now $V_f < V_i$. It is important to note that it is still the external pressure that determines the magnitude of the work. This somewhat perplexing conclusion seems to be inconsistent with the fact that the gas *inside* the container is opposing the compression. However, when a gas is compressed, the ability of the *surroundings* to do work is diminished by an amount determined by the weight that is lowered, and it is this energy that is transferred into the system.

Other types of work (for example, electrical work), which we shall call either **non-expansion work** or **additional work**, have analogous expressions, with each one the product of an intensive factor (the pressure, for instance) and an extensive factor (the change in volume). Some are collected in Table 2.1. For the present we continue with the work associated with changing the volume, the expansion work, and see what we can extract from eqns 2.5 and 2.6.

(b) Free expansion

By **free expansion** we mean expansion against zero opposing force. It occurs when $p_{\text{ex}} = 0$. According to eqn 2.5, $dw = 0$ for each stage of the expansion. Hence, overall:

$$\text{Free expansion:} \quad w = 0 \quad (2.7)$$

Table 2.1 Varieties of work*

Type of work	dw	Comments	Units†
Expansion	$-p_{\text{ex}}dV$	p_{ex} is the external pressure dV is the change in volume	Pa m^3
Surface expansion	$\gamma d\sigma$	γ is the surface tension $d\sigma$ is the change in area	N m^{-1} m^2
Extension	$f dl$	f is the tension dl is the change in length	N m
Electrical	ϕdQ	ϕ is the electric potential dQ is the change in charge	V C

* In general, the work done on a system can be expressed in the form $dw = -Fdz$, where F is a 'generalized force' and dz is a 'generalized displacement'.

† For work in joules (J). Note that $1 \text{ N m} = 1 \text{ J}$ and $1 \text{ V C} = 1 \text{ J}$.

That is, no work is done when a system expands freely. Expansion of this kind occurs when a system expands into a vacuum.

(c) Expansion against constant pressure

Now suppose that the external pressure is constant throughout the expansion. For example, the piston may be pressed on by the atmosphere, which exerts the same pressure throughout the expansion. A chemical example of this condition is the expansion of a gas formed in a chemical reaction. We can evaluate eqn 2.6 by taking the constant p_{ex} outside the integral:

$$w = -p_{\text{ex}} \int_{V_i}^{V_f} dV = -p_{\text{ex}}(V_f - V_i)$$

Therefore, if we write the change in volume as $\Delta V = V_f - V_i$,

$$w = -p_{\text{ex}} \Delta V \quad (2.8)$$

This result is illustrated graphically in Fig. 2.7, which makes use of the fact that an integral can be interpreted as an area. The magnitude of w , denoted $|w|$, is equal to the area beneath the horizontal line at $p = p_{\text{ex}}$ lying between the initial and final volumes. A p, V -graph used to compute expansion work is called an **indicator diagram**; James Watt first used one to indicate aspects of the operation of his steam engine.

(d) Reversible expansion

A **reversible change** in thermodynamics is a change that can be reversed by an infinitesimal modification of a variable. The key word ‘infinitesimal’ sharpens the everyday meaning of the word ‘reversible’ as something that can change direction. We say that a system is in **equilibrium** with its surroundings if an infinitesimal change in the conditions in opposite directions results in opposite changes in its state. One example of reversibility that we have encountered already is the thermal equilibrium of two systems with the same temperature. The transfer of energy as heat between the two is reversible because, if the temperature of either system is lowered infinitesimally, then energy flows into the system with the lower temperature. If the temperature of either system at thermal equilibrium is raised infinitesimally, then energy flows out of the hotter system.

Suppose a gas is confined by a piston and that the external pressure, p_{ex} , is set equal to the pressure, p , of the confined gas. Such a system is in mechanical equilibrium with its surroundings (as illustrated in Section 1.1) because an infinitesimal change in the external pressure in either direction causes changes in volume in opposite directions. If the external pressure is reduced infinitesimally, then the gas expands slightly. If the external pressure is increased infinitesimally, then the gas contracts slightly. In either case the change is reversible in the thermodynamic sense. If, on the other hand, the external pressure differs measurably from the internal pressure, then changing p_{ex} infinitesimally will not decrease it below the pressure of the gas, so will not change the direction of the process. Such a system is not in mechanical equilibrium with its surroundings and the expansion is thermodynamically irreversible.

To achieve reversible expansion we set p_{ex} equal to p at each stage of the expansion. In practice, this equalization could be achieved by gradually removing weights from the piston so that the downward force due to the weights always matched the changing upward force due to the pressure of the gas. When we set $p_{\text{ex}} = p$, eqn 2.5 becomes

$$dw = -p_{\text{ex}} dV = -p dV \quad (2.9)_{\text{rev}}$$

(Equations valid only for reversible processes are labelled with a subscript rev.) Although the pressure inside the system appears in this expression for the work, it

Fig. 2.7 The work done by a gas when it expands against a constant external pressure, p_{ex} , is equal to the shaded area in this example of an indicator diagram.

Comment 2.2

The value of the integral $\int_a^b f(x) dx$ is

equal to the area under the graph of $f(x)$ between $x = a$ and $x = b$. For instance, the area under the curve $f(x) = x^2$ shown in the illustration that lies between $x = 1$ and 3 is

$$\begin{aligned} \int_1^3 x^2 dx &= \left(\frac{1}{3} x^3 + \text{constant} \right) \Big|_1^3 \\ &= \frac{1}{3} (3^3 - 1^3) = \frac{26}{3} \approx 8.67 \end{aligned}$$

does so only because p_{ex} has been set equal to p to ensure reversibility. The total work of reversible expansion is therefore

$$w = - \int_{V_i}^{V_f} p dV \quad (2.10)_{\text{rev}}$$

We can evaluate the integral once we know how the pressure of the confined gas depends on its volume. Equation 2.10 is the link with the material covered in Chapter 1 for, if we know the equation of state of the gas, then we can express p in terms of V and evaluate the integral.

(e) Isothermal reversible expansion

Consider the isothermal, reversible expansion of a perfect gas. The expansion is made isothermal by keeping the system in thermal contact with its surroundings (which may be a constant-temperature bath). Because the equation of state is $pV = nRT$, we know that at each stage $p = nRT/V$, with V the volume at that stage of the expansion. The temperature T is constant in an isothermal expansion, so (together with n and R) it may be taken outside the integral. It follows that the work of reversible isothermal expansion of a perfect gas from V_i to V_f at a temperature T is

$$w = -nRT \int_{V_i}^{V_f} \frac{dV}{V} = -nRT \ln \frac{V_f}{V_i} \quad (2.11)_{\text{rev}}^{\circ}$$

When the final volume is greater than the initial volume, as in an expansion, the logarithm in eqn 2.11 is positive and hence $w < 0$. In this case, the system has done work on the surroundings and the internal energy of the system has decreased as a result.² The equations also show that more work is done for a given change of volume when the temperature is increased. The greater pressure of the confined gas then needs a higher opposing pressure to ensure reversibility.

We can express the result of the calculation as an indicator diagram, for the magnitude of the work done is equal to the area under the isotherm $p = nRT/V$ (Fig. 2.8). Superimposed on the diagram is the rectangular area obtained for irreversible expansion against constant external pressure fixed at the same final value as that reached in the reversible expansion. More work is obtained when the expansion is reversible (the area is greater) because matching the external pressure to the internal pressure at each stage of the process ensures that none of the system's pushing power is wasted. We cannot obtain more work than for the reversible process because increasing the external pressure even infinitesimally at any stage results in compression. We may infer from this discussion that, because some pushing power is wasted when $p > p_{\text{ex}}$, the maximum work available from a system operating between specified initial and final states and passing along a specified path is obtained when the change takes place reversibly.

We have introduced the connection between reversibility and maximum work for the special case of a perfect gas undergoing expansion. Later (in Section 3.5) we shall see that it applies to all substances and to all kinds of work.

Comment 2.3

An integral that occurs throughout thermodynamics is

$$\int_a^b \frac{1}{x} dx = (\ln x + \text{constant}) \Big|_a^b = \ln \frac{b}{a}$$

Fig. 2.8 The work done by a perfect gas when it expands reversibly and isothermally is equal to the area under the isotherm $p = nRT/V$. The work done during the irreversible expansion against the same final pressure is equal to the rectangular area shown slightly darker. Note that the reversible work is greater than the irreversible work.

Exploration Calculate the work of isothermal reversible expansion of 1.0 mol $\text{CO}_2(\text{g})$ at 298 K from 1.0 m^3 to 3.0 m^3 on the basis that it obeys the van der Waals equation of state.

Example 2.1 Calculating the work of gas production

Calculate the work done when 50 g of iron reacts with hydrochloric acid in (a) a closed vessel of fixed volume, (b) an open beaker at 25°C .

² We shall see later that there is a compensating influx of energy as heat, so overall the internal energy is constant for the isothermal expansion of a perfect gas.

Method We need to judge the magnitude of the volume change and then to decide how the process occurs. If there is no change in volume, there is no expansion work however the process takes place. If the system expands against a constant external pressure, the work can be calculated from eqn 2.8. A general feature of processes in which a condensed phase changes into a gas is that the volume of the former may usually be neglected relative to that of the gas it forms.

Answer In (a) the volume cannot change, so no expansion work is done and $w = 0$. In (b) the gas drives back the atmosphere and therefore $w = -p_{\text{ex}} \Delta V$. We can neglect the initial volume because the final volume (after the production of gas) is so much larger and $\Delta V = V_f - V_i \approx V_f = nRT/p_{\text{ex}}$, where n is the amount of H_2 produced. Therefore,

$$w = -p_{\text{ex}} \Delta V \approx -p_{\text{ex}} \times \frac{nRT}{p_{\text{ex}}} = -nRT$$

Because the reaction is $\text{Fe(s)} + 2 \text{HCl(aq)} \rightarrow \text{FeCl}_2\text{(aq)} + \text{H}_2\text{(g)}$, we know that 1 mol H_2 is generated when 1 mol Fe is consumed, and n can be taken as the amount of Fe atoms that react. Because the molar mass of Fe is 55.85 g mol^{-1} , it follows that

$$w \approx -\frac{50 \text{ g}}{55.85 \text{ g mol}^{-1}} \times (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K}) \\ \approx -2.2 \text{ kJ}$$

The system (the reaction mixture) does 2.2 kJ of work driving back the atmosphere. Note that (for this perfect gas system) the magnitude of the external pressure does not affect the final result: the lower the pressure, the larger the volume occupied by the gas, so the effects cancel.

Self-test 2.1 Calculate the expansion work done when 50 g of water is electrolysed under constant pressure at 25°C . [−10 kJ]

2.4 Heat transactions

In general, the change in internal energy of a system is

$$dU = dq + dw_{\text{exp}} + dw_{\text{e}} \quad (2.12)$$

where dw_{e} is work in addition (e for ‘extra’) to the expansion work, dw_{exp} . For instance, dw_{e} might be the electrical work of driving a current through a circuit. A system kept at constant volume can do no expansion work, so $dw_{\text{exp}} = 0$. If the system is also incapable of doing any other kind of work (if it is not, for instance, an electrochemical cell connected to an electric motor), then $dw_{\text{e}} = 0$ too. Under these circumstances:

$$dU = dq \quad (\text{at constant volume, no additional work}) \quad (2.13a)$$

We express this relation by writing $dU = dq_V$, where the subscript implies a change at constant volume. For a measurable change,

$$\Delta U = q_V \quad (2.13b)$$

It follows that, by measuring the energy supplied to a constant-volume system as heat ($q > 0$) or obtained from it as heat ($q < 0$) when it undergoes a change of state, we are in fact measuring the change in its internal energy.

Fig. 2.9 A constant-volume bomb calorimeter. The ‘bomb’ is the central vessel, which is strong enough to withstand high pressures. The calorimeter (for which the heat capacity must be known) is the entire assembly shown here. To ensure adiabaticity, the calorimeter is immersed in a water bath with a temperature continuously readjusted to that of the calorimeter at each stage of the combustion.

Comment 2.4

Electrical charge is measured in *coulombs*, C . The motion of charge gives rise to an electric current, I , measured in coulombs per second, or *amperes*, A , where $1\text{ A} = 1\text{ C s}^{-1}$. If a constant current I flows through a potential difference $\mathcal{V}$ (measured in volts, V), the total energy supplied in an interval t is

$$\text{Energy supplied} = I\mathcal{V}t$$

Because $1\text{ A V s} = 1\text{ (C s}^{-1}\text{) V s} = 1\text{ C V} = 1\text{ J}$, the energy is obtained in joules with the current in amperes, the potential difference in volts, and the time in seconds. We write the electrical power, P , as

$$P = (\text{energy supplied})/(\text{time interval}) \\ = I\mathcal{V}t/t = I\mathcal{V}$$

(a) Calorimetry

Calorimetry is the study of heat transfer during physical and chemical processes. A **calorimeter** is a device for measuring energy transferred as heat. The most common device for measuring ΔU is an **adiabatic bomb calorimeter** (Fig. 2.9). The process we wish to study—which may be a chemical reaction—is initiated inside a constant-volume container, the ‘bomb’. The bomb is immersed in a stirred water bath, and the whole device is the calorimeter. The calorimeter is also immersed in an outer water bath. The water in the calorimeter and of the outer bath are both monitored and adjusted to the same temperature. This arrangement ensures that there is no net loss of heat from the calorimeter to the surroundings (the bath) and hence that the calorimeter is adiabatic.

The change in temperature, ΔT , of the calorimeter is proportional to the heat that the reaction releases or absorbs. Therefore, by measuring ΔT we can determine q_V and hence find ΔU . The conversion of ΔT to q_V is best achieved by calibrating the calorimeter using a process of known energy output and determining the **calorimeter constant**, the constant C in the relation

$$q = C\Delta T \quad (2.14a)$$

The calorimeter constant may be measured electrically by passing a constant current, I , from a source of known potential difference, $\mathcal{V}$, through a heater for a known period of time, t , for then

$$q = I\mathcal{V}t \quad (2.14b)$$

Alternatively, C may be determined by burning a known mass of substance (benzoic acid is often used) that has a known heat output. With C known, it is simple to interpret an observed temperature rise as a release of heat.

Illustration 2.2 The calibration of a calorimeter

If we pass a current of 10.0 A from a 12 V supply for 300 s , then from eqn 2.14b the energy supplied as heat is

$$q = (10.0\text{ A}) \times (12\text{ V}) \times (300\text{ s}) = 3.6 \times 10^4\text{ A V s} = 36\text{ kJ}$$

because $1\text{ A V s} = 1\text{ J}$. If the observed rise in temperature is 5.5 K , then the calorimeter constant is $C = (36\text{ kJ})/(5.5\text{ K}) = 6.5\text{ kJ K}^{-1}$.

(b) Heat capacity

The internal energy of a substance increases when its temperature is raised. The increase depends on the conditions under which the heating takes place and for the present we suppose that the sample is confined to a constant volume. For example, the sample may be a gas in a container of fixed volume. If the internal energy is plotted against temperature, then a curve like that in Fig. 2.10 may be obtained. The slope of the tangent to the curve at any temperature is called the **heat capacity** of the system at that temperature. The **heat capacity at constant volume** is denoted C_V and is defined formally as³

³ If the system can change its composition, it is necessary to distinguish between equilibrium and fixed-composition values of C_V . All applications in this chapter refer to a single substance, so this complication can be ignored.

Fig. 2.10 The internal energy of a system increases as the temperature is raised; this graph shows its variation as the system is heated at constant volume. The slope of the tangent to the curve at any temperature is the heat capacity at constant volume at that temperature. Note that, for the system illustrated, the heat capacity is greater at B than at A.

Fig. 2.11 The internal energy of a system varies with volume and temperature, perhaps as shown here by the surface. The variation of the internal energy with temperature at one particular constant volume is illustrated by the curve drawn parallel to T . The slope of this curve at any point is the partial derivative $(\partial U/\partial T)_V$.

$$C_V = \left(\frac{\partial U}{\partial T} \right)_V \quad [2.15]$$

In this case, the internal energy varies with the temperature and the volume of the sample, but we are interested only in its variation with the temperature, the volume being held constant (Fig. 2.11).

Illustration 2.3 Estimating a constant-volume heat capacity

The heat capacity of a monatomic perfect gas can be calculated by inserting the expression for the internal energy derived in *Molecular interpretation 2.2*. There we saw that $U_m = U_m(0) + \frac{3}{2}RT$, so from eqn 2.15

$$C_{V,m} = \frac{\partial}{\partial T} (U_m(0) + \frac{3}{2}RT) = \frac{3}{2}R$$

The numerical value is $12.47 \text{ J K}^{-1} \text{ mol}^{-1}$.

Heat capacities are extensive properties: 100 g of water, for instance, has 100 times the heat capacity of 1 g of water (and therefore requires 100 times the energy as heat to bring about the same rise in temperature). The **molar heat capacity at constant volume**, $C_{V,m} = C_V/n$, is the heat capacity per mole of material, and is an intensive property (all molar quantities are intensive). Typical values of $C_{V,m}$ for polyatomic gases are close to $25 \text{ J K}^{-1} \text{ mol}^{-1}$. For certain applications it is useful to know the **specific heat capacity** (more informally, the ‘specific heat’) of a substance, which is the heat capacity of the sample divided by the mass, usually in grams: $C_{V,s} = C_V/m$. The specific heat capacity of water at room temperature is close to $4 \text{ J K}^{-1} \text{ g}^{-1}$. In general,

Comment 2.5

The partial-differential operation $(\partial z/\partial x)_y$ consists of taking the first derivative of $z(x,y)$ with respect to x , treating y as a constant. For example, if $z(x,y) = x^2y$, then

$$\left(\frac{\partial z}{\partial x} \right)_y = \left(\frac{\partial [x^2y]}{\partial x} \right)_y = y \frac{dx^2}{dx} = 2yx$$

Partial derivatives are reviewed in *Appendix 2*.

heat capacities depend on the temperature and decrease at low temperatures. However, over small ranges of temperature at and above room temperature, the variation is quite small and for approximate calculations heat capacities can be treated as almost independent of temperature.

The heat capacity is used to relate a change in internal energy to a change in temperature of a constant-volume system. It follows from eqn 2.15 that

$$dU = C_V dT \quad (\text{at constant volume}) \quad (2.16a)$$

That is, at constant volume, an infinitesimal change in temperature brings about an infinitesimal change in internal energy, and the constant of proportionality is C_V . If the heat capacity is independent of temperature over the range of temperatures of interest, a measurable change of temperature, ΔT , brings about a measurable increase in internal energy, ΔU , where

$$\Delta U = C_V \Delta T \quad (\text{at constant volume}) \quad (2.16b)$$

Because a change in internal energy can be identified with the heat supplied at constant volume (eqn 2.13b), the last equation can be written

$$q_V = C_V \Delta T \quad (2.17)$$

This relation provides a simple way of measuring the heat capacity of a sample: a measured quantity of energy is transferred as heat to the sample (electrically, for example), and the resulting increase in temperature is monitored. The ratio of the energy transferred as heat to the temperature rise it causes ($q_V/\Delta T$) is the constant-volume heat capacity of the sample.

A large heat capacity implies that, for a given quantity of energy transferred as heat, there will be only a small increase in temperature (the sample has a large capacity for heat). An infinite heat capacity implies that there will be no increase in temperature however much energy is supplied as heat. At a phase transition, such as at the boiling point of water, the temperature of a substance does not rise as energy is supplied as heat: the energy is used to drive the endothermic transition, in this case to vaporize the water, rather than to increase its temperature. Therefore, at the temperature of a phase transition, the heat capacity of a sample is infinite. The properties of heat capacities close to phase transitions are treated more fully in Section 4.7.

Fig. 2.12 When a system is subjected to constant pressure and is free to change its volume, some of the energy supplied as heat may escape back into the surroundings as work. In such a case, the change in internal energy is smaller than the energy supplied as heat.

2.5 Enthalpy

The change in internal energy is not equal to the energy transferred as heat when the system is free to change its volume. Under these circumstances some of the energy supplied as heat to the system is returned to the surroundings as expansion work (Fig. 2.12), so dU is less than dq . However, we shall now show that in this case the energy supplied as heat at constant pressure is equal to the change in another thermodynamic property of the system, the enthalpy.

(a) The definition of enthalpy

The **enthalpy**, H , is defined as

$$H = U + pV \quad [2.18]$$

where p is the pressure of the system and V is its volume. Because U , p , and V are all state functions, the enthalpy is a state function too. As is true of any state function, the change in enthalpy, ΔH , between any pair of initial and final states is independent of the path between them.

Although the definition of enthalpy may appear arbitrary, it has important implications for thermochemistry. For instance, we show in the following *Justification* that eqn 2.18 implies that *the change in enthalpy is equal to the energy supplied as heat at constant pressure* (provided the system does no additional work):

$$dH = dq \quad (\text{at constant pressure, no additional work}) \quad (2.19a)$$

For a measurable change,

$$\Delta H = q_p \quad (2.19b)$$

Justification 2.1 *The relation $\Delta H = q_p$*

For a general infinitesimal change in the state of the system, U changes to $U + dU$, p changes to $p + dp$, and V changes to $V + dV$, so from the definition in eqn 2.18, H changes from $U + pV$ to

$$\begin{aligned} H + dH &= (U + dU) + (p + dp)(V + dV) \\ &= U + dU + pV + pdV + Vdp + dpdV \end{aligned}$$

The last term is the product of two infinitesimally small quantities and can therefore be neglected. As a result, after recognizing $U + pV = H$ on the right, we find that H changes to

$$H + dH = H + dU + pdV + Vdp$$

and hence that

$$dH = dU + pdV + Vdp$$

If we now substitute $dU = dq + dw$ into this expression, we get

$$dH = dq + dw + pdV + Vdp$$

If the system is in mechanical equilibrium with its surroundings at a pressure p and does only expansion work, we can write $dw = -pdV$ and obtain

$$dH = dq + Vdp$$

Now we impose the condition that the heating occurs at constant pressure by writing $dp = 0$. Then

$$dH = dq \quad (\text{at constant pressure, no additional work})$$

as in eqn 2.19a.

The result expressed in eqn 2.19 states that, when a system is subjected to a constant pressure, and only expansion work can occur, the change in enthalpy is equal to the energy supplied as heat. For example, if we supply 36 kJ of energy through an electric heater immersed in an open beaker of water, then the enthalpy of the water increases by 36 kJ and we write $\Delta H = +36$ kJ.

(b) The measurement of an enthalpy change

An enthalpy change can be measured calorimetrically by monitoring the temperature change that accompanies a physical or chemical change occurring at constant pressure. A calorimeter for studying processes at constant pressure is called an **isobaric calorimeter**. A simple example is a thermally insulated vessel open to the atmosphere: the heat released in the reaction is monitored by measuring the change in temperature

Fig. 2.13 A constant-pressure flame calorimeter consists of this component immersed in a stirred water bath. Combustion occurs as a known amount of reactant is passed through to fuel the flame, and the rise of temperature is monitored.

of the contents. For a combustion reaction an **adiabatic flame calorimeter** may be used to measure ΔT when a given amount of substance burns in a supply of oxygen (Fig. 2.13). Another route to ΔH is to measure the internal energy change by using a bomb calorimeter, and then to convert ΔU to ΔH . Because solids and liquids have small molar volumes, for them pV_m is so small that the molar enthalpy and molar internal energy are almost identical ($H_m = U_m + pV_m \approx U_m$). Consequently, if a process involves only solids or liquids, the values of ΔH and ΔU are almost identical. Physically, such processes are accompanied by a very small change in volume, the system does negligible work on the surroundings when the process occurs, so the energy supplied as heat stays entirely within the system. The most sophisticated way to measure enthalpy changes, however, is to use a **differential scanning calorimeter** (DSC). Changes in enthalpy and internal energy may also be measured by noncalorimetric methods (see Chapter 7).

Example 2.2 Relating ΔH and ΔU

The internal energy change when 1.0 mol CaCO_3 in the form of calcite converts to aragonite is +0.21 kJ. Calculate the difference between the enthalpy change and the change in internal energy when the pressure is 1.0 bar given that the densities of the solids are 2.71 g cm^{-3} and 2.93 g cm^{-3} , respectively.

Method The starting point for the calculation is the relation between the enthalpy of a substance and its internal energy (eqn 2.18). The difference between the two quantities can be expressed in terms of the pressure and the difference of their molar volumes, and the latter can be calculated from their molar masses, M , and their mass densities, ρ , by using $\rho = M/V_m$.

Answer The change in enthalpy when the transition occurs is

$$\begin{aligned}\Delta H &= H(\text{aragonite}) - H(\text{calcite}) \\ &= \{U(a) + pV(a)\} - \{U(c) + pV(c)\} \\ &= \Delta U + p\{V(a) - V(c)\} = \Delta U + p\Delta V\end{aligned}$$

The volume of 1.0 mol CaCO_3 (100 g) as aragonite is 34 cm^3 , and that of 1.0 mol CaCO_3 as calcite is 37 cm^3 . Therefore,

$$p\Delta V = (1.0 \times 10^5 \text{ Pa}) \times (34 - 37) \times 10^{-6} \text{ m}^3 = -0.3 \text{ J}$$

(because $1 \text{ Pa m}^3 = 1 \text{ J}$). Hence,

$$\Delta H - \Delta U = -0.3 \text{ J}$$

which is only 0.1 per cent of the value of ΔU . We see that it is usually justifiable to ignore the difference between the enthalpy and internal energy of condensed phases, except at very high pressures, when pV is no longer negligible.

Self-test 2.2 Calculate the difference between ΔH and ΔU when 1.0 mol Sn(s, grey) of density 5.75 g cm^{-3} changes to Sn(s, white) of density 7.31 g cm^{-3} at 10.0 bar. At 298 K, $\Delta H = +2.1 \text{ kJ}$. $[\Delta H - \Delta U = -4.4 \text{ J}]$

The enthalpy of a perfect gas is related to its internal energy by using $pV = nRT$ in the definition of H :

$$H = U + pV = U + nRT \quad (2.20)^\circ$$

This relation implies that the change of enthalpy in a reaction that produces or consumes gas is

$$\Delta H = \Delta U + \Delta n_g RT \quad (2.21)^\circ$$

where Δn_g is the change in the amount of gas molecules in the reaction.

Illustration 2.4 *The relation between ΔH and ΔU for gas-phase reactions*

In the reaction $2 \text{H}_2(\text{g}) + \text{O}_2(\text{g}) \rightarrow 2 \text{H}_2\text{O}(\text{l})$, 3 mol of gas-phase molecules is replaced by 2 mol of liquid-phase molecules, so $\Delta n_g = -3$ mol. Therefore, at 298 K, when $RT = 2.5 \text{ kJ mol}^{-1}$, the enthalpy and internal energy changes taking place in the system are related by

$$\Delta H - \Delta U = (-3 \text{ mol}) \times RT \approx -7.4 \text{ kJ}$$

Note that the difference is expressed in kilojoules, not joules as in Example 2.2. The enthalpy change is smaller (in this case, less negative) than the change in internal energy because, although heat escapes from the system when the reaction occurs, the system contracts when the liquid is formed, so energy is restored to it from the surroundings.

Example 2.3 *Calculating a change in enthalpy*

Water is heated to boiling under a pressure of 1.0 atm. When an electric current of 0.50 A from a 12 V supply is passed for 300 s through a resistance in thermal contact with it, it is found that 0.798 g of water is vaporized. Calculate the molar internal energy and enthalpy changes at the boiling point (373.15 K).

Method Because the vaporization occurs at constant pressure, the enthalpy change is equal to the heat supplied by the heater. Therefore, the strategy is to calculate the energy supplied as heat (from $q = I\mathcal{V}t$), express that as an enthalpy change, and then convert the result to a molar enthalpy change by division by the amount of H_2O molecules vaporized. To convert from enthalpy change to internal energy change, we assume that the vapour is a perfect gas and use eqn 2.21.

Answer The enthalpy change is

$$\Delta H = q_p = (0.50 \text{ A}) \times (12 \text{ V}) \times (300 \text{ s}) = +(0.50 \times 12 \times 300) \text{ J}$$

Here we have used $1 \text{ A V s} = 1 \text{ J}$ (see *Comment 2.4*). Because 0.798 g of water is $(0.798 \text{ g})/(18.02 \text{ g mol}^{-1}) = (0.798/18.02) \text{ mol H}_2\text{O}$, the enthalpy of vaporization per mole of H_2O is

$$\Delta H_m = + \frac{0.50 \times 12 \times 300 \text{ J}}{(0.798/18.02) \text{ mol}} = +41 \text{ kJ mol}^{-1}$$

In the process $\text{H}_2\text{O}(\text{l}) \rightarrow \text{H}_2\text{O}(\text{g})$ the change in the amount of gas molecules is $\Delta n_g = +1$ mol, so

$$\Delta U_m = \Delta H_m - RT = +38 \text{ kJ mol}^{-1}$$

The plus sign is added to positive quantities to emphasize that they represent an increase in internal energy or enthalpy. Notice that the internal energy change is smaller than the enthalpy change because energy has been used to drive back the surrounding atmosphere to make room for the vapour.

Fig. 2.14 The slope of the tangent to a curve of the enthalpy of a system subjected to a constant pressure plotted against temperature is the constant-pressure heat capacity. The slope may change with temperature, in which case the heat capacity varies with temperature. Thus, the heat capacities at A and B are different. For gases, at a given temperature the slope of enthalpy versus temperature is steeper than that of internal energy versus temperature, and $C_{p,m}$ is larger than $C_{V,m}$.

Self-test 2.3 The molar enthalpy of vaporization of benzene at its boiling point (353.25 K) is 30.8 kJ mol^{-1} . What is the molar internal energy change? For how long would the same 12 V source need to supply a 0.50 A current in order to vaporize a 10 g sample? $[+27.9 \text{ kJ mol}^{-1}, 660 \text{ s}]$

(c) The variation of enthalpy with temperature

The enthalpy of a substance increases as its temperature is raised. The relation between the increase in enthalpy and the increase in temperature depends on the conditions (for example, constant pressure or constant volume). The most important condition is constant pressure, and the slope of the tangent to a plot of enthalpy against temperature at constant pressure is called the **heat capacity at constant pressure**, C_p , at a given temperature (Fig. 2.14). More formally:

$$C_p = \left(\frac{\partial H}{\partial T} \right)_p \quad [2.22]$$

The heat capacity at constant pressure is the analogue of the heat capacity at constant volume, and is an extensive property.⁴ The **molar heat capacity at constant pressure**, $C_{p,m}$, is the heat capacity per mole of material; it is an intensive property.

The heat capacity at constant pressure is used to relate the change in enthalpy to a change in temperature. For infinitesimal changes of temperature,

$$dH = C_p dT \quad (\text{at constant pressure}) \quad (2.23a)$$

If the heat capacity is constant over the range of temperatures of interest, then for a measurable increase in temperature

$$\Delta H = C_p \Delta T \quad (\text{at constant pressure}) \quad (2.23b)$$

Because an increase in enthalpy can be equated with the energy supplied as heat at constant pressure, the practical form of the latter equation is

$$q_p = C_p \Delta T \quad (2.24)$$

This expression shows us how to measure the heat capacity of a sample: a measured quantity of energy is supplied as heat under conditions of constant pressure (as in a sample exposed to the atmosphere and free to expand), and the temperature rise is monitored.

The variation of heat capacity with temperature can sometimes be ignored if the temperature range is small; this approximation is highly accurate for a monatomic perfect gas (for instance, one of the noble gases at low pressure). However, when it is necessary to take the variation into account, a convenient approximate empirical expression is

$$C_{p,m} = a + bT + \frac{c}{T^2} \quad (2.25)$$

The empirical parameters a , b , and c are independent of temperature (Table 2.2).

⁴ As in the case of C_V , if the system can change its composition it is necessary to distinguish between equilibrium and fixed-composition values. All applications in this chapter refer to pure substances, so this complication can be ignored.

Synoptic Table 2.2* Temperature variation of molar heat capacities, $C_{p,m}/(\text{J K}^{-1} \text{mol}^{-1}) = a + bT + c/T^2$

	a	$b/(10^{-3} \text{ K})$	$c/(10^5 \text{ K}^2)$
C(s, graphite)	16.86	4.77	-8.54
CO ₂ (g)	44.22	8.79	-8.62
H ₂ O(l)	75.29	0	0
N ₂ (g)	28.58	3.77	-0.50

* More values are given in the *Data section*.

Example 2.4 Evaluating an increase in enthalpy with temperature

What is the change in molar enthalpy of N₂ when it is heated from 25°C to 100°C? Use the heat capacity information in Table 2.2.

Method The heat capacity of N₂ changes with temperature, so we cannot use eqn 2.23b (which assumes that the heat capacity of the substance is constant). Therefore, we must use eqn 2.23a, substitute eqn 2.25 for the temperature dependence of the heat capacity, and integrate the resulting expression from 25°C to 100°C.

Answer For convenience, we denote the two temperatures T_1 (298 K) and T_2 (373 K). The integrals we require are

$$\int_{H(T_1)}^{H(T_2)} dH = \int_{T_1}^{T_2} \left(a + bT + \frac{c}{T^2} \right) dT$$

Notice how the limits of integration correspond on each side of the equation: the integration over H on the left ranges from $H(T_1)$, the value of H at T_1 , up to $H(T_2)$, the value of H at T_2 , while on the right the integration over the temperature ranges from T_1 to T_2 . Now we use the integrals

$$\int dx = x + \text{constant} \quad \int x dx = \frac{1}{2}x^2 + \text{constant} \quad \int \frac{dx}{x^2} = -\frac{1}{x} + \text{constant}$$

to obtain

$$H(T_2) - H(T_1) = a(T_2 - T_1) + \frac{1}{2}b(T_2^2 - T_1^2) - c\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

Substitution of the numerical data results in

$$H(373 \text{ K}) = H(298 \text{ K}) + 2.20 \text{ kJ mol}^{-1}$$

If we had assumed a constant heat capacity of $29.14 \text{ J K}^{-1} \text{mol}^{-1}$ (the value given by eqn 2.25 at 25°C), we would have found that the two enthalpies differed by 2.19 kJ mol^{-1} .

Self-test 2.4 At very low temperatures the heat capacity of a solid is proportional to T^3 , and we can write $C_p = aT^3$. What is the change in enthalpy of such a substance when it is heated from 0 to a temperature T (with T close to 0)? $[\Delta H = \frac{1}{4}aT^4]$

Comment 2.6

Integrals commonly encountered in physical chemistry are listed inside the front cover.

Most systems expand when heated at constant pressure. Such systems do work on the surroundings and therefore some of the energy supplied to them as heat escapes

Fig. 2.15 A differential scanning calorimeter. The sample and a reference material are heated in separate but identical metal heat sinks. The output is the difference in power needed to maintain the heat sinks at equal temperatures as the temperature rises.

Fig. 2.16 A thermogram for the protein ubiquitin at pH = 2.45. The protein retains its native structure up to about 45°C and then undergoes an endothermic conformational change. (Adapted from B. Chowdhry and S. LeHarne, *J. Chem. Educ.* 74, 236 (1997).)

back to the surroundings. As a result, the temperature of the system rises less than when the heating occurs at constant volume. A smaller increase in temperature implies a larger heat capacity, so we conclude that in most cases the heat capacity at constant pressure of a system is larger than its heat capacity at constant volume. We show later (Section 2.11) that there is a simple relation between the two heat capacities of a perfect gas:

$$C_p - C_V = nR \quad (2.26)^\circ$$

It follows that the molar heat capacity of a perfect gas is about $8 \text{ J K}^{-1} \text{ mol}^{-1}$ larger at constant pressure than at constant volume. Because the heat capacity at constant volume of a monatomic gas is about $12 \text{ J K}^{-1} \text{ mol}^{-1}$, the difference is highly significant and must be taken into account.

IMPACT ON BIOCHEMISTRY AND MATERIALS SCIENCE

12.1 Differential scanning calorimetry

A *differential scanning calorimeter* (DSC) measures the energy transferred as heat to or from a sample at constant pressure during a physical or chemical change. The term ‘differential’ refers to the fact that the behaviour of the sample is compared to that of a reference material which does not undergo a physical or chemical change during the analysis. The term ‘scanning’ refers to the fact that the temperatures of the sample and reference material are increased, or scanned, during the analysis.

A DSC consists of two small compartments that are heated electrically at a constant rate. The temperature, T , at time t during a linear scan is $T = T_0 + \alpha t$, where T_0 is the initial temperature and α is the temperature scan rate (in kelvin per second, K s^{-1}). A computer controls the electrical power output in order to maintain the same temperature in the sample and reference compartments throughout the analysis (see Fig. 2.15).

The temperature of the sample changes significantly relative to that of the reference material if a chemical or physical process involving the transfer of energy as heat occurs in the sample during the scan. To maintain the same temperature in both compartments, excess energy is transferred as heat to or from the sample during the process. For example, an endothermic process lowers the temperature of the sample relative to that of the reference and, as a result, the sample must be heated more strongly than the reference in order to maintain equal temperatures.

If no physical or chemical change occurs in the sample at temperature T , we write the heat transferred to the sample as $q_p = C_p \Delta T$, where $\Delta T = T - T_0$ and we have assumed that C_p is independent of temperature. The chemical or physical process requires the transfer of $q_p + q_{p,\text{ex}}$, where $q_{p,\text{ex}}$ is excess energy transferred as heat, to attain the same change in temperature of the sample. We interpret $q_{p,\text{ex}}$ in terms of an apparent change in the heat capacity at constant pressure of the sample, C_p , during the temperature scan. Then we write the heat capacity of the sample as $C_p + C_{p,\text{ex}}$, and

$$q_p + q_{p,\text{ex}} = (C_p + C_{p,\text{ex}}) \Delta T$$

It follows that

$$C_{p,\text{ex}} = \frac{q_{p,\text{ex}}}{\Delta T} = \frac{q_{p,\text{ex}}}{\alpha t} = \frac{P_{\text{ex}}}{\alpha}$$

where $P_{\text{ex}} = q_{p,\text{ex}}/t$ is the excess electrical power necessary to equalize the temperature of the sample and reference compartments.

A DSC trace, also called a *thermogram*, consists of a plot of P_{ex} or $C_{p,\text{ex}}$ against T (see Fig. 2.16). Broad peaks in the thermogram indicate processes requiring transfer of energy as heat. From eqn 2.23a, the enthalpy change associated with the process is

$$\Delta H = \int_{T_1}^{T_2} C_{p,\text{ex}} dT$$

where T_1 and T_2 are, respectively, the temperatures at which the process begins and ends. This relation shows that the enthalpy change is then the area under the curve of $C_{p,\text{ex}}$ against T . With a DSC, enthalpy changes may be determined in samples of masses as low as 0.5 mg, which is a significant advantage over bomb or flame calorimeters, which require several grams of material.

Differential scanning calorimetry is used in the chemical industry to characterize polymers and in the biochemistry laboratory to assess the stability of proteins, nucleic acids, and membranes. Large molecules, such as synthetic or biological polymers, attain complex three-dimensional structures due to intra- and intermolecular interactions, such as hydrogen bonding and hydrophobic interactions (Chapter 18). Disruption of these interactions is an endothermic process that can be studied with a DSC. For example, the thermogram shown in the illustration indicated that the protein ubiquitin retains its native structure up to about 45°C. At higher temperatures, the protein undergoes an endothermic conformational change that results in the loss of its three-dimensional structure. The same principles also apply to the study of structural integrity and stability of synthetic polymers, such as plastics.

2.6 Adiabatic changes

We are now equipped to deal with the changes that occur when a perfect gas expands adiabatically. A decrease in temperature should be expected: because work is done but no heat enters the system, the internal energy falls, and therefore the temperature of the working gas also falls. In molecular terms, the kinetic energy of the molecules falls as work is done, so their average speed decreases, and hence the temperature falls.

The change in internal energy of a perfect gas when the temperature is changed from T_i to T_f and the volume is changed from V_i to V_f can be expressed as the sum of two steps (Fig. 2.17). In the first step, only the volume changes and the temperature is held constant at its initial value. However, because the internal energy of a perfect gas is independent of the volume the molecules occupy, the overall change in internal energy arises solely from the second step, the change in temperature at constant volume. Provided the heat capacity is independent of temperature, this change is

$$\Delta U = C_V(T_f - T_i) = C_V\Delta T$$

Because the expansion is adiabatic, we know that $q = 0$; because $\Delta U = q + w$, it then follows that $\Delta U = w_{\text{ad}}$. The subscript 'ad' denotes an adiabatic process. Therefore, by equating the two values we have obtained for ΔU , we obtain

$$w_{\text{ad}} = C_V\Delta T \quad (2.27)$$

That is, the work done during an adiabatic expansion of a perfect gas is proportional to the temperature difference between the initial and final states. That is exactly what we expect on molecular grounds, because the mean kinetic energy is proportional to T , so a change in internal energy arising from temperature alone is also expected to be proportional to ΔT . In *Further information 2.1* we show that the initial and final temperatures of a perfect gas that undergoes reversible adiabatic expansion (reversible expansion in a thermally insulated container) can be calculated from

$$T_f = T_i \left(\frac{V_i}{V_f} \right)^{1/c} \quad (2.28a)_{\text{rev}}^{\circ}$$

Fig. 2.17 To achieve a change of state from one temperature and volume to another temperature and volume, we may consider the overall change as composed of two steps. In the first step, the system expands at constant temperature; there is no change in internal energy if the system consists of a perfect gas. In the second step, the temperature of the system is reduced at constant volume. The overall change in internal energy is the sum of the changes for the two steps.

where $c = C_{V,m}/R$, or equivalently

$$V_i T_i^c = V_f T_f^c \quad (2.28b)_{\text{rev}}^{\circ}$$

This result is often summarized in the form $VT^c = \text{constant}$.

Illustration 2.5 Work of adiabatic expansion

Consider the adiabatic, reversible expansion of 0.020 mol Ar, initially at 25°C, from 0.50 dm³ to 1.00 dm³. The molar heat capacity of argon at constant volume is 12.48 J K⁻¹ mol⁻¹, so $c = 1.501$. Therefore, from eqn 2.28a,

$$T_f = (298 \text{ K}) \times \left(\frac{0.50 \text{ dm}^3}{1.00 \text{ dm}^3} \right)^{1/1.501} = 188 \text{ K}$$

It follows that $\Delta T = -110 \text{ K}$, and therefore, from eqn 2.27, that

$$w = \{(0.020 \text{ mol}) \times (12.48 \text{ J K}^{-1} \text{ mol}^{-1})\} \times (-110 \text{ K}) = -27 \text{ J}$$

Note that temperature change is independent of the amount of gas but the work is not.

Self-test 2.5 Calculate the final temperature, the work done, and the change of internal energy when ammonia is used in a reversible adiabatic expansion from 0.50 dm³ to 2.00 dm³, the other initial conditions being the same.

[195 K, -56 J, -56 J]

Fig. 2.18 An adiabat depicts the variation of pressure with volume when a gas expands adiabatically. (a) An adiabat for a perfect gas undergoing reversible expansion. (b) Note that the pressure declines more steeply for an adiabat than it does for an isotherm because the temperature decreases in the former.

Exploration Explore how the parameter γ affects the dependence of the pressure on the volume. Does the pressure–volume dependence become stronger or weaker with increasing volume?

We also show in *Further information 2.1* that the pressure of a perfect gas that undergoes reversible adiabatic expansion from a volume V_i to a volume V_f is related to its initial pressure by

$$p_f V_f^\gamma = p_i V_i^\gamma \quad (2.29)_{\text{rev}}^{\circ}$$

where $\gamma = C_{p,m}/C_{V,m}$. This result is summarized in the form $pV^\gamma = \text{constant}$. For a monatomic perfect gas, $C_{V,m} = \frac{3}{2}R$ (see *Illustration 2.3*), and from eqn 2.26 $C_{p,m} = \frac{5}{2}R$; so $\gamma = \frac{5}{3}$. For a gas of nonlinear polyatomic molecules (which can rotate as well as translate), $C_{V,m} = 3R$, so $\gamma = \frac{4}{3}$. The curves of pressure versus volume for adiabatic change are known as **adiabats**, and one for a reversible path is illustrated in Fig. 2.18. Because $\gamma > 1$, an adiabat falls more steeply ($p \propto 1/V^\gamma$) than the corresponding isotherm ($p \propto 1/V$). The physical reason for the difference is that, in an isothermal expansion, energy flows into the system as heat and maintains the temperature; as a result, the pressure does not fall as much as in an adiabatic expansion.

Illustration 2.6 The pressure change accompanying adiabatic expansion

When a sample of argon (for which $\gamma = \frac{5}{3}$) at 100 kPa expands reversibly and adiabatically to twice its initial volume the final pressure will be

$$p_f = \left(\frac{V_i}{V_f} \right)^\gamma p_i = \left(\frac{1}{2} \right)^{5/3} \times (100 \text{ kPa}) = 32 \text{ kPa}$$

For an isothermal doubling of volume, the final pressure would be 50 kPa.

Thermochemistry

The study of the energy transferred as heat during the course of chemical reactions is called **thermochemistry**. Thermochemistry is a branch of thermodynamics because a reaction vessel and its contents form a system, and chemical reactions result in the exchange of energy between the system and the surroundings. Thus we can use calorimetry to measure the energy supplied or discarded as heat by a reaction, and can identify q with a change in internal energy (if the reaction occurs at constant volume) or a change in enthalpy (if the reaction occurs at constant pressure). Conversely, if we know ΔU or ΔH for a reaction, we can predict the energy (transferred as heat) the reaction can produce.

We have already remarked that a process that releases energy by heating the surroundings is classified as exothermic and one that absorbs energy by cooling the surroundings is classified as endothermic. Because the release of energy by heating the surroundings signifies a decrease in the enthalpy of a system (at constant pressure), we can now see that an exothermic process at constant pressure is one for which $\Delta H < 0$. Conversely, because the absorption of energy by cooling the surroundings results in an increase in enthalpy, an endothermic process at constant pressure has $\Delta H > 0$.

2.7 Standard enthalpy changes

Changes in enthalpy are normally reported for processes taking place under a set of standard conditions. In most of our discussions we shall consider the **standard enthalpy change**, ΔH° , the change in enthalpy for a process in which the initial and final substances are in their standard states:

The **standard state** of a substance at a specified temperature is its pure form at 1 bar.⁵

For example, the standard state of liquid ethanol at 298 K is pure liquid ethanol at 298 K and 1 bar; the standard state of solid iron at 500 K is pure iron at 500 K and 1 bar. The standard enthalpy change for a reaction or a physical process is the difference between the products in their standard states and the reactants in their standard states, all at the same specified temperature.

As an example of a standard enthalpy change, the *standard enthalpy of vaporization*, $\Delta_{\text{vap}}H^\circ$, is the enthalpy change per mole when a pure liquid at 1 bar vaporizes to a gas at 1 bar, as in

As implied by the examples, standard enthalpies may be reported for any temperature. However, the conventional temperature for reporting thermodynamic data is 298.15 K (corresponding to 25.00°C). Unless otherwise mentioned, all thermodynamic data in this text will refer to this conventional temperature.

A note on good practice The attachment of the name of the transition to the symbol Δ , as in $\Delta_{\text{vap}}H$, is the modern convention. However, the older convention, ΔH_{vap} , is still widely used. The new convention is more logical because the subscript identifies the type of change, not the physical observable related to the change.

⁵ The definition of standard state is more sophisticated for a real gas (*Further information 3.2*) and for solutions (Sections 5.6 and 5.7).

Synoptic Table 2.3* Standard enthalpies of fusion and vaporization at the transition temperature, $\Delta_{\text{trs}}H^\circ/(\text{kJ mol}^{-1})$

	T_f/K	Fusion	T_b/K	Vaporization
Ar	83.81	1.188	87.29	6.506
C ₆ H ₆	278.61	10.59	353.2	30.8
H ₂ O	273.15	6.008	373.15	40.656 (44.016 at 298 K)
He	3.5	0.021	4.22	0.084

* More values are given in the *Data section*.**(a) Enthalpies of physical change**

The standard enthalpy change that accompanies a change of physical state is called the **standard enthalpy of transition** and is denoted $\Delta_{\text{trs}}H^\circ$ (Table 2.3). The **standard enthalpy of vaporization**, $\Delta_{\text{vap}}H^\circ$, is one example. Another is the **standard enthalpy of fusion**, $\Delta_{\text{fus}}H^\circ$, the standard enthalpy change accompanying the conversion of a solid to a liquid, as in

As in this case, it is sometimes convenient to know the standard enthalpy change at the transition temperature as well as at the conventional temperature.

Because enthalpy is a state function, a change in enthalpy is independent of the path between the two states. This feature is of great importance in thermochemistry, for it implies that the same value of ΔH° will be obtained however the change is brought about between the same initial and final states. For example, we can picture the conversion of a solid to a vapour either as occurring by sublimation (the direct conversion from solid to vapour),

or as occurring in two steps, first fusion (melting) and then vaporization of the resulting liquid:

Because the overall result of the indirect path is the same as that of the direct path, the overall enthalpy change is the same in each case (1), and we can conclude that (for processes occurring at the same temperature)

$$\Delta_{\text{sub}}H^\circ = \Delta_{\text{fus}}H^\circ + \Delta_{\text{vap}}H^\circ \quad (2.30)$$

An immediate conclusion is that, because all enthalpies of fusion are positive, the enthalpy of sublimation of a substance is greater than its enthalpy of vaporization (at a given temperature).

Another consequence of H being a state function is that the standard enthalpy changes of a forward process and its reverse differ in sign (2):

$$\Delta H^\circ(\text{A} \rightarrow \text{B}) = -\Delta H^\circ(\text{B} \rightarrow \text{A}) \quad (2.31)$$

For instance, because the enthalpy of vaporization of water is $+44 \text{ kJ mol}^{-1}$ at 298 K, its enthalpy of condensation at that temperature is -44 kJ mol^{-1} .

Table 2.4 Enthalpies of transition

Transition	Process	Symbol*
Transition	Phase $\alpha \rightarrow$ phase β	$\Delta_{\text{trs}}H$
Fusion	$s \rightarrow l$	$\Delta_{\text{fus}}H$
Vaporization	$l \rightarrow g$	$\Delta_{\text{vap}}H$
Sublimation	$s \rightarrow g$	$\Delta_{\text{sub}}H$
Mixing	Pure $\rightarrow$ mixture	$\Delta_{\text{mix}}H$
Solution	Solute $\rightarrow$ solution	$\Delta_{\text{sol}}H$
Hydration	$X^{\pm}(g) \rightarrow X^{\pm}(aq)$	$\Delta_{\text{hyd}}H$
Atomization	Species(s, l, g) $\rightarrow$ atoms(g)	$\Delta_{\text{at}}H$
Ionization	$X(g) \rightarrow X^+(g) + e^-(g)$	$\Delta_{\text{ion}}H$
Electron gain	$X(g) + e^-(g) \rightarrow X^-(g)$	$\Delta_{\text{eg}}H$
Reaction	Reactants $\rightarrow$ products	Δ_rH
Combustion	Compounds(s, l, g) + $O_2(g) \rightarrow CO_2(g), H_2O(l, g)$	Δ_cH
Formation	Elements $\rightarrow$ compound	Δ_fH
Activation	Reactants $\rightarrow$ activated complex	$\Delta^\ddagger H$

* IUPAC recommendations. In common usage, the transition subscript is often attached to ΔH , as in ΔH_{trs} .

The different types of enthalpies encountered in thermochemistry are summarized in Table 2.4. We shall meet them again in various locations throughout the text.

(b) Enthalpies of chemical change

Now we consider enthalpy changes that accompany chemical reactions. There are two ways of reporting the change in enthalpy that accompanies a chemical reaction. One is to write the **thermochemical equation**, a combination of a chemical equation and the corresponding change in standard enthalpy:

ΔH° is the change in enthalpy when reactants in their standard states change to products in their standard states:

Pure, separate reactants in their standard states
 $\rightarrow$ pure, separate products in their standard states

Except in the case of ionic reactions in solution, the enthalpy changes accompanying mixing and separation are insignificant in comparison with the contribution from the reaction itself. For the combustion of methane, the standard value refers to the reaction in which 1 mol CH_4 in the form of pure methane gas at 1 bar reacts completely with 2 mol O_2 in the form of pure oxygen gas to produce 1 mol CO_2 as pure carbon dioxide at 1 bar and 2 mol H_2O as pure liquid water at 1 bar; the numerical value is for the reaction at 298 K.

Alternatively, we write the chemical equation and then report the **standard reaction enthalpy**, $\Delta_r H^\circ$. Thus, for the combustion of reaction, we write

For the reaction

Synoptic Table 2.5* Standard enthalpies of formation and combustion of organic compounds at 298 K

	$\Delta_f H^\circ / (\text{kJ mol}^{-1})$	$\Delta_c H^\circ / (\text{kJ mol}^{-1})$
Benzene, $\text{C}_6\text{H}_6(\text{l})$	+49.0	−3268
Ethane, $\text{C}_2\text{H}_6(\text{g})$	−84.7	−1560
Glucose, $\text{C}_6\text{H}_{12}\text{O}_6(\text{s})$	−1274	−2808
Methane, $\text{CH}_4(\text{g})$	−74.8	−890
Methanol, $\text{CH}_3\text{OH}(\text{l})$	−238.7	−721

* More values are given in the *Data section*.

the standard reaction enthalpy is

$$\Delta_r H^\circ = \{3H_m^\circ(\text{C}) + H_m^\circ(\text{D})\} - \{2H_m^\circ(\text{A}) + H_m^\circ(\text{B})\}$$

where $H_m^\circ(\text{J})$ is the standard molar enthalpy of species J at the temperature of interest. Note how the ‘per mole’ of $\Delta_r H^\circ$ comes directly from the fact that molar enthalpies appear in this expression. We interpret the ‘per mole’ by noting the stoichiometric coefficients in the chemical equation. In this case ‘per mole’ in $\Delta_r H^\circ$ means ‘per 2 mol A’, ‘per mole B’, ‘per 3 mol C’, or ‘per mol D’. In general,

$$\Delta_r H^\circ = \sum_{\text{Products}} \nu H_m^\circ - \sum_{\text{Reactants}} \nu H_m^\circ \quad (2.32)$$

where in each case the molar enthalpies of the species are multiplied by their stoichiometric coefficients, ν .⁶

Some standard reaction enthalpies have special names and a particular significance. For instance, the **standard enthalpy of combustion**, $\Delta_c H^\circ$, is the standard reaction enthalpy for the complete oxidation of an organic compound to CO_2 gas and liquid H_2O if the compound contains C, H, and O, and to N_2 gas if N is also present. An example is the combustion of glucose:

The value quoted shows that 2808 kJ of heat is released when 1 mol $\text{C}_6\text{H}_{12}\text{O}_6$ burns under standard conditions (at 298 K). Some further values are listed in Table 2.5.

IMPACT ON BIOLOGY

12.2 Food and energy reserves

The thermochemical properties of fuels Table 2.6 and foods are commonly discussed in terms of their *specific enthalpy*, the enthalpy of combustion per gram of material. Thus, if the standard enthalpy of combustion is $\Delta_c H^\circ$ and the molar mass of the compound is M , then the specific enthalpy is $\Delta_c H^\circ / M$. Table 2.6 lists the specific enthalpies of several fuels.

A typical 18–20 year old man requires a daily input of about 12 MJ; a woman of the same age needs about 9 MJ. If the entire consumption were in the form of glucose (3; which has a specific enthalpy of 16 kJ g^{-1}), that would require the consumption of 750 g of glucose for a man and 560 g for a woman. In fact, digestible carbohydrates have a slightly higher specific enthalpy (17 kJ g^{-1}) than glucose itself, so a carbohydrate

3

⁶ In this and similar expressions, all stoichiometric coefficients are positive. For a more sophisticated way of writing eqn 2.32, see Section 7.2.

Table 2.6 Thermochemical properties of some fuels

Fuel	Combustion equation	$\Delta_c H^\circ$ / (kJ mol ⁻¹)	Specific enthalpy/ (kJ g ⁻¹)	Enthalpy density/ (kJ dm ⁻³)
Hydrogen	$\text{H}_2(\text{g}) + \frac{1}{2} \text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\text{l})$	-286	142	13
Methane	$\text{CH}_4(\text{g}) + 2 \text{O}_2(\text{g}) \rightarrow \text{CO}_2(\text{g}) + 2 \text{H}_2\text{O}(\text{l})$	-890	55	40
Octane	$\text{C}_8\text{H}_{18}(\text{l}) + \frac{25}{2} \text{O}_2(\text{g}) \rightarrow 8 \text{CO}_2(\text{g}) + 9 \text{H}_2\text{O}(\text{l})$	-5471	48	3.8×10^4
Methanol	$\text{CH}_3\text{OH}(\text{l}) + \frac{3}{2} \text{O}_2(\text{g}) \rightarrow \text{CO}_2(\text{g}) + 2 \text{H}_2\text{O}(\text{l})$	-726	23	1.8×10^4

diet is slightly less daunting than a pure glucose diet, as well as being more appropriate in the form of fibre, the indigestible cellulose that helps move digestion products through the intestine.

The specific enthalpy of fats, which are long-chain esters like tristearin (beef fat), is much greater than that of carbohydrates, at around 38 kJ g^{-1} , slightly less than the value for the hydrocarbon oils used as fuel (48 kJ g^{-1}). Fats are commonly used as an energy store, to be used only when the more readily accessible carbohydrates have fallen into short supply. In Arctic species, the stored fat also acts as a layer of insulation; in desert species (such as the camel), the fat is also a source of water, one of its oxidation products.

Proteins are also used as a source of energy, but their components, the amino acids, are often too valuable to squander in this way, and are used to construct other proteins instead. When proteins are oxidized (to urea, $\text{CO}(\text{NH}_2)_2$), the equivalent enthalpy density is comparable to that of carbohydrates.

The heat released by the oxidation of foods needs to be discarded in order to maintain body temperature within its typical range of $35.6\text{--}37.8^\circ\text{C}$. A variety of mechanisms contribute to this aspect of homeostasis, the ability of an organism to counteract environmental changes with physiological responses. The general uniformity of temperature throughout the body is maintained largely by the flow of blood. When heat needs to be dissipated rapidly, warm blood is allowed to flow through the capillaries of the skin, so producing flushing. Radiation is one means of discarding heat; another is evaporation and the energy demands of the enthalpy of vaporization of water. Evaporation removes about 2.4 kJ per gram of water perspired. When vigorous exercise promotes sweating (through the influence of heat selectors on the hypothalamus), $1\text{--}2 \text{ dm}^3$ of perspired water can be produced per hour, corresponding to a heat loss of $2.4\text{--}5.0 \text{ MJ h}^{-1}$.

(c) Hess's law

Standard enthalpies of individual reactions can be combined to obtain the enthalpy of another reaction. This application of the First Law is called **Hess's law**:

The standard enthalpy of an overall reaction is the sum of the standard enthalpies of the individual reactions into which a reaction may be divided.

The individual steps need not be realizable in practice: they may be hypothetical reactions, the only requirement being that their chemical equations should balance. The thermodynamic basis of the law is the path-independence of the value of $\Delta_r H^\circ$ and the implication that we may take the specified reactants, pass through any (possibly hypothetical) set of reactions to the specified products, and overall obtain the same change of enthalpy. The importance of Hess's law is that information about a

reaction of interest, which may be difficult to determine directly, can be assembled from information on other reactions.

Example 2.5 Using Hess's law

The standard reaction enthalpy for the hydrogenation of propene,

is -124 kJ mol^{-1} . The standard reaction enthalpy for the combustion of propane,

is $-2220 \text{ kJ mol}^{-1}$. Calculate the standard enthalpy of combustion of propene.

Method The skill to develop is the ability to assemble a given thermochemical equation from others. Add or subtract the reactions given, together with any others needed, so as to reproduce the reaction required. Then add or subtract the reaction enthalpies in the same way. Additional data are in Table 2.5.

Answer The combustion reaction we require is

This reaction can be recreated from the following sum:

	$\Delta_r H^\ominus / (\text{kJ mol}^{-1})$
$\text{C}_3\text{H}_6(\text{g}) + \text{H}_2(\text{g}) \rightarrow \text{C}_3\text{H}_8(\text{g})$	-124
$\text{C}_3\text{H}_8(\text{g}) + 5 \text{O}_2(\text{g}) \rightarrow 3 \text{CO}_2(\text{g}) + 4 \text{H}_2\text{O}(\text{l})$	-2220
$\text{H}_2\text{O}(\text{l}) \rightarrow \text{H}_2(\text{g}) + \frac{1}{2} \text{O}_2(\text{g})$	+286
$\text{C}_3\text{H}_6(\text{g}) + \frac{9}{2} \text{O}_2(\text{g}) \rightarrow 3 \text{CO}_2(\text{g}) + 3 \text{H}_2\text{O}(\text{l})$	-2058

Self-test 2.6 Calculate the enthalpy of hydrogenation of benzene from its enthalpy of combustion and the enthalpy of combustion of cyclohexane. $[-205 \text{ kJ mol}^{-1}]$

Synoptic Table 2.7* Standard enthalpies of formation of inorganic compounds at 298 K

	$\Delta_f H^\ominus / (\text{kJ mol}^{-1})$
$\text{H}_2\text{O}(\text{l})$	-285.83
$\text{H}_2\text{O}(\text{g})$	-187.78
$\text{NH}_3(\text{g})$	-46.11
$\text{N}_2\text{H}_4(\text{l})$	+50.63
$\text{NO}_2(\text{g})$	33.18
$\text{N}_2\text{O}_4(\text{g})$	+9.16
$\text{NaCl}(\text{s})$	-411.15
$\text{KCl}(\text{s})$	-436.75

* More values are given in the Data section.

Comment 2.7

The NIST WebBook listed in the web site for this book links to online databases of thermochemical data.

2.8 Standard enthalpies of formation

The **standard enthalpy of formation**, $\Delta_f H^\ominus$, of a substance is the standard reaction enthalpy for the formation of the compound from its elements in their reference states. The **reference state** of an element is its most stable state at the specified temperature and 1 bar. For example, at 298 K the reference state of nitrogen is a gas of N_2 molecules, that of mercury is liquid mercury, that of carbon is graphite, and that of tin is the white (metallic) form. There is one exception to this general prescription of reference states: the reference state of phosphorus is taken to be white phosphorus despite this allotrope not being the most stable form but simply the more reproducible form of the element. Standard enthalpies of formation are expressed as enthalpies per mole of molecules or (for ionic substances) formula units of the compound. The standard enthalpy of formation of liquid benzene at 298 K, for example, refers to the reaction

and is $+49.0 \text{ kJ mol}^{-1}$. The standard enthalpies of formation of elements in their reference states are zero at all temperatures because they are the enthalpies of such 'null' reactions as $\text{N}_2(\text{g}) \rightarrow \text{N}_2(\text{g})$. Some enthalpies of formation are listed in Tables 2.5 and 2.7.

The standard enthalpy of formation of ions in solution poses a special problem because it is impossible to prepare a solution of cations alone or of anions alone. This problem is solved by defining one ion, conventionally the hydrogen ion, to have zero standard enthalpy of formation at all temperatures:

$$\Delta_f H^\ominus(\text{H}^+, \text{aq}) = 0 \quad [2.33]$$

Thus, if the enthalpy of formation of $\text{HBr}(\text{aq})$ is found to be -122 kJ mol^{-1} , then the whole of that value is ascribed to the formation of $\text{Br}^-(\text{aq})$, and we write $\Delta_f H^\ominus(\text{Br}^-, \text{aq}) = -122 \text{ kJ mol}^{-1}$. That value may then be combined with, for instance, the enthalpy formation of $\text{AgBr}(\text{aq})$ to determine the value of $\Delta_f H^\ominus(\text{Ag}^+, \text{aq})$, and so on. In essence, this definition adjusts the actual values of the enthalpies of formation of ions by a fixed amount, which is chosen so that the standard value for one of them, $\text{H}^+(\text{aq})$, has the value zero.

(a) The reaction enthalpy in terms of enthalpies of formation

Conceptually, we can regard a reaction as proceeding by decomposing the reactants into their elements and then forming those elements into the products. The value of $\Delta_r H^\ominus$ for the overall reaction is the sum of these ‘unforming’ and forming enthalpies. Because ‘unforming’ is the reverse of forming, the enthalpy of an unforming step is the negative of the enthalpy of formation (4). Hence, in the enthalpies of formation of substances, we have enough information to calculate the enthalpy of any reaction by using

$$\Delta_r H^\ominus = \sum_{\text{Products}} \nu \Delta_f H^\ominus - \sum_{\text{Reactants}} \nu \Delta_f H^\ominus \quad (2.34)$$

where in each case the enthalpies of formation of the species that occur are multiplied by their stoichiometric coefficients.

Illustration 2.7 Using standard enthalpies of formation

The standard reaction enthalpy of $2 \text{HN}_3(\text{l}) + 2 \text{NO}(\text{g}) \rightarrow \text{H}_2\text{O}_2(\text{l}) + 4 \text{N}_2(\text{g})$ is calculated as follows:

$$\begin{aligned} \Delta_r H^\ominus &= \{\Delta_f H^\ominus(\text{H}_2\text{O}_2, \text{l}) + 4\Delta_f H^\ominus(\text{N}_2, \text{g})\} - \{2\Delta_f H^\ominus(\text{HN}_3, \text{l}) + 2\Delta_f H^\ominus(\text{NO}, \text{g})\} \\ &= \{-187.78 + 4(0)\} \text{ kJ mol}^{-1} - \{2(264.0) + 2(90.25)\} \text{ kJ mol}^{-1} \\ &= -896.3 \text{ kJ mol}^{-1} \end{aligned}$$

(b) Enthalpies of formation and molecular modelling

We have seen how to construct standard reaction enthalpies by combining standard enthalpies of formation. The question that now arises is whether we can construct standard enthalpies of formation from a knowledge of the chemical constitution of the species. The short answer is that there is no thermodynamically exact way of expressing enthalpies of formation in terms of contributions from individual atoms and bonds. In the past, approximate procedures based on **mean bond enthalpies**, $\Delta H(\text{A}-\text{B})$, the average enthalpy change associated with the breaking of a specific $\text{A}-\text{B}$ bond,

Fig. 2.19 An illustration of the content of Kirchhoff's law. When the temperature is increased, the enthalpy of the products and the reactants both increase, but may do so to different extents. In each case, the change in enthalpy depends on the heat capacities of the substances. The change in reaction enthalpy reflects the difference in the changes of the enthalpies.

have been used. However, this procedure is notoriously unreliable, in part because the $\Delta H(A-B)$ are average values for a series of related compounds. Nor does the approach distinguish between geometrical isomers, where the same atoms and bonds may be present but experimentally the enthalpies of formation might be significantly different.

Computer-aided molecular modelling has largely displaced this more primitive approach. Commercial software packages use the principles developed in Chapter 11 to calculate the standard enthalpy of formation of a molecule drawn on the computer screen. These techniques can be applied to different conformations of the same molecule. In the case of methylcyclohexane, for instance, the calculated conformational energy difference ranges from 5.9 to 7.9 kJ mol⁻¹, with the equatorial conformer having the lower standard enthalpy of formation. These estimates compare favourably with the experimental value of 7.5 kJ mol⁻¹. However, good agreement between calculated and experimental values is relatively rare. Computational methods almost always predict correctly which conformer is more stable but do not always predict the correct magnitude of the conformational energy difference.

2.9 The temperature-dependence of reaction enthalpies

The standard enthalpies of many important reactions have been measured at different temperatures. However, in the absence of this information, standard reaction enthalpies at different temperatures may be calculated from heat capacities and the reaction enthalpy at some other temperature (Fig. 2.19). In many cases heat capacity data are more accurate than reaction enthalpies so, providing the information is available, the procedure we are about to describe is more accurate than a direct measurement of a reaction enthalpy at an elevated temperature.

It follows from eqn 2.23a that, when a substance is heated from T_1 to T_2 , its enthalpy changes from $H(T_1)$ to

$$H(T_2) = H(T_1) + \int_{T_1}^{T_2} C_p dT \quad (2.35)$$

(We have assumed that no phase transition takes place in the temperature range of interest.) Because this equation applies to each substance in the reaction, the standard reaction enthalpy changes from $\Delta_r H^\circ(T_1)$ to

$$\Delta_r H^\circ(T_2) = \Delta_r H^\circ(T_1) + \int_{T_1}^{T_2} \Delta_r C_p^\circ dT \quad (2.36)$$

where $\Delta_r C_p^\circ$ is the difference of the molar heat capacities of products and reactants under standard conditions weighted by the stoichiometric coefficients that appear in the chemical equation:

$$\Delta_r C_p^\circ = \sum_{\text{Products}} \nu C_{p,m}^\circ - \sum_{\text{Reactants}} \nu C_{p,m}^\circ \quad [2.37]$$

Equation 2.36 is known as **Kirchhoff's law**. It is normally a good approximation to assume that $\Delta_r C_p$ is independent of the temperature, at least over reasonably limited ranges, as illustrated in the following example. Although the individual heat capacities may vary, their difference varies less significantly. In some cases the temperature dependence of heat capacities is taken into account by using eqn 2.25.

Example 2.6 Using Kirchhoff's law

The standard enthalpy of formation of gaseous H_2O at 298 K is $-241.82 \text{ kJ mol}^{-1}$. Estimate its value at 100°C given the following values of the molar heat capacities at constant pressure: $\text{H}_2\text{O}(\text{g})$: $33.58 \text{ J K}^{-1} \text{ mol}^{-1}$; $\text{H}_2(\text{g})$: $28.84 \text{ J K}^{-1} \text{ mol}^{-1}$; $\text{O}_2(\text{g})$: $29.37 \text{ J K}^{-1} \text{ mol}^{-1}$. Assume that the heat capacities are independent of temperature.

Method When $\Delta C_p^\ominus$ is independent of temperature in the range T_1 to T_2 , the integral in eqn 2.36 evaluates to $(T_2 - T_1)\Delta_r C_p^\ominus$. Therefore,

$$\Delta_r H^\ominus(T_2) = \Delta_r H^\ominus(T_1) + (T_2 - T_1)\Delta_r C_p^\ominus$$

To proceed, write the chemical equation, identify the stoichiometric coefficients, and calculate $\Delta_r C_p^\ominus$ from the data.

Answer The reaction is $\text{H}_2(\text{g}) + \frac{1}{2} \text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\text{g})$, so

$$\Delta_r C_p^\ominus = C_{p,m}^\ominus(\text{H}_2\text{O}, \text{g}) - \{C_{p,m}^\ominus(\text{H}_2, \text{g}) + \frac{1}{2}C_{p,m}^\ominus(\text{O}_2, \text{g})\} = -9.94 \text{ J K}^{-1} \text{ mol}^{-1}$$

It then follows that

$$\Delta_r H^\ominus(373 \text{ K}) = -241.82 \text{ kJ mol}^{-1} + (75 \text{ K}) \times (-9.94 \text{ J K}^{-1} \text{ mol}^{-1}) = -242.6 \text{ kJ mol}^{-1}$$

Self-test 2.7 Estimate the standard enthalpy of formation of cyclohexene at 400 K from the data in Table 2.5. $[-163 \text{ kJ mol}^{-1}]$

State functions and exact differentials

We saw in Section 2.2 that a 'state function' is a property that is independent of how a sample is prepared. In general, such properties are functions of variables that define the current state of the system, such as pressure and temperature. The internal energy and enthalpy are examples of state functions, for they depend on the current state of the system and are independent of its previous history. Processes that describe the preparation of the state are called **path functions**. Examples of path functions are the work and heating that are done when preparing a state. We do not speak of a system in a particular state as possessing work or heat. In each case, the energy transferred as work or heat relates to the path being taken between states, not the current state itself.

We can use the mathematical properties of state functions to draw far-reaching conclusions about the relations between physical properties and establish connections that may be completely unexpected. The practical importance of these results is that we can combine measurements of different properties to obtain the value of a property we require.

2.10 Exact and inexact differentials

Consider a system undergoing the changes depicted in Fig. 2.20. The initial state of the system is *i* and in this state the internal energy is U_i . Work is done by the system as it expands adiabatically to a state *f*. In this state the system has an internal energy U_f and the work done on the system as it changes along Path 1 from *i* to *f* is w . Notice our use of language: U is a property of the state; w is a property of the path. Now consider another process, Path 2, in which the initial and final states are the same as those in Path 1 but in which the expansion is not adiabatic. The internal energy of both the

Fig. 2.20 As the volume and temperature of a system are changed, the internal energy changes. An adiabatic and a non-adiabatic path are shown as Path 1 and Path 2, respectively: they correspond to different values of q and w but to the same value of ΔU .

initial and the final states are the same as before (because U is a state function). However, in the second path an energy q' enters the system as heat and the work w' is not the same as w . The work and the heat are path functions. In terms of the mountaineering analogy in Section 2.2, the change in altitude (a state function) is independent of the path, but the distance travelled (a path function) does depend on the path taken between the fixed endpoints.

If a system is taken along a path (for example, by heating it), U changes from U_i to U_f and the overall change is the sum (integral) of all the infinitesimal changes along the path:

$$\Delta U = \int_i^f dU \quad (2.38)$$

The value of ΔU depends on the initial and final states of the system but is independent of the path between them. This path-independence of the integral is expressed by saying that dU is an 'exact differential'. In general, an **exact differential** is an infinitesimal quantity that, when integrated, gives a result that is independent of the path between the initial and final states.

When a system is heated, the total energy transferred as heat is the sum of all individual contributions at each point of the path:

$$q = \int_{i, \text{ path}}^f dq \quad (2.39)$$

Notice the difference between this equation and eqn 2.38. First, we do not write Δq , because q is not a state function and the energy supplied as heat cannot be expressed as $q_f - q_i$. Secondly, we must specify the path of integration because q depends on the path selected (for example, an adiabatic path has $q = 0$, whereas a nonadiabatic path between the same two states would have $q \neq 0$). This path-dependence is expressed by saying that dq is an 'inexact differential'. In general, an **inexact differential** is an infinitesimal quantity that, when integrated, gives a result that depends on the path between the initial and final states. Often dq is written δq to emphasize that it is inexact and requires the specification of a path.

The work done on a system to change it from one state to another depends on the path taken between the two specified states; for example, in general the work is different if the change takes place adiabatically and non-adiabatically. It follows that dw is an inexact differential. It is often written δw .

Example 2.7 Calculating work, heat, and internal energy

Consider a perfect gas inside a cylinder fitted with a piston. Let the initial state be T, V_i and the final state be T, V_f . The change of state can be brought about in many ways, of which the two simplest are the following: Path 1, in which there is free expansion against zero external pressure; Path 2, in which there is reversible, isothermal expansion. Calculate w , q , and ΔU for each process.

Method To find a starting point for a calculation in thermodynamics, it is often a good idea to go back to first principles, and to look for a way of expressing the quantity we are asked to calculate in terms of other quantities that are easier to calculate. We saw in *Molecular interpretation* 2.2 that the internal energy of a perfect gas depends only on the temperature and is independent of the volume those molecules occupy, so for any isothermal change, $\Delta U = 0$. We also know that in general $\Delta U = q + w$. The question depends on being able to combine the two

expressions. In this chapter, we derived a number of expressions for the work done in a variety of processes, and here we need to select the appropriate ones.

Answer Because $\Delta U = 0$ for both paths and $\Delta U = q + w$, in each case $q = -w$. The work of free expansion is zero (Section 2.3b); so in Path 1, $w = 0$ and $q = 0$. For Path 2, the work is given by eqn 2.11, so $w = -nRT \ln(V_f/V_i)$ and consequently $q = nRT \ln(V_f/V_i)$. These results are consequences of the path independence of U , a state function, and the path dependence of q and w , which are path functions.

Self-test 2.8 Calculate the values of q , w , and ΔU for an irreversible isothermal expansion of a perfect gas against a constant nonzero external pressure.

$$[q = p_{\text{ex}} \Delta V, w = -p_{\text{ex}} \Delta V, \Delta U = 0]$$

2.11 Changes in internal energy

We begin to unfold the consequences of dU being an exact differential by exploring a closed system of constant composition (the only type of system considered in the rest of this chapter). The internal energy U can be regarded as a function of V , T , and p , but, because there is an equation of state, stating the values of two of the variables fixes the value of the third. Therefore, it is possible to write U in terms of just two independent variables: V and T , p and T , or p and V . Expressing U as a function of volume and temperature fits the purpose of our discussion.

(a) General considerations

When V changes to $V + dV$ at constant temperature, U changes to

$$U' = U + \left(\frac{\partial U}{\partial V} \right)_T dV$$

The coefficient $(\partial U / \partial V)_T$, the slope of a plot of U against V at constant temperature, is the partial derivative of U with respect to V (Fig. 2.21). If, instead, T changes to $T + dT$ at constant volume (Fig. 2.22), then the internal energy changes to

Fig. 2.21 The partial derivative $(\partial U / \partial V)_T$ is the slope of U with respect to V with the temperature T held constant.

Fig. 2.22 The partial derivative $(\partial U / \partial T)_V$ is the slope of U with respect to T with the volume V held constant.

Fig. 2.23 An overall change in U , which is denoted dU , arises when both V and T are allowed to change. If second-order infinitesimals are ignored, the overall change is the sum of changes for each variable separately.

Fig. 2.24 The internal pressure, π_T , is the slope of U with respect to V with the temperature T held constant.

$$U' = U + \left(\frac{\partial U}{\partial T} \right)_V dT$$

Now suppose that V and T both change infinitesimally (Fig. 2.23). The new internal energy, neglecting second-order infinitesimals (those proportional to $dVdT$), is the sum of the changes arising from each increment:

$$U' = U + \left(\frac{\partial U}{\partial V} \right)_T dV + \left(\frac{\partial U}{\partial T} \right)_V dT$$

As a result of the infinitesimal changes in conditions, the internal energy U' differs from U by the infinitesimal amount dU , so we can write $U' = U + dU$. Therefore, from the last equation we obtain the very important result that

$$dU = \left(\frac{\partial U}{\partial V} \right)_T dV + \left(\frac{\partial U}{\partial T} \right)_V dT \quad (2.40)$$

The interpretation of this equation is that, in a closed system of constant composition, any infinitesimal change in the internal energy is proportional to the infinitesimal changes of volume and temperature, the coefficients of proportionality being the two partial derivatives.

In many cases partial derivatives have a straightforward physical interpretation, and thermodynamics gets shapeless and difficult only when that interpretation is not kept in sight. In the present case, we have already met $(\partial U/\partial T)_V$ in eqn 2.15, where we saw that it is the constant-volume heat capacity, C_V . The other coefficient, $(\partial U/\partial V)_T$, plays a major role in thermodynamics because it is a measure of the variation of the internal energy of a substance as its volume is changed at constant temperature (Fig. 2.24). We shall denote it π_T and, because it has the same dimensions as pressure, call it the **internal pressure**:

$$\pi_T = \left(\frac{\partial U}{\partial V} \right)_T \quad (2.41)$$

In terms of the notation C_V and π_T , eqn 2.40 can now be written

$$dU = \pi_T dV + C_V dT \quad (2.42)$$

(b) The Joule experiment

When there are no interactions between the molecules, the internal energy is independent of their separation and hence independent of the volume of the sample (see *Molecular interpretation 2.2*). Therefore, for a perfect gas we can write $\pi_T = 0$. The statement $\pi_T = 0$ (that is, the internal energy is independent of the volume occupied by the sample) can be taken to be the definition of a perfect gas, for later we shall see that it implies the equation of state $pV = nRT$. If the internal energy increases ($dU > 0$) as the volume of the sample expands isothermally ($dV > 0$), which is the case when there are attractive forces between the particles, then a plot of internal energy against volume slopes upwards and $\pi_T > 0$ (Fig. 2.25).

James Joule thought that he could measure π_T by observing the change in temperature of a gas when it is allowed to expand into a vacuum. He used two metal vessels immersed in a water bath (Fig. 2.26). One was filled with air at about 22 atm and the other was evacuated. He then tried to measure the change in temperature of the water of the bath when a stopcock was opened and the air expanded into a vacuum. He observed no change in temperature.

Fig. 2.25 For a perfect gas, the internal energy is independent of the volume (at constant temperature). If attractions are dominant in a real gas, the internal energy increases with volume because the molecules become farther apart on average. If repulsions are dominant, the internal energy decreases as the gas expands.

Fig. 2.26 A schematic diagram of the apparatus used by Joule in an attempt to measure the change in internal energy when a gas expands isothermally. The heat absorbed by the gas is proportional to the change in temperature of the bath.

The thermodynamic implications of the experiment are as follows. No work was done in the expansion into a vacuum, so $w = 0$. No energy entered or left the system (the gas) as heat because the temperature of the bath did not change, so $q = 0$. Consequently, within the accuracy of the experiment, $\Delta U = 0$. It follows that U does not change much when a gas expands isothermally and therefore that $\pi_T = 0$.

Joule's experiment was crude. In particular, the heat capacity of the apparatus was so large that the temperature change that gases do in fact cause was too small to measure. From his experiment Joule extracted an essential limiting property of a gas, a property of a perfect gas, without detecting the small deviations characteristic of real gases.

(c) Changes in internal energy at constant pressure

Partial derivatives have many useful properties and some that we shall draw on frequently are reviewed in *Appendix 2*. Skilful use of them can often turn some unfamiliar quantity into a quantity that can be recognized, interpreted, or measured.

As an example, suppose we want to find out how the internal energy varies with temperature when the pressure of the system is kept constant. If we divide both sides of eqn 2.42 by dT and impose the condition of constant pressure on the resulting differentials, so that dU/dT on the left becomes $(\partial U/\partial T)_p$, we obtain

$$\left(\frac{\partial U}{\partial T}\right)_p = \pi_T \left(\frac{\partial V}{\partial T}\right)_p + C_V$$

It is usually sensible in thermodynamics to inspect the output of a manipulation like this to see if it contains any recognizable physical quantity. The partial derivative on the right in this expression is the slope of the plot of volume against temperature (at

Synoptic Table 2.8* Expansion coefficients (α) and isothermal compressibilities (κ_T) at 298 K

* More values are given in the Data section.

constant pressure). This property is normally tabulated as the **expansion coefficient**, α , of a substance,⁷ which is defined as

$$\alpha = \frac{1}{V} \left(\frac{\partial V}{\partial T} \right)_p \quad [2.43]$$

and physically is the fractional change in volume that accompanies a rise in temperature. A large value of α means that the volume of the sample responds strongly to changes in temperature. Table 2.8 lists some experimental values of α and of the **isothermal compressibility**, κ_T (kappa), which is defined as

$$\kappa_T = -\frac{1}{V} \left(\frac{\partial V}{\partial p} \right)_T \quad [2.44]$$

The isothermal compressibility is a measure of the fractional change in volume when the pressure is increased by a small amount; the negative sign in the definition ensures that the compressibility is a positive quantity, because an increase of pressure, implying a positive dp , brings about a reduction of volume, a negative dV .

Example 2.8 Calculating the expansion coefficient of a gas

Derive an expression for the expansion coefficient of a perfect gas.

Method The expansion coefficient is defined in eqn 2.43. To use this expression, substitute the expression for V in terms of T obtained from the equation of state for the gas. As implied by the subscript in eqn 2.43, the pressure, p , is treated as a constant.

Answer Because $pV = nRT$, we can write

$$\alpha = \frac{1}{V} \left(\frac{\partial(nRT/p)}{\partial T} \right)_p = \frac{1}{V} \times \frac{nR}{p} \frac{dT}{dT} = \frac{nR}{pV} = \frac{1}{T}$$

The higher the temperature, the less responsive is the volume of a perfect gas to a change in temperature.

Self-test 2.9 Derive an expression for the isothermal compressibility of a perfect gas. [$\kappa_T = 1/p$]

When we introduce the definition of α into the equation for $(\partial U/\partial T)_p$, we obtain

$$\left(\frac{\partial U}{\partial T} \right)_p = \alpha \pi_T V + C_V \quad (2.45)$$

This equation is entirely general (provided the system is closed and its composition is constant). It expresses the dependence of the internal energy on the temperature at constant pressure in terms of C_V , which can be measured in one experiment, in terms of α , which can be measured in another, and in terms of the quantity π_T . For a perfect gas, $\pi_T = 0$, so then

$$\left(\frac{\partial U}{\partial T} \right)_p = C_V \quad (2.46)^\circ$$

⁷ As for heat capacities, the expansion coefficients of a mixture depends on whether or not the composition is allowed to change. Throughout this chapter, we deal only with pure substances, so this complication can be disregarded.

That is, although the constant-volume heat capacity of a perfect gas is defined as the slope of a plot of internal energy against temperature at constant volume, for a perfect gas C_V is also the slope at constant pressure.

Equation 2.46 provides an easy way to derive the relation between C_p and C_V for a perfect gas expressed in eqn 2.26. Thus, we can use it to express both heat capacities in terms of derivatives at constant pressure:

$$C_p - C_V = \left(\frac{\partial H}{\partial T} \right)_p - \left(\frac{\partial U}{\partial T} \right)_p \quad (2.47)^\circ$$

Then we introduce $H = U + pV = U + nRT$ into the first term, which results in

$$C_p - C_V = \left(\frac{\partial U}{\partial T} \right)_p + nR - \left(\frac{\partial U}{\partial T} \right)_p = nR \quad (2.48)^\circ$$

which is eqn 2.26. We show in *Further information 2.2* that in general

$$C_p - C_V = \frac{\alpha^2 TV}{\kappa_T} \quad (2.49)$$

Equation 2.49 applies to any substance (that is, it is ‘universally true’). It reduces to eqn 2.48 for a perfect gas when we set $\alpha = 1/T$ and $\kappa_T = 1/p$. Because expansion coefficients α of liquids and solids are small, it is tempting to deduce from eqn 2.49 that for them $C_p \approx C_V$. But this is not always so, because the compressibility κ_T might also be small, so α^2/κ_T might be large. That is, although only a little work need be done to push back the atmosphere, a great deal of work may have to be done to pull atoms apart from one another as the solid expands. As an illustration, for water at 25°C, eqn 2.49 gives $C_{p,m} = 75.3 \text{ J K}^{-1} \text{ mol}^{-1}$ compared with $C_{V,m} = 74.8 \text{ J K}^{-1} \text{ mol}^{-1}$. In some cases, the two heat capacities differ by as much as 30 per cent.

2.12 The Joule–Thomson effect

We can carry out a similar set of operations on the enthalpy, $H = U + pV$. The quantities U , p , and V are all state functions; therefore H is also a state function and dH is an exact differential. It turns out that H is a useful thermodynamic function when the pressure is under our control: we saw a sign of that in the relation $\Delta H = q_p$ (eqn 2.19). We shall therefore regard H as a function of p and T , and adapt the argument in Section 2.10 to find an expression for the variation of H with temperature at constant volume. As set out in *Justification 2.2*, we find that for a closed system of constant composition,

$$dH = -\mu C_p dp + C_p dT \quad (2.50)$$

where the **Joule–Thomson coefficient**, μ (mu), is defined as

$$\mu = \left(\frac{\partial T}{\partial p} \right)_H \quad [2.51]$$

This relation will prove useful for relating the heat capacities at constant pressure and volume and for a discussion of the liquefaction of gases.

Justification 2.2 The variation of enthalpy with pressure and temperature

By the same argument that led to eqn 2.40 but with H regarded as a function of p and T we can write

$$dH = \left(\frac{\partial H}{\partial p} \right)_T dp + \left(\frac{\partial H}{\partial T} \right)_p dT \quad (2.52)$$

Fig. 2.27 The apparatus used for measuring the Joule–Thomson effect. The gas expands through the porous barrier, which acts as a throttle, and the whole apparatus is thermally insulated. As explained in the text, this arrangement corresponds to an isenthalpic expansion (expansion at constant enthalpy). Whether the expansion results in a heating or a cooling of the gas depends on the conditions.

The second partial derivative is C_p ; our task here is to express $(\partial H/\partial p)_T$ in terms of recognizable quantities. The chain relation (see *Further information 2.2*) lets us write

$$\left(\frac{\partial H}{\partial p}\right)_T = -\frac{1}{(\partial p/\partial T)_H(\partial T/\partial H)_p}$$

and both partial derivatives can be brought into the numerator by using the reciprocal identity (see *Further information 2.2*) twice:

$$\left(\frac{\partial H}{\partial p}\right)_T = -\frac{(\partial T/\partial p)_H}{(\partial T/\partial H)_p} = \left(\frac{\partial T}{\partial p}\right)_H \left(\frac{\partial H}{\partial T}\right)_p = -\mu C_p \quad (2.53)$$

We have used the definitions of the constant-pressure heat capacity, C_p , and the Joule–Thomson coefficient, μ (eqn 2.51). Equation 2.50 now follows directly.

The analysis of the Joule–Thomson coefficient is central to the technological problems associated with the liquefaction of gases. We need to be able to interpret it physically and to measure it. As shown in the *Justification* below, the cunning required to impose the constraint of constant enthalpy, so that the process is **isenthalpic**, was supplied by Joule and William Thomson (later Lord Kelvin). They let a gas expand through a porous barrier from one constant pressure to another, and monitored the difference of temperature that arose from the expansion (Fig. 2.27). The whole apparatus was insulated so that the process was adiabatic. They observed a lower temperature on the low pressure side, the difference in temperature being proportional to the pressure difference they maintained. This cooling by isenthalpic expansion is now called the **Joule–Thomson effect**.

Justification 2.3 The Joule–Thomson effect

Here we show that the experimental arrangement results in expansion at constant enthalpy. Because all changes to the gas occur adiabatically,

$$q = 0, \text{ which implies } \Delta U = w$$

Consider the work done as the gas passes through the barrier. We focus on the passage of a fixed amount of gas from the high pressure side, where the pressure is p_i , the temperature T_i , and the gas occupies a volume V_i (Fig. 2.28). The gas emerges on the low pressure side, where the same amount of gas has a pressure p_f , a temperature T_f , and occupies a volume V_f . The gas on the left is compressed isothermally by the upstream gas acting as a piston. The relevant pressure is p_i and the volume changes from V_i to 0; therefore, the work done on the gas is

$$w_1 = -p_i(0 - V_i) = p_i V_i$$

The gas expands isothermally on the right of the barrier (but possibly at a different constant temperature) against the pressure p_f provided by the downstream gas acting as a piston to be driven out. The volume changes from 0 to V_f , so the work done on the gas in this stage is

$$w_2 = -p_f(V_f - 0) = -p_f V_f$$

The total work done on the gas is the sum of these two quantities, or

$$w = w_1 + w_2 = p_i V_i - p_f V_f$$

It follows that the change of internal energy of the gas as it moves adiabatically from one side of the barrier to the other is

$$U_f - U_i = w = p_i V_i - p_f V_f$$

Reorganization of this expression gives

$$U_f + p_f V_f = U_i + p_i V_i, \text{ or } H_f = H_i$$

Therefore, the expansion occurs without change of enthalpy.

The property measured in the experiment is the ratio of the temperature change to the change of pressure, $\Delta T/\Delta p$. Adding the constraint of constant enthalpy and taking the limit of small Δp implies that the thermodynamic quantity measured is $(\partial T/\partial p)_H$, which is the Joule–Thomson coefficient, μ . In other words, the physical interpretation of μ is that it is the ratio of the change in temperature to the change in pressure when a gas expands under conditions that ensure there is no change in enthalpy.

The modern method of measuring μ is indirect, and involves measuring the **isothermal Joule–Thomson coefficient**, the quantity

$$\mu_T = \left(\frac{\partial H}{\partial p} \right)_T \quad [2.54]$$

which is the slope of a plot of enthalpy against pressure at constant temperature (Fig. 2.29). Comparing eqns 2.53 and 2.54, we see that the two coefficients are related by:

$$\mu_T = -C_p \mu \quad (2.55)$$

To measure μ_T , the gas is pumped continuously at a steady pressure through a heat exchanger (which brings it to the required temperature), and then through a porous plug inside a thermally insulated container. The steep pressure drop is measured, and the cooling effect is exactly offset by an electric heater placed immediately after the plug (Fig. 2.30). The energy provided by the heater is monitored. Because the energy transferred as heat can be identified with the value of ΔH for the gas (because

Fig. 2.28 The thermodynamic basis of Joule–Thomson expansion. The pistons represent the upstream and downstream gases, which maintain constant pressures either side of the throttle. The transition from the top diagram to the bottom diagram, which represents the passage of a given amount of gas through the throttle, occurs without change of enthalpy.

Fig. 2.29 The isothermal Joule–Thomson coefficient is the slope of the enthalpy with respect to changing pressure, the temperature being held constant.

Fig. 2.30 A schematic diagram of the apparatus used for measuring the isothermal Joule–Thomson coefficient. The electrical heating required to offset the cooling arising from expansion is interpreted as ΔH and used to calculate $(\partial H/\partial p)_T$, which is then converted to μ as explained in the text.

Synoptic Table 2.9* Inversion temperatures (T_i), normal freezing (T_f) and boiling (T_b) points, and Joule–Thomson coefficient (μ) at 1 atm and 298 K

	T_i/K	T_f/K	T_b/K	$\mu/(\text{K bar}^{-1})$
Ar	723	83.8	87.3	
CO ₂	1500		194.7	+1.10
He	40		4.2	−0.060
N ₂	621	63.3	77.4	+0.25

* More values are given in the Data section.

Fig. 2.31 The sign of the Joule–Thomson coefficient, μ , depends on the conditions. Inside the boundary, the shaded area, it is positive and outside it is negative. The temperature corresponding to the boundary at a given pressure is the ‘inversion temperature’ of the gas at that pressure. For a given pressure, the temperature must be below a certain value if cooling is required but, if it becomes too low, the boundary is crossed again and heating occurs. Reduction of pressure under adiabatic conditions moves the system along one of the isenthalps, or curves of constant enthalpy. The inversion temperature curve runs through the points of the isenthalps where their slope changes from negative to positive.

$\Delta H = q_p$), and the pressure change Δp is known, we can find μ_T from the limiting value of $\Delta H/\Delta p$ as $\Delta p \rightarrow 0$, and then convert it to μ . Table 2.9 lists some values obtained in this way.

Real gases have nonzero Joule–Thomson coefficients. Depending on the identity of the gas, the pressure, the relative magnitudes of the attractive and repulsive intermolecular forces (see *Molecular interpretation 2.1*), and the temperature, the sign of the coefficient may be either positive or negative (Fig. 2.31). A positive sign implies that dT is negative when dp is negative, in which case the gas cools on expansion. Gases that show a heating effect ($\mu < 0$) at one temperature show a cooling effect ($\mu > 0$) when the temperature is below their upper **inversion temperature**, T_i (Table 2.9, Fig. 2.32). As indicated in Fig. 2.32, a gas typically has two inversion temperatures, one at high temperature and the other at low.

The ‘Linde refrigerator’ makes use of Joule–Thomson expansion to liquefy gases (Fig. 2.33). The gas at high pressure is allowed to expand through a throttle; it cools and is circulated past the incoming gas. That gas is cooled, and its subsequent expansion cools it still further. There comes a stage when the circulating gas becomes so cold that it condenses to a liquid.

For a perfect gas, $\mu = 0$; hence, the temperature of a perfect gas is unchanged by Joule–Thomson expansion.⁸ This characteristic points clearly to the involvement of intermolecular forces in determining the size of the effect. However, the Joule–Thomson coefficient of a real gas does not necessarily approach zero as the pressure is reduced even though the equation of state of the gas approaches that of a perfect gas. The coefficient behaves like the properties discussed in Section 1.3b in the sense that it depends on derivatives and not on p , V , and T themselves.

Fig. 2.32 The inversion temperatures for three real gases, nitrogen, hydrogen, and helium.

Fig. 2.33 The principle of the Linde refrigerator is shown in this diagram. The gas is recirculated, and so long as it is beneath its inversion temperature it cools on expansion through the throttle. The cooled gas cools the high-pressure gas, which cools still further as it expands. Eventually liquefied gas drips from the throttle.

⁸ Simple adiabatic expansion does cool a perfect gas, because the gas does work; recall Section 2.6.

Molecular interpretation 2.3 *Molecular interactions and the Joule–Thomson effect*

The kinetic model of gases (*Molecular interpretation 1.1*) and the equipartition theorem (*Molecular interpretation 2.2*) imply that the mean kinetic energy of molecules in a gas is proportional to the temperature. It follows that reducing the average speed of the molecules is equivalent to cooling the gas. If the speed of the molecules can be reduced to the point that neighbours can capture each other by their intermolecular attractions, then the cooled gas will condense to a liquid.

To slow the gas molecules, we make use of an effect similar to that seen when a ball is thrown into the air: as it rises it slows in response to the gravitational attraction of the Earth and its kinetic energy is converted into potential energy. We saw in Section 1.3 that molecules in a real gas attract each other (the attraction is not gravitational, but the effect is the same). It follows that, if we can cause the molecules to move apart from each other, like a ball rising from a planet, then they should slow. It is very easy to move molecules apart from each other: we simply allow the gas to expand, which increases the average separation of the molecules. To cool a gas, therefore, we allow it to expand without allowing any energy to enter from outside as heat. As the gas expands, the molecules move apart to fill the available volume, struggling as they do so against the attraction of their neighbours. Because some kinetic energy must be converted into potential energy to reach greater separations, the molecules travel more slowly as their separation increases. This sequence of molecular events explains the Joule–Thomson effect: the cooling of a real gas by adiabatic expansion. The cooling effect, which corresponds to $\mu > 0$, is observed under conditions when attractive interactions are dominant ($Z < 1$, eqn 1.17), because the molecules have to climb apart against the attractive force in order for them to travel more slowly. For molecules under conditions when repulsions are dominant ($Z > 1$), the Joule–Thomson effect results in the gas becoming warmer, or $\mu < 0$.

Checklist of key ideas

☐ 1. Thermodynamics is the study of the transformations of energy. ☐ 2. The system is the part of the world in which we have a special interest. The surroundings is the region outside the system where we make our measurements. ☐ 3. An open system has a boundary through which matter can be transferred. A closed system has a boundary through which matter cannot be transferred. An isolated system has a boundary through which neither matter nor energy can be transferred. ☐ 4. Energy is the capacity to do work. The internal energy is the total energy of a system. ☐ 5. Work is the transfer of energy by motion against an opposing force, $dw = -Fdz$. Heat is the transfer of energy as a result of a temperature difference between the system and the surroundings.	☐ 6. An exothermic process releases energy as heat to the surroundings. An endothermic process absorbs energy as heat from the surroundings. ☐ 7. A state function is a property that depends only on the current state of the system and is independent of how that state has been prepared. ☐ 8. The First Law of thermodynamics states that the internal energy of an isolated system is constant, $\Delta U = q + w$. ☐ 9. Expansion work is the work of expansion (or compression) of a system, $dw = -p_{\text{ex}}dV$. The work of free expansion is $w = 0$. The work of expansion against a constant external pressure is $w = -p_{\text{ex}}\Delta V$. The work of isothermal reversible expansion of a perfect gas is $w = -nRT \ln(V_f/V_i)$. ☐ 10. A reversible change is a change that can be reversed by an infinitesimal modification of a variable. ☐ 11. Maximum work is achieved in a reversible change.

12. Calorimetry is the study of heat transfers during physical and chemical processes.
13. The heat capacity at constant volume is defined as $C_V = (\partial U / \partial T)_V$. The heat capacity at constant pressure is $C_p = (\partial H / \partial T)_p$. For a perfect gas, the heat capacities are related by $C_p - C_V = nR$.
14. The enthalpy is defined as $H = U + pV$. The enthalpy change is the energy transferred as heat at constant pressure, $\Delta H = q_p$.
15. During a reversible adiabatic change, the temperature of a perfect gas varies according to $T_f = T_i (V_i / V_f)^{1/c}$, $c = C_{V,m} / R$. The pressure and volume are related by $pV^\gamma = \text{constant}$, with $\gamma = C_{p,m} / C_{V,m}$.
16. The standard enthalpy change is the change in enthalpy for a process in which the initial and final substances are in their standard states. The standard state is the pure substance at 1 bar.
17. Enthalpy changes are additive, as in $\Delta_{\text{sub}} H^\circ = \Delta_{\text{fus}} H^\circ + \Delta_{\text{vap}} H^\circ$.
18. The enthalpy change for a process and its reverse are related by $\Delta_{\text{forward}} H^\circ = -\Delta_{\text{reverse}} H^\circ$.
19. The standard enthalpy of combustion is the standard reaction enthalpy for the complete oxidation of an organic compound to CO_2 gas and liquid H_2O if the compound contains C, H, and O, and to N_2 gas if N is also present.
20. Hess's law states that the standard enthalpy of an overall reaction is the sum of the standard enthalpies of the individual reactions into which a reaction may be divided.
21. The standard enthalpy of formation ($\Delta_f H^\circ$) is the standard reaction enthalpy for the formation of the compound from its elements in their reference states. The reference state is the most stable state of an element at the specified temperature and 1 bar.
22. The standard reaction enthalpy may be estimated by combining enthalpies of formation, $\Delta_r H^\circ = \sum_{\text{Products}} \nu \Delta_f H^\circ - \sum_{\text{Reactants}} \nu \Delta_f H^\circ$.
23. The temperature dependence of the reaction enthalpy is given by Kirchhoff's law, $\Delta_r H^\circ(T_2) = \Delta_r H^\circ(T_1) + \int_{T_1}^{T_2} \Delta_r C_p^\circ dT$.
24. An exact differential is an infinitesimal quantity that, when integrated, gives a result that is independent of the path between the initial and final states. An inexact differential is an infinitesimal quantity that, when integrated, gives a result that depends on the path between the initial and final states.
25. The internal pressure is defined as $\pi_T = (\partial U / \partial V)_T$. For a perfect gas, $\pi_T = 0$.
26. The Joule–Thomson effect is the cooling of a gas by isenthalpic expansion.
27. The Joule–Thomson coefficient is defined as $\mu = (\partial T / \partial p)_H$. The isothermal Joule–Thomson coefficient is defined as $\mu_T = (\partial H / \partial p)_T = -C_p \mu$.
28. The inversion temperature is the temperature at which the Joule–Thomson coefficient changes sign.

Further information

Further information 2.1 Adiabatic processes

Consider a stage in a reversible adiabatic expansion when the pressure inside and out is p . The work done when the gas expands by dV is $dw = -pdV$; however, for a perfect gas, $dU = C_V dT$.

Therefore, because for an adiabatic change ($dq = 0$) $dU = dw + dq = dw$, we can equate these two expressions for dU and write

$$C_V dT = -pdV$$

We are dealing with a perfect gas, so we can replace p by nRT/V and obtain

$$\frac{C_V dT}{T} = -\frac{nR dV}{V}$$

To integrate this expression we note that T is equal to T_i when V is equal to V_i , and is equal to T_f when V is equal to V_f at the end of the expansion. Therefore,

$$C_V \int_{T_i}^{T_f} \frac{dT}{T} = -nR \int_{V_i}^{V_f} \frac{dV}{V}$$

(We are taking C_V to be independent of temperature.) Then, because $\int dx/x = \ln x + \text{constant}$, we obtain

$$C_V \ln \frac{T_f}{T_i} = -nR \ln \frac{V_f}{V_i}$$

Because $\ln(x/y) = -\ln(y/x)$, this expression rearranges to

$$\frac{C_V}{nR} \ln \frac{T_f}{T_i} = \ln \frac{V_i}{V_f}$$

With $c = C_V/nR$ we obtain (because $\ln x^a = a \ln x$)

$$\ln \left(\frac{T_f}{T_i} \right)^c = \ln \left(\frac{V_i}{V_f} \right)$$

which implies that $(T_f/T_i)^c = (V_i/V_f)$ and, upon rearrangement, eqn 2.28.

The initial and final states of a perfect gas satisfy the perfect gas law regardless of how the change of state takes place, so we can use $pV = nRT$ to write

$$\frac{p_i V_i}{p_f V_f} = \frac{T_i}{T_f}$$

However, we have just shown that

$$\frac{T_i}{T_f} = \left(\frac{V_f}{V_i} \right)^{1/c} = \left(\frac{V_f}{V_i} \right)^{\gamma-1}$$

where we use the definition of the heat capacity ratio where $\gamma = C_{p,m}/C_{v,m}$ and the fact that, for a perfect gas, $C_{p,m} - C_{v,m} = R$ (the molar version of eqn 2.26). Then we combine the two expressions, to obtain

$$\frac{p_i}{p_f} = \frac{V_f}{V_i} \times \left(\frac{V_f}{V_i} \right)^{\gamma-1} = \left(\frac{V_f}{V_i} \right)^{\gamma}$$

which rearranges to $p_i V_i^\gamma = p_f V_f^\gamma$, which is eqn 2.29.

Further information 2.2 The relation between heat capacities

A useful rule when doing a problem in thermodynamics is to go back to first principles. In the present problem we do this twice, first by expressing C_p and C_V in terms of their definitions and then by inserting the definition $H = U + pV$:

$$\begin{aligned} C_p - C_V &= \left(\frac{\partial H}{\partial T} \right)_p - \left(\frac{\partial U}{\partial T} \right)_V \\ &= \left(\frac{\partial U}{\partial T} \right)_p + \left(\frac{\partial(pV)}{\partial T} \right)_p - \left(\frac{\partial U}{\partial T} \right)_V \end{aligned}$$

We have already calculated the difference of the first and third terms on the right, and eqn 2.45 lets us write this difference as $\alpha \pi_T V$. The factor αV gives the change in volume when the temperature is raised, and $\pi_T = (\partial U/\partial V)_T$ converts this change in volume into a change in internal energy. We can simplify the remaining term by noting that, because p is constant,

$$\left(\frac{\partial(pV)}{\partial T} \right)_p = p \left(\frac{\partial V}{\partial T} \right)_p = \alpha p V$$

The middle term of this expression identifies it as the contribution to the work of pushing back the atmosphere: $(\partial V/\partial T)_p$ is the change of volume caused by a change of temperature, and multiplication by p converts this expansion into work.

Collecting the two contributions gives

$$C_p - C_V = \alpha(p + \pi_T)V \quad (2.56)$$

As just remarked, the first term on the right, $\alpha p V$, is a measure of the work needed to push back the atmosphere; the second term on the right, $\alpha \pi_T V$, is the work required to separate the molecules composing the system.

At this point we can go further by using the result we prove in Section 3.8 that

$$\pi_T = T \left(\frac{\partial p}{\partial T} \right)_V - p$$

When this expression is inserted in the last equation we obtain

$$C_p - C_V = \alpha T V \left(\frac{\partial p}{\partial T} \right)_V \quad (2.57)$$

We now transform the remaining partial derivative. It follows from Euler's chain relation that

$$\left(\frac{\partial p}{\partial T} \right)_V \left(\frac{\partial T}{\partial V} \right)_p \left(\frac{\partial V}{\partial p} \right)_T = -1$$

Comment 2.8

The Euler chain relation states that, for a differentiable function $z = z(x, y)$,

$$\left(\frac{\partial y}{\partial x} \right)_z \left(\frac{\partial x}{\partial z} \right)_y \left(\frac{\partial z}{\partial y} \right)_x = -1$$

For instance, if $z(x, y) = x^2 y$,

$$\begin{aligned}\left(\frac{\partial y}{\partial x}\right)_z &= \left(\frac{\partial(z/x^2)}{\partial x}\right)_z = z \frac{d(1/x^2)}{dx} = -\frac{2z}{x^3} \\ \left(\frac{\partial x}{\partial z}\right)_y &= \left(\frac{\partial(z/y)^{1/2}}{\partial z}\right)_y = \frac{1}{y^{1/2}} \frac{dz^{1/2}}{dz} = \frac{1}{2(yz)^{1/2}} \\ \left(\frac{\partial z}{\partial y}\right)_x &= \left(\frac{\partial(x^2y)}{\partial y}\right)_x = x^2 \frac{dy}{dy} = x^2\end{aligned}$$

Multiplication of the three terms together gives the result -1 .

and therefore that

$$\left(\frac{\partial p}{\partial T}\right)_V = -\frac{1}{(\partial T/\partial V)_p (\partial V/\partial p)_T}$$

Unfortunately, $(\partial T/\partial V)_p$ occurs instead of $(\partial V/\partial T)_p$. However, the 'reciprocal identity' allows us to invert partial derivatives and to write

$$\left(\frac{\partial p}{\partial T}\right)_V = -\frac{(\partial V/\partial T)_p}{(\partial V/\partial p)_T} = \frac{\alpha}{\kappa_T}$$

Comment 2.9

The reciprocal identity states that

$$\left(\frac{\partial y}{\partial x}\right)_z = \frac{1}{(\partial x/\partial y)_z}$$

For example, for the function $z(x,y) = x^2y$,

$$\left(\frac{\partial y}{\partial x}\right)_z = \left(\frac{\partial(z/x^2)}{\partial x}\right)_z = z \frac{d(1/x^2)}{dx} = -\frac{2z}{x^3}$$

We can also write $x = (z/y)^{1/2}$, in which case

$$\begin{aligned}\left(\frac{\partial x}{\partial y}\right)_z &= \left(\frac{\partial(z/y)^{1/2}}{\partial y}\right)_z = z^{1/2} \frac{d(1/y^{1/2})}{dy} \\ &= -\frac{z^{1/2}}{2y^{3/2}} = -\frac{z^{1/2}}{2(z/x^2)^{3/2}} = -\frac{x^3}{2z}\end{aligned}$$

which is the reciprocal of the coefficient derived above.

Insertion of this relation into eqn 2.57 produces eqn 2.49.

Discussion questions

2.1 Provide mechanical and molecular definitions of work and heat.

2.2 Consider the reversible expansion of a perfect gas. Provide a physical interpretation for the fact that $pV^\gamma = \text{constant}$ for an adiabatic change, whereas $pV = \text{constant}$ for an isothermal change.

2.3 Explain the difference between the change in internal energy and the change in enthalpy accompanying a chemical or physical process.

2.4 Explain the significance of a physical observable being a state function and compile a list of as many state functions as you can identify.

2.5 Explain the significance of the Joule and Joule–Thomson experiments. What would Joule observe in a more sensitive apparatus?

2.6 Suggest (with explanation) how the internal energy of a van der Waals gas should vary with volume at constant temperature.

2.7 In many experimental thermograms, such as that shown in Fig. 2.16, the baseline below T_1 is at a different level from that above T_2 . Explain this observation.

Exercises

Assume all gases are perfect unless stated otherwise. Unless otherwise stated, thermochemical data are for 298.15 K.

2.1(a) Calculate the work needed for a 65 kg person to climb through 4.0 m on the surface of (a) the Earth and (b) the Moon ($g = 1.60 \text{ m s}^{-2}$).

2.1(b) Calculate the work needed for a bird of mass 120 g to fly to a height of 50 m from the surface of the Earth.

2.2(a) A chemical reaction takes place in a container of cross-sectional area 100 cm^2 . As a result of the reaction, a piston is pushed out through 10 cm against an external pressure of 1.0 atm. Calculate the work done by the system.

2.2(b) A chemical reaction takes place in a container of cross-sectional area 50.0 cm^2 . As a result of the reaction, a piston is pushed out through 15 cm against an external pressure of 121 kPa. Calculate the work done by the system.

2.3(a) A sample consisting of 1.00 mol Ar is expanded isothermally at 0°C from 22.4 dm^3 to 44.8 dm^3 (a) reversibly, (b) against a constant external pressure equal to the final pressure of the gas, and (c) freely (against zero external pressure). For the three processes calculate q , w , ΔU , and ΔH .

2.3(b) A sample consisting of 2.00 mol He is expanded isothermally at 22°C from 22.8 dm^3 to 31.7 dm^3 (a) reversibly, (b) against a constant external pressure equal to the final pressure of the gas, and (c) freely (against zero external pressure). For the three processes calculate q , w , ΔU , and ΔH .

2.4(a) A sample consisting of 1.00 mol of perfect gas atoms, for which $C_{V,m} = \frac{3}{2}R$, initially at $p_1 = 1.00 \text{ atm}$ and $T_1 = 300 \text{ K}$, is heated reversibly to 400 K at constant volume. Calculate the final pressure, ΔU , q , and w .

2.4(b) A sample consisting of 2.00 mol of perfect gas molecules, for which $C_{V,m} = \frac{5}{2}R$, initially at $p_1 = 111 \text{ kPa}$ and $T_1 = 277 \text{ K}$, is heated reversibly to 356 K at constant volume. Calculate the final pressure, ΔU , q , and w .

2.5(a) A sample of 4.50 g of methane occupies 12.7 dm^3 at 310 K. (a) Calculate the work done when the gas expands isothermally against a constant external pressure of 200 Torr until its volume has increased by 3.3 dm^3 . (b) Calculate the work that would be done if the same expansion occurred reversibly.

2.5(b) A sample of argon of mass 6.56 g occupies 18.5 dm^3 at 305 K. (a) Calculate the work done when the gas expands isothermally against a

constant external pressure of 7.7 kPa until its volume has increased by 2.5 dm³.
(b) Calculate the work that would be done if the same expansion occurred reversibly.

2.6(a) A sample of 1.00 mol H₂O(g) is condensed isothermally and reversibly to liquid water at 100°C. The standard enthalpy of vaporization of water at 100°C is 40.656 kJ mol⁻¹. Find w , q , ΔU , and ΔH for this process.

2.6(b) A sample of 2.00 mol CH₃OH(g) is condensed isothermally and reversibly to liquid at 64°C. The standard enthalpy of vaporization of methanol at 64°C is 35.3 kJ mol⁻¹. Find w , q , ΔU , and ΔH for this process.

2.7(a) A strip of magnesium of mass 15 g is dropped into a beaker of dilute hydrochloric acid. Calculate the work done by the system as a result of the reaction. The atmospheric pressure is 1.0 atm and the temperature 25°C.

2.7(b) A piece of zinc of mass 5.0 g is dropped into a beaker of dilute hydrochloric acid. Calculate the work done by the system as a result of the reaction. The atmospheric pressure is 1.1 atm and the temperature 23°C.

2.8(a) The constant-pressure heat capacity of a sample of a perfect gas was found to vary with temperature according to the expression $C_p/(J K^{-1}) = 20.17 + 0.3665(T/K)$. Calculate q , w , ΔU , and ΔH when the temperature is raised from 25°C to 200°C (a) at constant pressure, (b) at constant volume.

2.8(b) The constant-pressure heat capacity of a sample of a perfect gas was found to vary with temperature according to the expression $C_p/(J K^{-1}) = 20.17 + 0.4001(T/K)$. Calculate q , w , ΔU , and ΔH when the temperature is raised from 0°C to 100°C (a) at constant pressure, (b) at constant volume.

2.9(a) Calculate the final temperature of a sample of argon of mass 12.0 g that is expanded reversibly and adiabatically from 1.0 dm³ at 273.15 K to 3.0 dm³.

2.9(b) Calculate the final temperature of a sample of carbon dioxide of mass 16.0 g that is expanded reversibly and adiabatically from 500 cm³ at 298.15 K to 2.00 dm³.

2.10(a) A sample of carbon dioxide of mass 2.45 g at 27.0°C is allowed to expand reversibly and adiabatically from 500 cm³ to 3.00 dm³. What is the work done by the gas?

2.10(b) A sample of nitrogen of mass 3.12 g at 23.0°C is allowed to expand reversibly and adiabatically from 400 cm³ to 2.00 dm³. What is the work done by the gas?

2.11(a) Calculate the final pressure of a sample of carbon dioxide that expands reversibly and adiabatically from 57.4 kPa and 1.0 dm³ to a final volume of 2.0 dm³. Take $\gamma = 1.4$.

2.11(b) Calculate the final pressure of a sample of water vapour that expands reversibly and adiabatically from 87.3 Torr and 500 cm³ to a final volume of 3.0 dm³. Take $\gamma = 1.3$.

2.12(a) When 229 J of energy is supplied as heat to 3.0 mol Ar(g), the temperature of the sample increases by 2.55 K. Calculate the molar heat capacities at constant volume and constant pressure of the gas.

2.12(b) When 178 J of energy is supplied as heat to 1.9 mol of gas molecules, the temperature of the sample increases by 1.78 K. Calculate the molar heat capacities at constant volume and constant pressure of the gas.

2.13(a) When 3.0 mol O₂ is heated at a constant pressure of 3.25 atm, its temperature increases from 260 K to 285 K. Given that the molar heat capacity of O₂ at constant pressure is 29.4 J K⁻¹ mol⁻¹, calculate q , ΔH , and ΔU .

2.13(b) When 2.0 mol CO₂ is heated at a constant pressure of 1.25 atm, its temperature increases from 250 K to 277 K. Given that the molar heat capacity of CO₂ at constant pressure is 37.11 J K⁻¹ mol⁻¹, calculate q , ΔH , and ΔU .

2.14(a) A sample of 4.0 mol O₂ is originally confined in 20 dm³ at 270 K and then undergoes adiabatic expansion against a constant pressure of 600 Torr until the volume has increased by a factor of 3.0. Calculate q , w , ΔT , ΔU , and ΔH . (The final pressure of the gas is not necessarily 600 Torr.)

2.14(b) A sample of 5.0 mol CO₂ is originally confined in 15 dm³ at 280 K and then undergoes adiabatic expansion against a constant pressure of 78.5 kPa until the volume has increased by a factor of 4.0. Calculate q , w , ΔT , ΔU , and ΔH . (The final pressure of the gas is not necessarily 78.5 kPa.)

2.15(a) A sample consisting of 1.0 mol of perfect gas molecules with $C_V = 20.8 J K^{-1}$ is initially at 3.25 atm and 310 K. It undergoes reversible adiabatic expansion until its pressure reaches 2.50 atm. Calculate the final volume and temperature and the work done.

2.15(b) A sample consisting of 1.5 mol of perfect gas molecules with $C_{p,m} = 20.8 J K^{-1} mol^{-1}$ is initially at 230 kPa and 315 K. It undergoes reversible adiabatic expansion until its pressure reaches 170 kPa. Calculate the final volume and temperature and the work done.

2.16(a) A certain liquid has $\Delta_{vap}H^\circ = 26.0 kJ mol^{-1}$. Calculate q , w , ΔH , and ΔU when 0.50 mol is vaporized at 250 K and 750 Torr.

2.16(b) A certain liquid has $\Delta_{vap}H^\circ = 32.0 kJ mol^{-1}$. Calculate q , w , ΔH , and ΔU when 0.75 mol is vaporized at 260 K and 765 Torr.

2.17(a) The standard enthalpy of formation of ethylbenzene is $-12.5 kJ mol^{-1}$. Calculate its standard enthalpy of combustion.

2.17(b) The standard enthalpy of formation of phenol is $-165.0 kJ mol^{-1}$. Calculate its standard enthalpy of combustion.

2.18(a) The standard enthalpy of combustion of cyclopropane is $-2091 kJ mol^{-1}$ at 25°C. From this information and enthalpy of formation data for CO₂(g) and H₂O(g), calculate the enthalpy of formation of cyclopropane. The enthalpy of formation of propene is $+20.42 kJ mol^{-1}$. Calculate the enthalpy of isomerization of cyclopropane to propene.

2.18(b) From the following data, determine $\Delta_f H^\circ$ for diborane, B₂H₆(g), at 298 K:

2.19(a) When 120 mg of naphthalene, C₁₀H₈(s), was burned in a bomb calorimeter the temperature rose by 3.05 K. Calculate the calorimeter constant. By how much will the temperature rise when 10 mg of phenol, C₆H₅OH(s), is burned in the calorimeter under the same conditions?

2.19(b) When 2.25 mg of anthracene, C₁₄H₁₀(s), was burned in a bomb calorimeter the temperature rose by 1.35 K. Calculate the calorimeter constant. By how much will the temperature rise when 135 mg of phenol, C₆H₅OH(s), is burned in the calorimeter under the same conditions? ($\Delta_c H^\circ(C_{14}H_{10}, s) = -7061 kJ mol^{-1}$.)

2.20(a) Calculate the standard enthalpy of solution of AgCl(s) in water from the enthalpies of formation of the solid and the aqueous ions.

2.20(b) Calculate the standard enthalpy of solution of AgBr(s) in water from the enthalpies of formation of the solid and the aqueous ions.

2.21(a) The standard enthalpy of decomposition of the yellow complex H₃NSO₂ into NH₃ and SO₂ is $+40 kJ mol^{-1}$. Calculate the standard enthalpy of formation of H₃NSO₂.

2.21(b) Given that the standard enthalpy of combustion of graphite is $-393.51 kJ mol^{-1}$ and that of diamond is $-395.41 kJ mol^{-1}$, calculate the enthalpy of the graphite-to-diamond transition.

2.22(a) Given the reactions (1) and (2) below, determine (a) $\Delta_r H^\circ$ and $\Delta_r U^\circ$ for reaction (3), (b) $\Delta_r H^\circ$ for both HCl(g) and H₂O(g) all at 298 K.

2.22(b) Given the reactions (1) and (2) below, determine (a) $\Delta_r H^\circ$ and $\Delta_r U^\circ$ for reaction (3), (b) $\Delta_r H^\circ$ for both HCl(g) and $\text{H}_2\text{O(g)}$ all at 298 K.

2.23(a) For the reaction $\text{C}_2\text{H}_5\text{OH(l)} + 3 \text{O}_2(\text{g}) \rightarrow 2 \text{CO}_2(\text{g}) + 3 \text{H}_2\text{O(g)}$, $\Delta_r U^\circ = -1373 \text{ kJ mol}^{-1}$ at 298 K. Calculate $\Delta_r H^\circ$.

2.23(b) For the reaction $2 \text{C}_6\text{H}_5\text{COOH(s)} + 13 \text{O}_2(\text{g}) \rightarrow 12 \text{CO}_2(\text{g}) + 6 \text{H}_2\text{O(g)}$, $\Delta_r U^\circ = -772.7 \text{ kJ mol}^{-1}$ at 298 K. Calculate $\Delta_r H^\circ$.

2.24(a) Calculate the standard enthalpies of formation of (a) $\text{KClO}_3(\text{s})$ from the enthalpy of formation of KCl , (b) $\text{NaHCO}_3(\text{s})$ from the enthalpies of formation of CO_2 and NaOH together with the following information:

2.24(b) Calculate the standard enthalpy of formation of NOCl(g) from the enthalpy of formation of NO given in Table 2.5, together with the following information:

2.25(a) Use the information in Table 2.5 to predict the standard reaction enthalpy of $2 \text{NO}_2(\text{g}) \rightarrow \text{N}_2\text{O}_4(\text{g})$ at 100°C from its value at 25°C .

2.25(b) Use the information in Table 2.5 to predict the standard reaction enthalpy of $2 \text{H}_2(\text{g}) + \text{O}_2(\text{g}) \rightarrow 2 \text{H}_2\text{O(l)}$ at 100°C from its value at 25°C .

2.26(a) From the data in Table 2.5, calculate $\Delta_r H^\circ$ and $\Delta_r U^\circ$ at (a) 298 K, (b) 378 K for the reaction $\text{C(graphite)} + \text{H}_2\text{O(g)} \rightarrow \text{CO(g)} + \text{H}_2(\text{g})$. Assume all heat capacities to be constant over the temperature range of interest.

2.26(b) Calculate $\Delta_r H^\circ$ and $\Delta_r U^\circ$ at 298 K and $\Delta_r H^\circ$ at 348 K for the hydrogenation of ethyne (acetylene) to ethene (ethylene) from the enthalpy of combustion and heat capacity data in Tables 2.5 and 2.7. Assume the heat capacities to be constant over the temperature range involved.

2.27(a) Calculate $\Delta_r H^\circ$ for the reaction $\text{Zn(s)} + \text{CuSO}_4(\text{aq}) \rightarrow \text{ZnSO}_4(\text{aq}) + \text{Cu(s)}$ from the information in Table 2.7 in the *Data section*.

2.27(b) Calculate $\Delta_r H^\circ$ for the reaction $\text{NaCl(aq)} + \text{AgNO}_3(\text{aq}) \rightarrow \text{AgCl(s)} + \text{NaNO}_3(\text{aq})$ from the information in Table 2.7 in the *Data section*.

2.28(a) Set up a thermodynamic cycle for determining the enthalpy of hydration of Mg^{2+} ions using the following data: enthalpy of sublimation of Mg(s) , $+167.2 \text{ kJ mol}^{-1}$; first and second ionization enthalpies of Mg(g) , 7.646 eV and 15.035 eV ; dissociation enthalpy of $\text{Cl}_2(\text{g})$, $+241.6 \text{ kJ mol}^{-1}$; electron gain enthalpy of Cl(g) , -3.78 eV ; enthalpy of solution of $\text{MgCl}_2(\text{s})$, $-150.5 \text{ kJ mol}^{-1}$; enthalpy of hydration of $\text{Cl}^-(\text{g})$, $-383.7 \text{ kJ mol}^{-1}$.

2.28(b) Set up a thermodynamic cycle for determining the enthalpy of hydration of Ca^{2+} ions using the following data: enthalpy of sublimation of Ca(s) , $+178.2 \text{ kJ mol}^{-1}$; first and second ionization enthalpies of Ca(g) , $589.7 \text{ kJ mol}^{-1}$ and 1145 kJ mol^{-1} ; enthalpy of vaporization of bromine, $+30.91 \text{ kJ mol}^{-1}$; dissociation enthalpy of $\text{Br}_2(\text{g})$, $+192.9 \text{ kJ mol}^{-1}$; electron gain enthalpy of Br(g) , $-331.0 \text{ kJ mol}^{-1}$; enthalpy of solution of $\text{CaBr}_2(\text{s})$, $-103.1 \text{ kJ mol}^{-1}$; enthalpy of hydration of $\text{Br}^-(\text{g})$, -337 kJ mol^{-1} .

2.29(a) When a certain freon used in refrigeration was expanded adiabatically from an initial pressure of 32 atm and 0°C to a final pressure of 1.00 atm, the temperature fell by 22 K. Calculate the Joule–Thomson coefficient, μ , at 0°C , assuming it remains constant over this temperature range.

2.29(b) A vapour at 22 atm and 5°C was allowed to expand adiabatically to a final pressure of 1.00 atm; the temperature fell by 10 K. Calculate the Joule–Thomson coefficient, μ , at 5°C , assuming it remains constant over this temperature range.

2.30(a) For a van der Waals gas, $\pi_T = a/V_m^2$. Calculate ΔU_m for the isothermal expansion of nitrogen gas from an initial volume of 1.00 dm^3 to 24.8 dm^3 at 298 K. What are the values of q and w ?

2.30(b) Repeat Exercise 2.30(a) for argon, from an initial volume of 1.00 dm^3 to 22.1 dm^3 at 298 K.

2.31(a) The volume of a certain liquid varies with temperature as

$$V = V' \{0.75 + 3.9 \times 10^{-4}(T/\text{K}) + 1.48 \times 10^{-6}(T/\text{K})^2\}$$

where V' is its volume at 300 K. Calculate its expansion coefficient, α , at 320 K.

2.31(b) The volume of a certain liquid varies with temperature as

$$V = V' \{0.77 + 3.7 \times 10^{-4}(T/\text{K}) + 1.52 \times 10^{-6}(T/\text{K})^2\}$$

where V' is its volume at 298 K. Calculate its expansion coefficient, α , at 310 K.

2.32(a) The isothermal compressibility of copper at 293 K is $7.35 \times 10^{-7} \text{ atm}^{-1}$. Calculate the pressure that must be applied in order to increase its density by 0.08 per cent.

2.32(b) The isothermal compressibility of lead at 293 K is $2.21 \times 10^{-6} \text{ atm}^{-1}$. Calculate the pressure that must be applied in order to increase its density by 0.08 per cent.

2.33(a) Given that $\mu = 0.25 \text{ K atm}^{-1}$ for nitrogen, calculate the value of its isothermal Joule–Thomson coefficient. Calculate the energy that must be supplied as heat to maintain constant temperature when 15.0 mol N_2 flows through a throttle in an isothermal Joule–Thomson experiment and the pressure drop is 75 atm.

2.33(b) Given that $\mu = 1.11 \text{ K atm}^{-1}$ for carbon dioxide, calculate the value of its isothermal Joule–Thomson coefficient. Calculate the energy that must be supplied as heat to maintain constant temperature when 12.0 mol CO_2 flows through a throttle in an isothermal Joule–Thomson experiment and the pressure drop is 55 atm.

Problems*

Assume all gases are perfect unless stated otherwise. Note that 1 atm = 1.013 25 bar. Unless otherwise stated, thermochemical data are for 298.15 K.

Numerical problems

2.1 A sample consisting of 1 mol of perfect gas atoms (for which $C_{V,m} = \frac{3}{2}R$) is taken through the cycle shown in Fig. 2.34. (a) Determine the temperature at the points 1, 2, and 3. (b) Calculate q , w , ΔU , and ΔH for each step and for the overall cycle. If a numerical answer cannot be obtained from the information given, then write in +, −, 0, or ? as appropriate.

Fig. 2.34

2.2 A sample consisting of 1.0 mol $\text{CaCO}_3(\text{s})$ was heated to 800°C , when it decomposed. The heating was carried out in a container fitted with a piston that was initially resting on the solid. Calculate the work done during complete decomposition at 1.0 atm. What work would be done if instead of having a piston the container was open to the atmosphere?

2.3 A sample consisting of 2.0 mol CO_2 occupies a fixed volume of 15.0 dm^3 at 300 K. When it is supplied with 2.35 kJ of energy as heat its temperature increases to 341 K. Assume that CO_2 is described by the van der Waals equation of state, and calculate w , ΔU , and ΔH .

2.4 A sample of 70 mmol $\text{Kr}(\text{g})$ expands reversibly and isothermally at 373 K from 5.25 cm^3 to 6.29 cm^3 , and the internal energy of the sample is known to increase by 83.5 J. Use the virial equation of state up to the second coefficient $B = -28.7 \text{ cm}^3 \text{ mol}^{-1}$ to calculate w , q , and ΔH for this change of state.

2.5 A sample of 1.00 mol perfect gas molecules with $C_{p,m} = \frac{7}{2}R$ is put through the following cycle: (a) constant-volume heating to twice its initial volume, (b) reversible, adiabatic expansion back to its initial temperature, (c) reversible isothermal compression back to 1.00 atm. Calculate q , w , ΔU , and ΔH for each step and overall.

2.6 Calculate the work done during the isothermal reversible expansion of a van der Waals gas. Account physically for the way in which the coefficients a and b appear in the final expression. Plot on the same graph the indicator diagrams for the isothermal reversible expansion of (a) a perfect gas, (b) a van der Waals gas in which $a = 0$ and $b = 5.11 \times 10^{-2} \text{ dm}^3 \text{ mol}^{-1}$, and (c) $a = 4.2 \text{ dm}^6 \text{ atm mol}^{-2}$ and $b = 0$. The values selected exaggerate the imperfections but give rise to significant effects on the indicator diagrams. Take $V_1 = 1.0 \text{ dm}^3$, $n = 1.0 \text{ mol}$, and $T = 298 \text{ K}$.

2.7 The molar heat capacity of ethane is represented in the temperature range 298 K to 400 K by the empirical expression $C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1}) = 14.73 + 0.1272(T/\text{K})$. The corresponding expressions for $\text{C}(\text{s})$ and $\text{H}_2(\text{g})$ are given in

Table 2.2. Calculate the standard enthalpy of formation of ethane at 350 K from its value at 298 K.

2.8 A sample of the sugar D-ribose ($\text{C}_5\text{H}_{10}\text{O}_5$) of mass 0.727 g was placed in a calorimeter and then ignited in the presence of excess oxygen. The temperature rose by 0.910 K. In a separate experiment in the same calorimeter, the combustion of 0.825 g of benzoic acid, for which the internal energy of combustion is $-3251 \text{ kJ mol}^{-1}$, gave a temperature rise of 1.940 K. Calculate the internal energy of combustion of D-ribose and its enthalpy of formation.

2.9 The standard enthalpy of formation of the metallocene bis(benzene)chromium was measured in a calorimeter. It was found for the reaction $\text{Cr}(\text{C}_6\text{H}_6)_2(\text{s}) \rightarrow \text{Cr}(\text{s}) + 2 \text{C}_6\text{H}_6(\text{g})$ that $\Delta_r U^\circ(583 \text{ K}) = +8.0 \text{ kJ mol}^{-1}$. Find the corresponding reaction enthalpy and estimate the standard enthalpy of formation of the compound at 583 K. The constant-pressure molar heat capacity of benzene is $136.1 \text{ J K}^{-1} \text{ mol}^{-1}$ in its liquid range and $81.67 \text{ J K}^{-1} \text{ mol}^{-1}$ as a gas.

2.10† From the enthalpy of combustion data in Table 2.5 for the alkanes methane through octane, test the extent to which the relation $\Delta_c H^\circ = k\{(M/(\text{g mol}^{-1}))^n\}$ holds and find the numerical values for k and n . Predict $\Delta_c H^\circ$ for decane and compare to the known value.

2.11 It is possible to investigate the thermochemical properties of hydrocarbons with molecular modelling methods. (a) Use electronic structure software to predict $\Delta_c H^\circ$ values for the alkanes methane through pentane. To calculate $\Delta_c H^\circ$ values, estimate the standard enthalpy of formation of $\text{C}_n\text{H}_{2(n+1)}(\text{g})$ by performing semi-empirical calculations (for example, AM1 or PM3 methods) and use experimental standard enthalpy of formation values for $\text{CO}_2(\text{g})$ and $\text{H}_2\text{O}(\text{l})$. (b) Compare your estimated values with the experimental values of $\Delta_c H^\circ$ (Table 2.5) and comment on the reliability of the molecular modelling method. (c) Test the extent to which the relation $\Delta_c H^\circ = k\{(M/(\text{g mol}^{-1}))^n\}$ holds and find the numerical values for k and n .

2.12† When 1.3584 g of sodium acetate trihydrate was mixed into 100.0 cm^3 of $0.2000 \text{ M HCl}(\text{aq})$ at 25°C in a solution calorimeter, its temperature fell by 0.397°C on account of the reaction:

The heat capacity of the calorimeter is 91.0 J K^{-1} and the heat capacity density of the acid solution is $4.144 \text{ J K}^{-1} \text{ cm}^{-3}$. Determine the standard enthalpy of formation of the aqueous sodium cation. The standard enthalpy of formation of sodium acetate trihydrate is $-1064 \text{ kJ mol}^{-1}$.

2.13† Since their discovery in 1985, fullerenes have received the attention of many chemical researchers. Kolesov *et al.* reported the standard enthalpy of combustion and of formation of crystalline C_{60} based on calorimetric measurements (V.P. Kolesov, S.M. Pimenova, V.K. Pavlovich, N.B. Tamm, and A.A. Kurskaya, *J. Chem. Thermodynamics* **28**, 1121 (1996)). In one of their runs, they found the standard specific internal energy of combustion to be $-36.0334 \text{ kJ g}^{-1}$ at 298.15 K. Compute $\Delta_c H^\circ$ and $\Delta_f H^\circ$ of C_{60} .

2.14† A thermodynamic study of DyCl_3 (E.H.P. Cordfunke, A.S. Booji, and M. Yu. Furkaliouk, *J. Chem. Thermodynamics* **28**, 1387 (1996)) determined its standard enthalpy of formation from the following information

Determine $\Delta_f H^\circ(\text{DyCl}_3, \text{s})$ from these data.

* Problems denoted with the symbol ‡ were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

2.15† Silylene (SiH_2) is a key intermediate in the thermal decomposition of silicon hydrides such as silane (SiH_4) and disilane (Si_2H_6). Moffat *et al.* (H.K. Moffat, K.F. Jensen, and R.W. Carr, *J. Phys. Chem.* **95**, 145 (1991)) report $\Delta_f H^\circ(\text{SiH}_2) = +274 \text{ kJ mol}^{-1}$. If $\Delta_f H^\circ(\text{SiH}_4) = +34.3 \text{ kJ mol}^{-1}$ and $\Delta_f H^\circ(\text{Si}_2\text{H}_6) = +80.3 \text{ kJ mol}^{-1}$ (CRC Handbook (2004)), compute the standard enthalpies of the following reactions:

- (a) $\text{SiH}_4(\text{g}) \rightarrow \text{SiH}_2(\text{g}) + \text{H}_2(\text{g})$
 (b) $\text{Si}_2\text{H}_6(\text{g}) \rightarrow \text{SiH}_2(\text{g}) + \text{SiH}_4(\text{g})$

2.16† Silanone (SiH_2O) and silanol (SiH_3OH) are species believed to be important in the oxidation of silane (SiH_4). These species are much more elusive than their carbon counterparts. C.L. Darling and H.B. Schlegel (*J. Phys. Chem.* **97**, 8207 (1993)) report the following values (converted from calories) from a computational study: $\Delta_f H^\circ(\text{SiH}_2\text{O}) = -98.3 \text{ kJ mol}^{-1}$ and $\Delta_f H^\circ(\text{SiH}_3\text{OH}) = -282 \text{ kJ mol}^{-1}$. Compute the standard enthalpies of the following reactions:

- (a) $\text{SiH}_4(\text{g}) + \frac{1}{2} \text{O}_2(\text{g}) \rightarrow \text{SiH}_3\text{OH}(\text{g})$
 (b) $\text{SiH}_4(\text{g}) + \text{O}_2(\text{g}) \rightarrow \text{SiH}_2\text{O}(\text{g}) + \text{H}_2\text{O}(\text{l})$
 (c) $\text{SiH}_3\text{OH}(\text{g}) \rightarrow \text{SiH}_2\text{O}(\text{g}) + \text{H}_2(\text{g})$

Note that $\Delta_f H^\circ(\text{SiH}_4, \text{g}) = +34.3 \text{ kJ mol}^{-1}$ (CRC Handbook (2004)).

2.17 The constant-volume heat capacity of a gas can be measured by observing the decrease in temperature when it expands adiabatically and reversibly. If the decrease in pressure is also measured, we can use it to infer the value of $\gamma = C_p/C_V$ and hence, by combining the two values, deduce the constant-pressure heat capacity. A fluorocarbon gas was allowed to expand reversibly and adiabatically to twice its volume; as a result, the temperature fell from 298.15 K to 248.44 K and its pressure fell from 202.94 kPa to 81.840 kPa. Evaluate C_p .

2.18 A sample consisting of 1.00 mol of a van der Waals gas is compressed from 20.0 dm³ to 10.0 dm³ at 300 K. In the process, 20.2 kJ of work is done on the gas. Given that $\mu = \{(2a/RT) - b\}/C_{p,m}$, with $C_{p,m} = 38.4 \text{ J K}^{-1} \text{ mol}^{-1}$, $a = 3.60 \text{ dm}^6 \text{ atm mol}^{-2}$, and $b = 0.44 \text{ dm}^3 \text{ mol}^{-1}$, calculate ΔH for the process.

2.19 Take nitrogen to be a van der Waals gas with $a = 1.352 \text{ dm}^6 \text{ atm mol}^{-2}$ and $b = 0.0387 \text{ dm}^3 \text{ mol}^{-1}$, and calculate ΔH_m when the pressure on the gas is decreased from 500 atm to 1.00 atm at 300 K. For a van der Waals gas, $\mu = \{(2a/RT) - b\}/C_{p,m}$. Assume $C_{p,m} = \frac{7}{2}R$.

Theoretical problems

2.20 Show that the following functions have exact differentials: (a) $x^2y + 3y^2$, (b) $x \cos xy$, (c) x^3y^2 , (d) $t(t + e^t) + s$.

2.21 (a) What is the total differential of $z = x^2 + y^2 - 2xy + 2x - 4y - 8$? (b) Show that $\partial^2 z / \partial y \partial x = \partial^2 z / \partial x \partial y$ for this function. (c) Let $z = xy - y + \ln x + 2$. Find dz and show that it is exact.

2.22 (a) Express $(\partial C_V / \partial V)_T$ as a second derivative of U and find its relation to $(\partial U / \partial V)_T$ and $(\partial C_p / \partial p)_T$ as a second derivative of H and find its relation to $(\partial H / \partial p)_T$. (b) From these relations show that $(\partial C_V / \partial V)_T = 0$ and $(\partial C_p / \partial p)_T = 0$ for a perfect gas.

2.23 (a) Derive the relation $C_V = -(\partial U / \partial V)_T (\partial V / \partial T)_U$ from the expression for the total differential of $U(T, V)$ and (b) starting from the expression for the total differential of $H(T, p)$, express $(\partial H / \partial p)_T$ in terms of C_p and the Joule–Thomson coefficient, μ .

2.24 Starting from the expression $C_p - C_V = T(\partial p / \partial T)_V (\partial V / \partial T)_p$, use the appropriate relations between partial derivatives to show that

$$C_p - C_V = \frac{T(\partial V / \partial T)_p^2}{(\partial V / \partial T)_T}$$

Evaluate $C_p - C_V$ for a perfect gas.

2.25 (a) By direct differentiation of $H = U + pV$, obtain a relation between $(\partial H / \partial U)_p$ and $(\partial U / \partial V)_p$. (b) Confirm that $(\partial H / \partial U)_p = 1 + p(\partial V / \partial U)_p$ by

expressing $(\partial H / \partial U)_p$ as the ratio of two derivatives with respect to volume and then using the definition of enthalpy.

2.26 (a) Write expressions for dV and dp given that V is a function of p and T and p is a function of V and T . (b) Deduce expressions for $d \ln V$ and $d \ln p$ in terms of the expansion coefficient and the isothermal compressibility.

2.27 Calculate the work done during the isothermal reversible expansion of a gas that satisfies the virial equation of state, eqn 1.19. Evaluate (a) the work for 1.0 mol Ar at 273 K (for data, see Table 1.3) and (b) the same amount of a perfect gas. Let the expansion be from 500 cm³ to 1000 cm³ in each case.

2.28 Express the work of isothermal reversible expansion of a van der Waals gas in reduced variables and find a definition of reduced work that makes the overall expression independent of the identity of the gas. Calculate the work of isothermal reversible expansion along the critical isotherm from V_c to xV_c .

2.29† A gas obeying the equation of state $p(V - nb) = nRT$ is subjected to a Joule–Thomson expansion. Will the temperature increase, decrease, or remain the same?

2.30 Use the fact that $(\partial U / \partial V)_T = a/V_m^2$ for a van der Waals gas to show that $\mu C_{p,m} \approx (2a/RT) - b$ by using the definition of μ and appropriate relations between partial derivatives. (Hint. Use the approximation $pV_m \approx RT$ when it is justifiable to do so.)

2.31 Rearrange the van der Waals equation of state to give an expression for T as a function of p and V (with n constant). Calculate $(\partial T / \partial p)_V$ and confirm that $(\partial T / \partial p)_V = 1 / (\partial p / \partial T)_V$. Go on to confirm Euler's chain relation.

2.32 Calculate the isothermal compressibility and the expansion coefficient of a van der Waals gas. Show, using Euler's chain relation, that $\kappa_T R = \alpha(V_m - b)$.

2.33 Given that $\mu C_p = T(\partial V / \partial T)_p - V$, derive an expression for μ in terms of the van der Waals parameters a and b , and express it in terms of reduced variables. Evaluate μ at 25°C and 1.0 atm, when the molar volume of the gas is 24.6 dm³ mol⁻¹. Use the expression obtained to derive a formula for the inversion temperature of a van der Waals gas in terms of reduced variables, and evaluate it for the xenon sample.

2.34 The thermodynamic equation of state $(\partial U / \partial V)_T = T(\partial p / \partial T)_V - p$ was quoted in the chapter. Derive its partner

$$\left(\frac{\partial H}{\partial p} \right)_T = -T \left(\frac{\partial V}{\partial T} \right)_p + V$$

from it and the general relations between partial differentials.

2.35 Show that for a van der Waals gas,

$$C_{p,m} - C_{V,m} = \lambda R \quad \frac{1}{\lambda} = 1 - \frac{(3V_r - 1)^2}{4V_r^3 T_r}$$

and evaluate the difference for xenon at 25°C and 10.0 atm.

2.36 The speed of sound, c_s , in a gas of molar mass M is related to the ratio of heat capacities γ by $c_s = (\gamma RT / M)^{1/2}$. Show that $c_s = (\gamma p / \rho)^{1/2}$, where ρ is the mass density of the gas. Calculate the speed of sound in argon at 25°C.

2.37† A gas obeys the equation of state $V_m = RT/p + aT^2$ and its constant-pressure heat capacity is given by $C_{p,m} = A + BT + Cp$, where a , A , B , and C are constants independent of T and p . Obtain expressions for (a) the Joule–Thomson coefficient and (b) its constant-volume heat capacity.

Applications: to biology, materials science, and the environment

2.38 It is possible to see with the aid of a powerful microscope that a long piece of double-stranded DNA is flexible, with the distance between the ends of the chain adopting a wide range of values. This flexibility is important because it allows DNA to adopt very compact conformations as it is packaged in a chromosome (see Chapter 18). It is convenient to visualize a long piece

of DNA as a *freely jointed chain*, a chain of N small, rigid units of length l that are free to make any angle with respect to each other. The length l , the *persistence length*, is approximately 45 nm, corresponding to approximately 130 base pairs. You will now explore the work associated with extending a DNA molecule. (a) Suppose that a DNA molecule resists being extended from an equilibrium, more compact conformation with a *restoring force* $F = -k_F x$, where x is the difference in the end-to-end distance of the chain from an equilibrium value and k_F is the *force constant*. Systems showing this behaviour are said to obey *Hooke's law*. (i) What are the limitations of this model of the DNA molecule? (ii) Using this model, write an expression for the work that must be done to extend a DNA molecule by x . Draw a graph of your conclusion. (b) A better model of a DNA molecule is the *one-dimensional freely jointed chain*, in which a rigid unit of length l can only make an angle of 0° or 180° with an adjacent unit. In this case, the restoring force of a chain extended by $x = nl$ is given by

$$F = \frac{kT}{2l} \ln \left(\frac{1+v}{1-v} \right) \quad v = x/nl$$

where $k = 1.381 \times 10^{-23} \text{ J K}^{-1}$ is *Boltzmann's constant* (not a force constant). (i) What are the limitations of this model? (ii) What is the magnitude of the force that must be applied to extend a DNA molecule with $N = 200$ by 90 nm? (iii) Plot the restoring force against v , noting that v can be either positive or negative. How is the variation of the restoring force with end-to-end distance different from that predicted by Hooke's law? (iv) Keeping in mind that the difference in end-to-end distance from an equilibrium value is $x = nl$ and, consequently, $dx = ldn = Nl dv$, write an expression for the work of extending a DNA molecule. (v) Calculate the work of extending a DNA molecule from $v = 0$ to $v = 1.0$. *Hint*. You must integrate the expression for w . The task can be accomplished easily with mathematical software. (c) Show that for small extensions of the chain, when $v \ll 1$, the restoring force is given by

$$F \approx \frac{vkT}{l} = \frac{nkT}{Nl}$$

Hint. See Appendix 2 for a review of series expansions of functions. (d) Is the variation of the restoring force with extension of the chain given in part (c) different from that predicted by Hooke's law? Explain your answer.

2.39 There are no dietary recommendations for consumption of carbohydrates. Some nutritionists recommend diets that are largely devoid of carbohydrates, with most of the energy needs being met by fats. However, the most common recommendation is that at least 65 per cent of our food calories should come from carbohydrates. A $\frac{3}{4}$ -cup serving of pasta contains 40 g of carbohydrates. What percentage of the daily calorie requirement for a person on a 2200 Calorie diet (1 Cal = 1 kcal) does this serving represent?

2.40 An average human produces about 10 MJ of heat each day through metabolic activity. If a human body were an isolated system of mass 65 kg with the heat capacity of water, what temperature rise would the body experience? Human bodies are actually open systems, and the main mechanism of heat loss is through the evaporation of water. What mass of water should be evaporated each day to maintain constant temperature?

2.41 Glucose and fructose are simple sugars with the molecular formula $\text{C}_6\text{H}_{12}\text{O}_6$. Sucrose, or table sugar, is a complex sugar with molecular formula $\text{C}_{12}\text{H}_{22}\text{O}_{11}$ that consists of a glucose unit covalently bound to a fructose unit (a water molecule is given off as a result of the reaction between glucose and fructose to form sucrose). (a) Calculate the energy released as heat when a typical table sugar cube of mass 1.5 g is burned in air. (b) To what height could you climb on the energy a table sugar cube provides assuming 25 per cent of the energy is available for work? (c) The mass of a typical glucose tablet is 2.5 g. Calculate the energy released as heat when a glucose tablet is burned in air. (d) To what height could you climb on the energy a cube provides assuming 25 per cent of the energy is available for work?

2.42 In biological cells that have a plentiful supply of O_2 , glucose is oxidized completely to CO_2 and H_2O by a process called *aerobic oxidation*. Muscle cells may be deprived of O_2 during vigorous exercise and, in that case, one

molecule of glucose is converted to two molecules of lactic acid ($\text{CH}_3\text{CH}(\text{OH})\text{COOH}$) by a process called *anaerobic glycolysis* (see *Impact I7.2*). (a) When 0.3212 g of glucose was burned in a bomb calorimeter of calorimeter constant 641 J K^{-1} the temperature rose by 7.793 K. Calculate (i) the standard molar enthalpy of combustion, (ii) the standard internal energy of combustion, and (iii) the standard enthalpy of formation of glucose. (b) What is the biological advantage (in kilojoules per mole of energy released as heat) of complete aerobic oxidation compared with anaerobic glycolysis to lactic acid?

2.43 You have at your disposal a sample of pure polymer P and a sample of P that has just been synthesized in a large chemical reactor and that may contain impurities. Describe how you would use differential scanning calorimetry to determine the mole percentage composition of P in the allegedly impure sample.

2.44† Alkyl radicals are important intermediates in the combustion and atmospheric chemistry of hydrocarbons. Seakins *et al.* (P.W. Seakins, M.J. Pilling, J.T. Niiranen, D. Gutman, and L.N. Krasnoperov, *J. Phys. Chem.* **96**, 9847 (1992)) report $\Delta_f H^\circ$ for a variety of alkyl radicals in the gas phase, information that is applicable to studies of pyrolysis and oxidation reactions of hydrocarbons. This information can be combined with thermodynamic data on alkenes to determine the reaction enthalpy for possible fragmentation of a large alkyl radical into smaller radicals and alkenes. Use the following set of data to compute the standard reaction enthalpies for three possible fates of the *tert*-butyl radical, namely, (a) *tert*- $\text{C}_4\text{H}_9 \rightarrow \text{sec-C}_4\text{H}_9$, (b) *tert*- $\text{C}_4\text{H}_9 \rightarrow \text{C}_3\text{H}_6 + \text{CH}_3$, (c) *tert*- $\text{C}_4\text{H}_9 \rightarrow \text{C}_2\text{H}_4 + \text{C}_2\text{H}_5$.

Species:	C_2H_5	<i>sec</i> - C_4H_9	<i>tert</i> - C_4H_9
$\Delta_f H^\circ / (\text{kJ mol}^{-1})$	+121.0	+67.5	+51.3

2.45† In 1995, the Intergovernmental Panel on Climate Change (IPCC) considered a global average temperature rise of 1.0–3.5°C likely by the year 2100, with 2.0°C its best estimate. Predict the average rise in sea level due to thermal expansion of sea water based on temperature rises of 1.0°C, 2.0°C, and 3.5°C given that the volume of the Earth's oceans is $1.37 \times 10^9 \text{ km}^3$ and their surface area is $361 \times 10^6 \text{ km}^2$, and state the approximations that go into the estimates.

2.46† Concerns over the harmful effects of chlorofluorocarbons on stratospheric ozone have motivated a search for new refrigerants. One such alternative is 2,2-dichloro-1,1,1-trifluoroethane (refrigerant 123). Younglove and McLinden published a compendium of thermophysical properties of this substance (B.A. Younglove and M. McLinden, *J. Phys. Chem. Ref. Data* **23**, 7 (1994)), from which properties such as the Joule–Thomson coefficient μ can be computed. (a) Compute μ at 1.00 bar and 50°C given that $(\partial H / \partial p)_T = -3.29 \times 10^3 \text{ J MPa}^{-1} \text{ mol}^{-1}$ and $C_{p,m} = 110.0 \text{ J K}^{-1} \text{ mol}^{-1}$. (b) Compute the temperature change that would accompany adiabatic expansion of 2.0 mol of this refrigerant from 1.5 bar to 0.5 bar at 50°C.

2.47† Another alternative refrigerant (see preceding problem) is 1,1,1,2-tetrafluoroethane (refrigerant HFC-134a). Tillner-Roth and Baehr published a compendium of thermophysical properties of this substance (R. Tillner-Roth and H.D. Baehr, *J. Phys. Chem. Ref. Data* **23**, 657 (1994)), from which properties such as the Joule–Thomson coefficient μ can be computed. (a) Compute μ at 0.100 MPa and 300 K from the following data (all referring to 300 K):

p/MPa	0.080	0.100	0.12
Specific enthalpy/ (kJ kg^{-1})	426.48	426.12	425.76

(The specific constant-pressure heat capacity is $0.7649 \text{ kJ K}^{-1} \text{ kg}^{-1}$.)

(b) Compute μ at 1.00 MPa and 350 K from the following data (all referring to 350 K):

p/MPa	0.80	1.00	1.2
Specific enthalpy/ (kJ kg^{-1})	461.93	459.12	456.15

(The specific constant-pressure heat capacity is $1.0392 \text{ kJ K}^{-1} \text{ kg}^{-1}$.)

Problems

The purpose of this chapter is to explain the origin of the spontaneity of physical and chemical change. We examine two simple processes and show how to define, measure, and use a property, the entropy, to discuss spontaneous changes quantitatively. The chapter also introduces a major subsidiary thermodynamic property, the Gibbs energy, which lets us express the spontaneity of a process in terms of the properties of a system. The Gibbs energy also enables us to predict the maximum non-expansion work that a process can do. As we began to see in Chapter 2, one application of thermodynamics is to find relations between properties that might not be thought to be related. Several relations of this kind can be established by making use of the fact that the Gibbs energy is a state function. We also see how to derive expressions for the variation of the Gibbs energy with temperature and pressure and how to formulate expressions that are valid for real gases. These expressions will prove useful later when we discuss the effect of temperature and pressure on equilibrium constants.

Some things happen naturally; some things don't. A gas expands to fill the available volume, a hot body cools to the temperature of its surroundings, and a chemical reaction runs in one direction rather than another. Some aspect of the world determines the **spontaneous** direction of change, the direction of change that does not require work to be done to bring it about. A gas can be confined to a smaller volume, an object can be cooled by using a refrigerator, and some reactions can be driven in reverse (as in the electrolysis of water). However, none of these processes is spontaneous; each one must be brought about by doing work. An important point, though, is that throughout this text 'spontaneous' must be interpreted as a natural *tendency* that may or may not be realized in practice. Thermodynamics is silent on the rate at which a spontaneous change in fact occurs, and some spontaneous processes (such as the conversion of diamond to graphite) may be so slow that the tendency is never realized in practice whereas others (such as the expansion of a gas into a vacuum) are almost instantaneous.

The recognition of two classes of process, spontaneous and non-spontaneous, is summarized by the **Second Law of thermodynamics**. This law may be expressed in a variety of equivalent ways. One statement was formulated by Kelvin:

No process is possible in which the sole result is the absorption of heat from a reservoir and its complete conversion into work.

For example, it has proved impossible to construct an engine like that shown in Fig. 3.1, in which heat is drawn from a hot reservoir and completely converted into work. All real heat engines have both a hot source and a cold sink; some energy is always discarded into the cold sink as heat and not converted into work. The Kelvin

statement is a generalization of another everyday observation, that a ball at rest on a surface has never been observed to leap spontaneously upwards. An upward leap of the ball would be equivalent to the conversion of heat from the surface into work.

The direction of spontaneous change

What determines the direction of spontaneous change? It is not the total energy of the isolated system. The First Law of thermodynamics states that energy is conserved in any process, and we cannot disregard that law now and say that everything tends towards a state of lower energy: the total energy of an isolated system is constant.

Is it perhaps the energy of the *system* that tends towards a minimum? Two arguments show that this cannot be so. First, a perfect gas expands spontaneously into a vacuum, yet its internal energy remains constant as it does so. Secondly, if the energy of a system does happen to decrease during a spontaneous change, the energy of its surroundings must increase by the same amount (by the First Law). The increase in energy of the surroundings is just as spontaneous a process as the decrease in energy of the system.

When a change occurs, the total energy of an isolated system remains constant but it is parcelled out in different ways. Can it be, therefore, that the direction of change is related to the *distribution* of energy? We shall see that this idea is the key, and that spontaneous changes are always accompanied by a dispersal of energy.

3.1 The dispersal of energy

We can begin to understand the role of the distribution of energy by thinking about a ball (the system) bouncing on a floor (the surroundings). The ball does not rise as high after each bounce because there are inelastic losses in the materials of the ball and floor. The kinetic energy of the ball's overall motion is spread out into the energy of thermal motion of its particles and those of the floor that it hits. The direction of spontaneous change is towards a state in which the ball is at rest with all its energy dispersed into random thermal motion of molecules in the air and of the atoms of the virtually infinite floor (Fig. 3.2).

A ball resting on a warm floor has never been observed to start bouncing. For bouncing to begin, something rather special would need to happen. In the first place, some of the thermal motion of the atoms in the floor would have to accumulate in a single, small object, the ball. This accumulation requires a spontaneous localization of energy from the myriad vibrations of the atoms of the floor into the much smaller number of atoms that constitute the ball (Fig. 3.3). Furthermore, whereas the thermal motion is random, for the ball to move upwards its atoms must all move in the same direction. The localization of random, disorderly motion as concerted, ordered motion is so unlikely that we can dismiss it as virtually impossible.¹

We appear to have found the signpost of spontaneous change: *we look for the direction of change that leads to dispersal of the total energy of the isolated system.* This principle accounts for the direction of change of the bouncing ball, because its energy is spread out as thermal motion of the atoms of the floor. The reverse process is not spontaneous because it is highly improbable that energy will become localized, leading to uniform motion of the ball's atoms. A gas does not contract spontaneously because

¹ Concerted motion, but on a much smaller scale, is observed as *Brownian motion*, the jittering motion of small particles suspended in water.

Fig. 3.1 The Kelvin statement of the Second Law denies the possibility of the process illustrated here, in which heat is changed completely into work, there being no other change. The process is not in conflict with the First Law because energy is conserved.

Fig. 3.2 The direction of spontaneous change for a ball bouncing on a floor. On each bounce some of its energy is degraded into the thermal motion of the atoms of the floor, and that energy disperses. The reverse has never been observed to take place on a macroscopic scale.

Fig. 3.3 The molecular interpretation of the irreversibility expressed by the Second Law. (a) A ball resting on a warm surface; the atoms are undergoing thermal motion (vibration, in this instance), as indicated by the arrows. (b) For the ball to fly upwards, some of the random vibrational motion would have to change into coordinated, directed motion. Such a conversion is highly improbable.

to do so the random motion of its molecules, which spreads out the distribution of kinetic energy throughout the container, would have to take them all into the same region of the container, thereby localizing the energy. The opposite change, spontaneous expansion, is a natural consequence of energy becoming more dispersed as the gas molecules occupy a larger volume. An object does not spontaneously become warmer than its surroundings because it is highly improbable that the jostling of randomly vibrating atoms in the surroundings will lead to the localization of thermal motion in the object. The opposite change, the spreading of the object's energy into the surroundings as thermal motion, is natural.

It may seem very puzzling that the spreading out of energy and matter, the collapse into disorder, can lead to the formation of such ordered structures as crystals or proteins. Nevertheless, in due course, we shall see that dispersal of energy and matter accounts for change in all its forms.

3.2 Entropy

The First Law of thermodynamics led to the introduction of the internal energy, U . The internal energy is a state function that lets us assess whether a change is permissible: only those changes may occur for which the internal energy of an isolated system remains constant. The law that is used to identify the signpost of spontaneous change, the Second Law of thermodynamics, may also be expressed in terms of another state function, the **entropy**, S . We shall see that the entropy (which we shall define shortly, but is a measure of the energy dispersed in a process) lets us assess whether one state is accessible from another by a spontaneous change. The First Law uses the internal energy to identify *permissible* changes; the Second Law uses the entropy to identify the *spontaneous changes* among those permissible changes.

The Second Law of thermodynamics can be expressed in terms of the entropy:

The entropy of an isolated system increases in the course of a spontaneous change:

$$\Delta S_{\text{tot}} > 0$$

where S_{tot} is the total entropy of the system and its surroundings. Thermodynamically irreversible processes (like cooling to the temperature of the surroundings and the free expansion of gases) are spontaneous processes, and hence must be accompanied by an increase in total entropy.

(a) The thermodynamic definition of entropy

The thermodynamic definition of entropy concentrates on the change in entropy, dS , that occurs as a result of a physical or chemical change (in general, as a result of a 'process'). The definition is motivated by the idea that a change in the extent to which energy is dispersed depends on how much energy is transferred as heat. As we have remarked, heat stimulates random motion in the surroundings. On the other hand, work stimulates uniform motion of atoms in the surroundings and so does not change their entropy.

The thermodynamic definition of entropy is based on the expression

$$dS = \frac{dq_{\text{rev}}}{T} \quad [3.1]$$

For a measurable change between two states i and f this expression integrates to

$$\Delta S = \int_i^f \frac{dq_{\text{rev}}}{T} \quad (3.2)$$

That is, to calculate the difference in entropy between any two states of a system, we find a *reversible* path between them, and integrate the energy supplied as heat at each stage of the path divided by the temperature at which heating occurs.

Example 3.1 Calculating the entropy change for the isothermal expansion of a perfect gas

Calculate the entropy change of a sample of perfect gas when it expands isothermally from a volume V_i to a volume V_f .

Method The definition of entropy instructs us to find the energy supplied as heat for a reversible path between the stated initial and final states regardless of the actual manner in which the process takes place. A simplification is that the expansion is isothermal, so the temperature is a constant and may be taken outside the integral in eqn 3.2. The energy absorbed as heat during a reversible isothermal expansion of a perfect gas can be calculated from $\Delta U = q + w$ and $\Delta U = 0$, which implies that $q = -w$ in general and therefore that $q_{\text{rev}} = -w_{\text{rev}}$ for a reversible change. The work of reversible isothermal expansion was calculated in Section 2.3.

Answer Because the temperature is constant, eqn 3.2 becomes

$$\Delta S = \frac{1}{T} \int_i^f dq_{\text{rev}} = \frac{q_{\text{rev}}}{T}$$

From eqn 2.11, we know that

$$q_{\text{rev}} = -w_{\text{rev}} = nRT \ln \frac{V_f}{V_i}$$

It follows that

$$\Delta S = nR \ln \frac{V_f}{V_i}$$

As an illustration of this formula, when the volume occupied by 1.00 mol of any perfect gas molecules is doubled at any constant temperature, $V_f/V_i = 2$ and

$$\Delta S = (1.00 \text{ mol}) \times (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times \ln 2 = +5.76 \text{ J K}^{-1}$$

A note on good practice According to eqn 3.2, when the energy transferred as heat is expressed in joules and the temperature is in kelvins, the units of entropy are joules per kelvin (J K^{-1}). Entropy is an extensive property. Molar entropy, the entropy divided by the amount of substance, is expressed in joules per kelvin per mole ($\text{J K}^{-1} \text{ mol}^{-1}$).² The molar entropy is an intensive property.

Self-test 3.1 Calculate the change in entropy when the pressure of a perfect gas is changed isothermally from p_i to p_f . $[\Delta S = nR \ln(p_i/p_f)]$

We can use the definition in eqn 3.1 to formulate an expression for the change in entropy of the surroundings, ΔS_{sur} . Consider an infinitesimal transfer of heat dq_{sur} to the surroundings. The surroundings consist of a reservoir of constant volume, so the energy supplied to them by heating can be identified with the change in their

² The units of entropy are the same as those of the gas constant, R , and molar heat capacities.

internal energy, dU_{sur} .³ The internal energy is a state function, and dU_{sur} is an exact differential. As we have seen, these properties imply that dU_{sur} is independent of how the change is brought about and in particular is independent of whether the process is reversible or irreversible. The same remarks therefore apply to dq_{sur} , to which dU_{sur} is equal. Therefore, we can adapt the definition in eqn 3.1 to write

$$dS_{\text{sur}} = \frac{dq_{\text{sur,rev}}}{T_{\text{sur}}} = \frac{dq_{\text{sur}}}{T_{\text{sur}}} \quad (3.3a)$$

Furthermore, because the temperature of the surroundings is constant whatever the change, for a measurable change

$$\Delta S_{\text{sur}} = \frac{q_{\text{sur}}}{T_{\text{sur}}} \quad (3.3b)$$

That is, regardless of how the change is brought about in the system, reversibly or irreversibly, we can calculate the change of entropy of the surroundings by dividing the heat transferred by the temperature at which the transfer takes place.

Equation 3.3 makes it very simple to calculate the changes in entropy of the surroundings that accompany any process. For instance, for any adiabatic change, $q_{\text{sur}} = 0$, so

$$\text{For an adiabatic change:} \quad \Delta S_{\text{sur}} = 0 \quad (3.4)$$

This expression is true however the change takes place, reversibly or irreversibly, provided no local hot spots are formed in the surroundings. That is, it is true so long as the surroundings remain in internal equilibrium. If hot spots do form, then the localized energy may subsequently disperse spontaneously and hence generate more entropy.

Illustration 3.1 Calculating the entropy change in the surroundings

To calculate the entropy change in the surroundings when 1.00 mol $\text{H}_2\text{O}(\text{l})$ is formed from its elements under standard conditions at 298 K, we use $\Delta H^\circ = -286 \text{ kJ}$ from Table 2.7. The energy released as heat is supplied to the surroundings, now regarded as being at constant pressure, so $q_{\text{sur}} = +286 \text{ kJ}$. Therefore,

$$\Delta S_{\text{sur}} = \frac{2.86 \times 10^5 \text{ J}}{298 \text{ K}} = +960 \text{ J K}^{-1}$$

This strongly exothermic reaction results in an increase in the entropy of the surroundings as energy is released as heat into them.

Self-test 3.2 Calculate the entropy change in the surroundings when 1.00 mol $\text{N}_2\text{O}_4(\text{g})$ is formed from 2.00 mol $\text{NO}_2(\text{g})$ under standard conditions at 298 K.
[−192 J K^{−1}]

Molecular interpretation 3.1 The statistical view of entropy

The entry point into the molecular interpretation of the Second Law of thermodynamics is the realization that an atom or molecule can possess only certain energies, called its ‘energy levels’. The continuous thermal agitation that molecules

³ Alternatively, the surroundings can be regarded as being at constant pressure, in which case we could equate dq_{sur} to dH_{sur} .

experience in a sample at $T > 0$ ensures that they are distributed over the available energy levels. One particular molecule may be in one low energy state at one instant, and then be excited into a high energy state a moment later. Although we cannot keep track of the energy state of a single molecule, we can speak of the **population** of the state, the average number of molecules in each state; these populations are constant in time provided the temperature remains the same.

Only the lowest energy state is occupied at $T = 0$. Raising the temperature excites some molecules into higher energy states, and more and more states become accessible as the temperature is raised further (Fig. 3.4). Nevertheless, whatever the temperature, there is always a higher population in a state of low energy than one of high energy. The only exception occurs when the temperature is infinite: then all states of the system are equally populated. These remarks were summarized quantitatively by the Austrian physicist Ludwig Boltzmann in the *Boltzmann distribution*:

$$N_i = \frac{N e^{-E_i/kT}}{\sum_i e^{-E_i/kT}}$$

where $k = 1.381 \times 10^{-23} \text{ J K}^{-1}$ and N_i is the number of molecules in a sample of N molecules that will be found in a state with an energy E_i when it is part of a system in thermal equilibrium at a temperature T . Care must be taken with the exact interpretation, though, because more than one state may correspond to the same energy: that is, an energy level may consist of several states.

Boltzmann also made the link between the distribution of molecules over energy levels and the entropy. He proposed that the entropy of a system is given by

$$S = k \ln W \quad (3.5)$$

where W is the number of *microstates*, the ways in which the molecules of a system can be arranged while keeping the total energy constant. Each microstate lasts only for an instant and has a distinct distribution of molecules over the available energy levels. When we measure the properties of a system, we are measuring an average taken over the many microstates the system can occupy under the conditions of the experiment. The concept of the number of microstates makes quantitative the ill-defined qualitative concepts of ‘disorder’ and ‘the dispersal of matter and energy’ that are used widely to introduce the concept of entropy: a more ‘disorderly’ distribution of energy and matter corresponds to a greater number of microstates associated with the same total energy.

Equation 3.5 is known as the **Boltzmann formula** and the entropy calculated from it is sometimes called the **statistical entropy**. We see that if $W = 1$, which corresponds to one microstate (only one way of achieving a given energy, all molecules in exactly the same state), then $S = 0$ because $\ln 1 = 0$. However, if the system can exist in more than one microstate, then $W > 1$ and $S > 0$. But, if more molecules can participate in the distribution of energy, then there are more microstates for a given total energy and the entropy is greater than when the energy is confined so a smaller number of molecules. Therefore, the statistical view of entropy summarized by the Boltzmann formula is consistent with our previous statement that the entropy is related to the dispersal of energy.

The molecular interpretation of entropy advanced by Boltzmann also suggests the thermodynamic definition given by eqn 3.1. To appreciate this point, consider that molecules in a system at high temperature can occupy a large number of the available energy levels, so a small additional transfer of energy as heat will lead to a relatively small change in the number of accessible energy levels. Consequently, the

Fig. 3.4 The Boltzmann distribution predicts that the population of a state decreases exponentially with the energy of the state. (a) At low temperatures, only the lowest states are significantly populated; (b) at high temperatures, there is significant population in high-energy states as well as in low-energy states. At infinite temperature (not shown), all states are equally populated.

Fig. 3.5 In a thermodynamic cycle, the overall change in a state function (from the initial state to the final state and then back to the initial state again) is zero.

number of microstates does not increase appreciably and neither does the entropy of the system. In contrast, the molecules in a system at low temperature have access to far fewer energy levels (at $T = 0$, only the lowest level is accessible), and the transfer of the same quantity of energy by heating will increase the number of accessible energy levels and the number of microstates rather significantly. Hence, the change in entropy upon heating will be greater when the energy is transferred to a cold body than when it is transferred to a hot body. This argument suggests that the change in entropy should be inversely proportional to the temperature at which the transfer takes place, as in eqn 3.1.

(b) The entropy as a state function

Entropy is a state function. To prove this assertion, we need to show that the integral of dS is independent of path. To do so, it is sufficient to prove that the integral of eqn 3.1 around an arbitrary cycle is zero, for that guarantees that the entropy is the same at the initial and final states of the system regardless of the path taken between them (Fig. 3.5). That is, we need to show that

$$\oint \frac{dq_{\text{rev}}}{T} = 0 \quad (3.6)$$

where the symbol $\oint$ denotes integration around a closed path. There are three steps in the argument:

1. First, to show that eqn 3.6 is true for a special cycle (a 'Carnot cycle') involving a perfect gas.
2. Then to show that the result is true whatever the working substance.
3. Finally, to show that the result is true for any cycle.

A **Carnot cycle**, which is named after the French engineer Sadi Carnot, consists of four reversible stages (Fig. 3.6):

1. Reversible isothermal expansion from A to B at T_h ; the entropy change is q_h/T_h , where q_h is the energy supplied to the system as heat from the hot source.
2. Reversible adiabatic expansion from B to C. No energy leaves the system as heat, so the change in entropy is zero. In the course of this expansion, the temperature falls from T_h to T_c , the temperature of the cold sink.
3. Reversible isothermal compression from C to D at T_c . Energy is released as heat to the cold sink; the change in entropy of the system is q_c/T_c ; in this expression q_c is negative.
4. Reversible adiabatic compression from D to A. No energy enters the system as heat, so the change in entropy is zero. The temperature rises from T_c to T_h .

The total change in entropy around the cycle is

$$\oint dS = \frac{q_h}{T_h} + \frac{q_c}{T_c}$$

However, we show in *Justification 3.1* that, for a perfect gas:

$$\frac{q_h}{q_c} = -\frac{T_h}{T_c} \quad (3.7)_{\text{rev}}$$

Substitution of this relation into the preceding equation gives zero on the right, which is what we wanted to prove.

Fig. 3.6 The basic structure of a Carnot cycle. In Step 1, there is isothermal reversible expansion at the temperature T_h . Step 2 is a reversible adiabatic expansion in which the temperature falls from T_h to T_c . In Step 3 there is an isothermal reversible compression at T_c , and that isothermal step is followed by an adiabatic reversible compression, which restores the system to its initial state.

Justification 3.1 Heating accompanying reversible adiabatic expansion

This *Justification* is based on the fact that the two temperatures in eqn 3.7 lie on the same adiabat in Fig. 3.6. As explained in Example 3.1, for a perfect gas:

$$q_h = nRT_h \ln \frac{V_B}{V_A} \quad q_c = nRT_c \ln \frac{V_D}{V_C}$$

From the relations between temperature and volume for reversible adiabatic processes (eqn 2.28):

$$V_A T_h^c = V_D T_c^c \quad V_C T_c^c = V_B T_h^c$$

Multiplication of the first of these expressions by the second gives

$$V_A V_C T_h^c T_c^c = V_D V_B T_h^c T_c^c$$

which simplifies to

$$\frac{V_A}{V_B} = \frac{V_D}{V_C}$$

Consequently,

$$q_c = nRT_c \ln \frac{V_D}{V_C} = nRT_c \ln \frac{V_A}{V_B} = -nRT_c \ln \frac{V_B}{V_A}$$

and therefore

$$\frac{q_h}{q_c} = \frac{nRT_h \ln(V_B/V_A)}{-nRT_c \ln(V_B/V_A)} = -\frac{T_h}{T_c}$$

as in eqn 3.7.

In the second step we need to show that eqn 3.7 applies to any material, not just a perfect gas (which is why, in anticipation, we have not labelled it with a $^\circ$). We begin this step of the argument by introducing the **efficiency**, ε (epsilon), of a heat engine:

$$\varepsilon = \frac{\text{work performed}}{\text{heat absorbed}} = \frac{|w|}{q_h} \quad [3.8]$$

The definition implies that, the greater the work output for a given supply of heat from the hot reservoir, the greater is the efficiency of the engine. We can express the definition in terms of the heat transactions alone, because (as shown in Fig. 3.7) the energy supplied as work by the engine is the difference between the energy supplied as heat by the hot reservoir and returned to the cold reservoir:

$$\varepsilon = \frac{q_h + q_c}{q_h} = 1 + \frac{q_c}{q_h} \quad (3.9)$$

(Remember that $q_c < 0$.) It then follows from eqn 3.7 that

$$\varepsilon_{\text{rev}} = 1 - \frac{T_c}{T_h} \quad (3.10)_{\text{rev}}$$

Now we are ready to generalize this conclusion. The Second Law of thermodynamics implies that *all reversible engines have the same efficiency regardless of their construction*. To see the truth of this statement, suppose two reversible engines are coupled together and run between the same two reservoirs (Fig. 3.8). The working substances and details of construction of the two engines are entirely arbitrary. Initially, suppose that

Fig. 3.7 Suppose an energy q_h (for example, 20 kJ) is supplied to the engine and q_c is lost from the engine (for example, $q_c = -15$ kJ) and discarded into the cold reservoir. The work done by the engine is equal to $q_h + q_c$ (for example, 20 kJ + (-15 kJ) = 5 kJ). The efficiency is the work done divided by the energy supplied as heat from the hot source.

Fig. 3.8 (a) The demonstration of the equivalence of the efficiencies of all reversible engines working between the same thermal reservoirs is based on the flow of energy represented in this diagram. (b) The net effect of the processes is the conversion of heat into work without there being a need for a cold sink: this is contrary to the Kelvin statement of the Second Law.

Fig. 3.9 A general cycle can be divided into small Carnot cycles. The match is exact in the limit of infinitesimally small cycles. Paths cancel in the interior of the collection, and only the perimeter, an increasingly good approximation to the true cycle as the number of cycles increases, survives. Because the entropy change around every individual cycle is zero, the integral of the entropy around the perimeter is zero too.

engine A is more efficient than engine B and that we choose a setting of the controls that causes engine B to acquire energy as heat q_c from the cold reservoir and to release a certain quantity of energy as heat into the hot reservoir. However, because engine A is more efficient than engine B, not all the work that A produces is needed for this process, and the difference can be used to do work. The net result is that the cold reservoir is unchanged, work has been done, and the hot reservoir has lost a certain amount of energy. This outcome is contrary to the Kelvin statement of the Second Law, because some heat has been converted directly into work. In molecular terms, the random thermal motion of the hot reservoir has been converted into ordered motion characteristic of work. Because the conclusion is contrary to experience, the initial assumption that engines A and B can have different efficiencies must be false. It follows that the relation between the heat transfers and the temperatures must also be independent of the working material, and therefore that eqn 3.7 is always true for any substance involved in a Carnot cycle.

For the final step in the argument, we note that any reversible cycle can be approximated as a collection of Carnot cycles and the cyclic integral around an arbitrary path is the sum of the integrals around each of the Carnot cycles (Fig. 3.9). This approximation becomes exact as the individual cycles are allowed to become infinitesimal. The entropy change around each individual cycle is zero (as demonstrated above), so the sum of entropy changes for all the cycles is zero. However, in the sum, the entropy change along any individual path is cancelled by the entropy change along the path it shares with the neighbouring cycle. Therefore, all the entropy changes cancel except for those along the perimeter of the overall cycle. That is,

$$\sum_{\text{all}} \frac{q_{\text{rev}}}{T} = \sum_{\text{perimeter}} \frac{q_{\text{rev}}}{T} = 0$$

In the limit of infinitesimal cycles, the non-cancelling edges of the Carnot cycles match the overall cycle exactly, and the sum becomes an integral. Equation 3.6 then follows immediately. This result implies that dS is an exact differential and therefore that S is a state function.

IMPACT ON ENGINEERING

13.1 Refrigeration

The discussion of the text is the basis of the thermodynamic assessment of the power needed to cool objects in refrigerators. First, we consider the work required to cool an object, and refer to Fig. 3.10.

When an energy $|q_c|$ is removed from a cool source at a temperature T_c and then deposited in a warmer sink at a temperature T_h , as in a typical refrigerator, the change in entropy is

$$\Delta S = -\frac{|q_c|}{T_c} + \frac{|q_c|}{T_h} < 0$$

The process is not spontaneous because not enough entropy is generated in the warm sink to overcome the entropy loss from the hot source. To generate more entropy, energy must be added to the stream that enters the warm sink. Our task is to find the minimum energy that needs to be supplied. The outcome is expressed as the *coefficient of performance*, c :

$$c = \frac{\text{energy transferred as heat}}{\text{energy transferred as work}} = \frac{|q_c|}{|w|}$$

The less the work that is required to achieve a given transfer, the greater the coefficient of performance and the more efficient the refrigerator.

Because $|q_c|$ is removed from the cold source, and the work $|w|$ is added to the energy stream, the energy deposited as heat in the hot sink is $|q_h| = |q_c| + |w|$. Therefore,

$$\frac{1}{c} = \frac{|q_h| - |q_c|}{|q_c|} = -\frac{|q_h|}{|q_c|} - 1$$

We can now use eqn 3.7 to express this result in terms of the temperatures alone, which is possible if the transfer is performed reversibly. This substitution leads to

$$c = \frac{T_c}{T_h - T_c}$$

for the thermodynamically optimum coefficient of performance. For a refrigerator withdrawing heat from ice-cold water ($T_c = 273 \text{ K}$) in a typical environment ($T_h = 293 \text{ K}$), $c = 14$, so, to remove 10 kJ (enough to freeze 30 g of water), requires transfer of at least 0.71 kJ as work. Practical refrigerators, of course, have a lower coefficient of performance.

The work to *maintain* a low temperature is also relevant to the design of refrigerators. No thermal insulation is perfect, so there is always a flow of energy as heat into the sample at a rate proportional to the temperature difference. If the rate at which energy leaks in is written $A(T_h - T_c)$, where A is a constant that depends on the size of the sample and the details of the insulation, then the minimum power, P , required to maintain the original temperature difference by pumping out that energy by heating the surroundings is

$$P = \frac{1}{c} \times A(T_h - T_c) = A \times \frac{(T_h - T_c)^2}{T_c}$$

Fig. 3.10 (a) The flow of energy as heat from a cold source to a hot sink is not spontaneous. As shown here, the entropy increase of the hot sink is smaller than the entropy increase of the cold source, so there is a net decrease in entropy. (b) The process becomes feasible if work is provided to add to the energy stream. Then the increase in entropy of the hot sink can be made to cancel the entropy decrease of the hot source.

Comment 3.1

The triple point of a substance represents the set of conditions at which the three phases coexist in equilibrium. For water, the triple point occurs at 273.16 K and 611 Pa. See Section 4.2 for details.

We see that the power increases as the square of the temperature difference we are trying to maintain. For this reason, air-conditioners are much more expensive to run on hot days than on mild days.

(c) The thermodynamic temperature

Suppose we have an engine that is working reversibly between a hot source at a temperature T_h and a cold sink at a temperature T ; then we know from eqn 3.10 that

$$T = (1 - \varepsilon)T_h \quad (3.11)$$

This expression enabled Kelvin to define the **thermodynamic temperature scale** in terms of the efficiency of a heat engine. The zero of the scale occurs for a Carnot efficiency of 1. The size of the unit is entirely arbitrary, but on the Kelvin scale is defined by setting the temperature of the triple point of water as 273.16 K exactly. Then, if the heat engine has a hot source at the triple point of water, the temperature of the cold sink (the object we want to measure) is found by measuring the efficiency of the engine. This result is independent of the working substance.

(d) The Clausius inequality

We now show that the definition of entropy is consistent with the Second Law. To begin, we recall that more energy flows as work under reversible conditions than under irreversible conditions. That is, $-dw_{\text{rev}} \geq -dw$, or $dw - dw_{\text{rev}} \geq 0$. Because the internal energy is a state function, its change is the same for irreversible and reversible paths between the same two states, so we can also write:

$$dU = dq + dw = dq_{\text{rev}} + dw_{\text{rev}}$$

It follows that $dq_{\text{rev}} - dq = dw - dw_{\text{rev}} \geq 0$, or $dq_{\text{rev}} \geq dq$, and therefore that $dq_{\text{rev}}/T \geq dq/T$. Now we use the thermodynamic definition of the entropy (eqn 3.1; $dS = dq_{\text{rev}}/T$) to write

$$dS \geq \frac{dq}{T} \quad (3.12)$$

This expression is the **Clausius inequality**. It will prove to be of great importance for the discussion of the spontaneity of chemical reactions, as we shall see in Section 3.5.

Fig. 3.11 When energy leaves a hot reservoir as heat, the entropy of the reservoir decreases. When the same quantity of energy enters a cooler reservoir, the entropy increases by a larger amount. Hence, overall there is an increase in entropy and the process is spontaneous. Relative changes in entropy are indicated by the sizes of the arrows.

Illustration 3.2 *Spontaneous cooling*

Consider the transfer of energy as heat from one system—the hot source—at a temperature T_h to another system—the cold sink—at a temperature T_c (Fig. 3.11). When $|dq|$ leaves the hot source (so $dq_h < 0$), the Clausius inequality implies that $dS \geq dq_h/T_h$. When $|dq|$ enters the cold sink the Clausius inequality implies that $dS \geq dq_c/T_c$ (with $dq_c > 0$). Overall, therefore,

$$dS \geq \frac{dq_h}{T_h} + \frac{dq_c}{T_c}$$

However, $dq_h = -dq_c$, so

$$dS \geq -\frac{dq_c}{T_h} + \frac{dq_c}{T_c} = dq_c \left(\frac{1}{T_c} - \frac{1}{T_h} \right)$$

which is positive (because $dq_c > 0$ and $T_h \geq T_c$). Hence, cooling (the transfer of heat from hot to cold) is spontaneous, as we know from experience.

We now suppose that the system is isolated from its surroundings, so that $dq = 0$. The Clausius inequality implies that

$$dS \geq 0$$

and we conclude that *in an isolated system the entropy cannot decrease when a spontaneous change occurs*. This statement captures the content of the Second Law.

3.3 Entropy changes accompanying specific processes

We now see how to calculate the entropy changes that accompany a variety of basic processes.

(a) Expansion

We established in Example 3.1 that the change in entropy of a perfect gas that expands isothermally from V_i to V_f is

$$\Delta S = nR \ln \frac{V_f}{V_i} \quad (3.13)^\circ$$

Because S is a state function, the value of ΔS of the system is independent of the path between the initial and final states, so this expression applies whether the change of state occurs reversibly or irreversibly. The logarithmic dependence of entropy on volume is illustrated in Fig. 3.12.

The *total* change in entropy, however, does depend on how the expansion takes place. For any process $dq_{\text{sur}} = -dq$, and for a reversible change we use the expression in Example 3.1; consequently, from eqn 3.3b

$$\Delta S_{\text{sur}} = \frac{q_{\text{sur}}}{T} = -\frac{q_{\text{rev}}}{T} = -nR \ln \frac{V_f}{V_i} \quad (3.14)_{\text{rev}}^\circ$$

This change is the negative of the change in the system, so we can conclude that $\Delta S_{\text{tot}} = 0$, which is what we should expect for a reversible process. If the isothermal expansion occurs freely ($w = 0$) and irreversibly, then $q = 0$ (because $\Delta U = 0$). Consequently, $\Delta S_{\text{sur}} = 0$, and the total entropy change is given by eqn 3.13 itself:

$$\Delta S_{\text{tot}} = nR \ln \frac{V_f}{V_i} \quad (3.15)^\circ$$

In this case, $\Delta S_{\text{tot}} > 0$, as we expect for an irreversible process.

(b) Phase transition

The degree of dispersal of matter and energy changes when a substance freezes or boils as a result of changes in the order with which the molecules pack together and the extent to which the energy is localized or dispersed. Therefore, we should expect the transition to be accompanied by a change in entropy. For example, when a substance vaporizes, a compact condensed phase changes into a widely dispersed gas and we can expect the entropy of the substance to increase considerably. The entropy of a solid also increases when it melts to a liquid and when that liquid turns into a gas.

Consider a system and its surroundings at the **normal transition temperature**, T_{trs} , the temperature at which two phases are in equilibrium at 1 atm. This temperature is 0°C (273 K) for ice in equilibrium with liquid water at 1 atm, and 100°C (373 K) for water in equilibrium with its vapour at 1 atm. At the transition temperature, any transfer of energy as heat between the system and its surroundings is reversible

Fig. 3.12 The logarithmic increase in entropy of a perfect gas as it expands isothermally.

Exploration Evaluate the change in entropy that accompanies the expansion of 1.00 mol $\text{CO}_2(\text{g})$ from 0.001 m^3 to 0.010 m^3 at 298 K, treated as a van der Waals gas.

Synoptic Table 3.1* Standard entropies (and temperatures) of phase transitions, $\Delta_{\text{trs}}S^\ominus/(\text{J K}^{-1} \text{mol}^{-1})$

	Fusion (at T_f)	Vaporization (at T_b)
Argon, Ar	14.17 (at 83.8 K)	74.53 (at 87.3 K)
Benzene, C_6H_6	38.00 (at 279 K)	87.19 (at 353 K)
Water, H_2O	22.00 (at 273.15 K)	109.0 (at 373.15 K)
Helium, He	4.8 (at 8 K and 30 bar)	19.9 (at 4.22K)

* More values are given in the *Data section*.**Synoptic Table 3.2*** The standard entropies of vaporization of liquids

	$\Delta_{\text{vap}}H^\ominus/(\text{kJ mol}^{-1})$	$\theta_b/^\circ\text{C}$	$\Delta_{\text{vap}}S^\ominus/(\text{J K}^{-1} \text{mol}^{-1})$
Benzene	30.8	80.1	87.2
Carbon tetrachloride	30	76.7	85.8
Cyclohexane	30.1	80.7	85.1
Hydrogen sulfide	18.7	−60.4	87.9
Methane	8.18	−161.5	73.2
Water	40.7	100.0	109.1

* More values are given in the *Data section*.

because the two phases in the system are in equilibrium. Because at constant pressure $q = \Delta_{\text{trs}}H$, the change in molar entropy of the system is⁴

$$\Delta_{\text{trs}}S = \frac{\Delta_{\text{trs}}H}{T_{\text{trs}}} \quad (3.16)$$

If the phase transition is exothermic ($\Delta_{\text{trs}}H < 0$, as in freezing or condensing), then the entropy change is negative. This decrease in entropy is consistent with localization of matter and energy that accompanies the formation of a solid from a liquid or a liquid from a gas. If the transition is endothermic ($\Delta_{\text{trs}}H > 0$, as in melting and vaporization), then the entropy change is positive, which is consistent with dispersal of energy and matter in the system.

Table 3.1 lists some experimental entropies of transition. Table 3.2 lists in more detail the standard entropies of vaporization of several liquids at their boiling points. An interesting feature of the data is that a wide range of liquids give approximately the same standard entropy of vaporization (about $85 \text{ J K}^{-1} \text{mol}^{-1}$): this empirical observation is called **Trouton's rule**.

Molecular interpretation 3.2 *Trouton's rule*

The explanation of Trouton's rule is that a comparable change in volume occurs (with an accompanying change in the number of accessible microstates) when any liquid evaporates and becomes a gas. Hence, all liquids can be expected to have similar standard entropies of vaporization.

⁴ Recall from Section 2.7 that $\Delta_{\text{trs}}H$ is an enthalpy change per mole of substance; so $\Delta_{\text{trs}}S$ is also a molar quantity.

Liquids that show significant deviations from Trouton's rule do so on account of strong molecular interactions that restrict molecular motion. As a result, there is a greater dispersal of energy and matter when the liquid turns into a vapour than would occur for a liquid in which molecular motion is less restricted. An example is water, where the large entropy of vaporization reflects the presence of structure arising from hydrogen-bonding in the liquid. Hydrogen bonds tend to organize the molecules in the liquid so that they are less random than, for example, the molecules in liquid hydrogen sulfide (in which there is no hydrogen bonding).

Methane has an unusually low entropy of vaporization. A part of the reason is that the entropy of the gas itself is slightly low ($186 \text{ J K}^{-1} \text{ mol}^{-1}$ at 298 K); the entropy of N_2 under the same conditions is $192 \text{ J K}^{-1} \text{ mol}^{-1}$. As we shall see in Chapter 13, small molecules are difficult to excite into rotation; as a result, only a few rotational states are accessible at room temperature and, consequently, the number of rotational energy levels among which energy can be dispersed is low.

Illustration 3.3 Using Trouton's rule

There is no hydrogen bonding in liquid bromine and Br_2 is a heavy molecule that is unlikely to display unusual behaviour in the gas phase, so it is probably safe to use Trouton's rule. To predict the standard molar enthalpy of vaporization of bromine given that it boils at 59.2°C , we use the rule in the form

$$\Delta_{\text{vap}}H^\ominus = T_b \times (85 \text{ J K}^{-1} \text{ mol}^{-1})$$

Substitution of the data then gives

$$\Delta_{\text{vap}}H^\ominus = (332.4 \text{ K}) \times (85 \text{ J K}^{-1} \text{ mol}^{-1}) = +2.8 \times 10^3 \text{ J mol}^{-1} = +28 \text{ kJ mol}^{-1}$$

The experimental value is $+29.45 \text{ kJ mol}^{-1}$.

Self-test 3.3 Predict the enthalpy of vaporization of ethane from its boiling point, -88.6°C .
[16 kJ mol^{-1}]

(c) Heating

We can use eqn 3.2 to calculate the entropy of a system at a temperature T_f from a knowledge of its entropy at a temperature T_i and the heat supplied to change its temperature from one value to the other:

$$S(T_f) = S(T_i) + \int_{T_i}^{T_f} \frac{dq_{\text{rev}}}{T} \quad (3.17)$$

We shall be particularly interested in the entropy change when the system is subjected to constant pressure (such as from the atmosphere) during the heating. Then, from the definition of constant-pressure heat capacity (eqn 2.22), $dq_{\text{rev}} = C_p dT$ provided the system is doing no non-expansion work. Consequently, at constant pressure:

$$S(T_f) = S(T_i) + \int_{T_i}^{T_f} \frac{C_p dT}{T} \quad (3.18)$$

The same expression applies at constant volume, but with C_p replaced by C_V . When C_p is independent of temperature in the temperature range of interest, it can be taken outside the integral and we obtain

Fig. 3.13 The logarithmic increase in entropy of a substance as it is heated at constant volume. Different curves correspond to different values of the constant-volume heat capacity (which is assumed constant over the temperature range) expressed as $C_{V,m}/R$.

Exploration Plot the change in entropy of a perfect gas of (a) atoms, (b) linear rotors, (c) nonlinear rotors as the sample is heated over the same range under conditions of (i) constant volume, (ii) constant pressure.

$$S(T_f) = S(T_i) + C_p \int_{T_i}^{T_f} \frac{dT}{T} = S(T_i) + C_p \ln \frac{T_f}{T_i} \quad (3.19)$$

with a similar expression for heating at constant volume. The logarithmic dependence of entropy on temperature is illustrated in Fig. 3.13.

Example 3.2 Calculating the entropy change

Calculate the entropy change when argon at 25°C and 1.00 bar in a container of volume 0.500 dm³ is allowed to expand to 1.000 dm³ and is simultaneously heated to 100°C.

Method Because S is a state function, we are free to choose the most convenient path from the initial state. One such path is reversible isothermal expansion to the final volume, followed by reversible heating at constant volume to the final temperature. The entropy change in the first step is given by eqn 3.13 and that of the second step, provided C_V is independent of temperature, by eqn 3.19 (with C_V in place of C_p). In each case we need to know n , the amount of gas molecules, and can calculate it from the perfect gas equation and the data for the initial state from $n = p_i V_i / RT_i$. The heat capacity at constant volume is given by the equipartition theorem as $\frac{3}{2}R$. (The equipartition theorem is reliable for monatomic gases: for others and in general use experimental data like that in Table 2.7, converting to the value at constant volume by using the relation $C_{p,m} - C_{v,m} = R$.)

Answer Because $n = p_i V_i / RT_i$, from eqn 3.13

$$\Delta S(\text{Step 1}) = \left(\frac{p_i V_i}{RT_i} \right) \times R \ln \frac{V_f}{V_i} = \frac{p_i V_i}{T_i} \ln \frac{V_f}{V_i}$$

The entropy change in the second step, from 298 K to 373 K at constant volume, is

$$\Delta S(\text{Step 2}) = \left(\frac{p_i V_i}{RT_i} \right) \times \frac{3}{2} R \ln \frac{T_f}{T_i} = \frac{p_i V_i}{T_i} \ln \left(\frac{T_f}{T_i} \right)^{3/2}$$

The overall entropy change, the sum of these two changes, is

$$\Delta S = \frac{p_i V_i}{T_i} \ln \frac{V_f}{V_i} + \frac{p_i V_i}{T_i} \ln \left(\frac{T_f}{T_i} \right)^{3/2} = \frac{p_i V_i}{T_i} \ln \left\{ \frac{V_f}{V_i} \left(\frac{T_f}{T_i} \right)^{3/2} \right\}$$

At this point we substitute the data and obtain (by using 1 Pa m³ = 1 J)

$$\begin{aligned} \Delta S &= \frac{(1.00 \times 10^5 \text{ Pa}) \times (0.500 \times 10^{-3} \text{ m}^3)}{298 \text{ K}} \ln \left\{ \frac{1.000}{0.500} \left(\frac{373}{298} \right)^{3/2} \right\} \\ &= +0.173 \text{ J K}^{-1} \end{aligned}$$

A note on good practice It is sensible to proceed as generally as possible before inserting numerical data so that, if required, the formula can be used for other data and to avoid rounding errors.

Self-test 3.4 Calculate the entropy change when the same initial sample is compressed to 0.0500 dm³ and cooled to −25°C. [−0.44 J K^{−1}]

(d) The measurement of entropy

The entropy of a system at a temperature T is related to its entropy at $T = 0$ by measuring its heat capacity C_p at different temperatures and evaluating the integral in eqn 3.18, taking care to add the entropy of transition ($\Delta_{\text{trs}}H/T_{\text{trs}}$) for each phase transition between $T = 0$ and the temperature of interest. For example, if a substance melts at T_f and boils at T_b , then its entropy above its boiling temperature is given by

$$S(T) = S(0) + \int_0^{T_f} \frac{C_p(s)dT}{T} + \frac{\Delta_{\text{fus}}H}{T_f} + \int_{T_f}^{T_b} \frac{C_p(l)dT}{T} + \frac{\Delta_{\text{vap}}H}{T_b} + \int_{T_b}^T \frac{C_p(g)dT}{T} \quad (3.20)$$

All the properties required, except $S(0)$, can be measured calorimetrically, and the integrals can be evaluated either graphically or, as is now more usual, by fitting a polynomial to the data and integrating the polynomial analytically. The former procedure is illustrated in Fig. 3.14: the area under the curve of C_p/T against T is the integral required. Because $dT/T = d \ln T$, an alternative procedure is to evaluate the area under a plot of C_p against $\ln T$.

One problem with the determination of entropy is the difficulty of measuring heat capacities near $T = 0$. There are good theoretical grounds for assuming that the heat capacity is proportional to T^3 when T is low (see Section 8.1), and this dependence is the basis of the **Debye extrapolation**. In this method, C_p is measured down to as low a temperature as possible, and a curve of the form aT^3 is fitted to the data. That fit determines the value of a , and the expression $C_p = aT^3$ is assumed valid down to $T = 0$.

Fig. 3.14 The calculation of entropy from heat capacity data. (a) The variation of C_p/T with the temperature for a sample. (b) The entropy, which is equal to the area beneath the upper curve up to the corresponding temperature, plus the entropy of each phase transition passed.

Exploration Allow for the temperature dependence of the heat capacity by writing $C = a + bT + c/T^2$, and plot the change in entropy for different values of the three coefficients (including negative values of c).

Illustration 3.4 Calculating a standard molar entropy

The standard molar entropy of nitrogen gas at 25°C has been calculated from the following data:

	$S_m^\circ/(\text{J K}^{-1} \text{ mol}^{-1})$
Debye extrapolation	1.92
Integration, from 10 K to 35.61 K	25.25
Phase transition at 35.61 K	6.43
Integration, from 35.61 K to 63.14 K	23.38
Fusion at 63.14 K	11.42
Integration, from 63.14 K to 77.32 K	11.41
Vaporization at 77.32 K	72.13
Integration, from 77.32 K to 298.15 K	39.20
Correction for gas imperfection	0.92
Total	192.06

Therefore,

$$S_m(298.15 \text{ K}) = S_m(0) + 192.1 \text{ J K}^{-1} \text{ mol}^{-1}$$

Example 3.3 Calculating the entropy at low temperatures

The molar constant-pressure heat capacity of a certain solid at 4.2 K is $0.43 \text{ J K}^{-1} \text{ mol}^{-1}$. What is its molar entropy at that temperature?

Method Because the temperature is so low, we can assume that the heat capacity varies with temperature as aT^3 , in which case we can use eqn 3.18 to calculate the entropy at a temperature T in terms of the entropy at $T = 0$ and the constant a . When the integration is carried out, it turns out that the result can be expressed in terms of the heat capacity at the temperature T , so the data can be used directly to calculate the entropy.

Answer The integration required is

$$S(T) = S(0) + \int_0^T \frac{aT^3 dT}{T} = S(0) + a \int_0^T T^2 dT = S(0) + \frac{1}{3}aT^3$$

However, because aT^3 is the heat capacity at the temperature T ,

$$S(T) = S(0) + \frac{1}{3}C_p(T)$$

from which it follows that

$$S_m(10 \text{ K}) = S_m(0) + 0.14 \text{ J K}^{-1} \text{ mol}^{-1}$$

Self-test 3.5 For metals, there is also a contribution to the heat capacity from the electrons which is linearly proportional to T when the temperature is low. Find its contribution to the entropy at low temperatures. $[S(T) = S(0) + C_p(T)]$

3.4 The Third Law of thermodynamics

At $T = 0$, all energy of thermal motion has been quenched, and in a perfect crystal all the atoms or ions are in a regular, uniform array. The localization of matter and the absence of thermal motion suggest that such materials also have zero entropy. This conclusion is consistent with the molecular interpretation of entropy, because $S = 0$ if there is only one way of arranging the molecules and only one microstate is accessible (the ground state).

(a) The Nernst heat theorem

The experimental observation that turns out to be consistent with the view that the entropy of a regular array of molecules is zero at $T = 0$ is summarized by the **Nernst heat theorem**:

The entropy change accompanying any physical or chemical transformation approaches zero as the temperature approaches zero: $\Delta S \rightarrow 0$ as $T \rightarrow 0$ provided all the substances involved are perfectly crystalline.

Illustration 3.5 Using the Nernst heat theorem

Consider the entropy of the transition between orthorhombic sulfur, $S(\alpha)$, and monoclinic sulfur, $S(\beta)$, which can be calculated from the transition enthalpy (-402 J mol^{-1}) at the transition temperature (369 K):

$$\Delta_{\text{trs}}S = S_m(\alpha) - S_m(\beta) = \frac{(-402 \text{ J mol}^{-1})}{369 \text{ K}} = -1.09 \text{ J K}^{-1} \text{ mol}^{-1}$$

The two individual entropies can also be determined by measuring the heat capacities from $T = 0$ up to $T = 369 \text{ K}$. It is found that $S_m(\alpha) = S_m(\alpha, 0) + 37 \text{ J K}^{-1} \text{ mol}^{-1}$

and $S_m(\beta) = S_m(\beta, 0) + 38 \text{ J K}^{-1} \text{ mol}^{-1}$. These two values imply that at the transition temperature

$$\Delta_{\text{trs}} S = S_m(\alpha, 0) - S_m(\beta, 0) = -1 \text{ J K}^{-1} \text{ mol}^{-1}$$

On comparing this value with the one above, we conclude that $S_m(\alpha, 0) - S_m(\beta, 0) \approx 0$, in accord with the theorem.

It follows from the Nernst theorem that, if we arbitrarily ascribe the value zero to the entropies of elements in their perfect crystalline form at $T = 0$, then all perfect crystalline compounds also have zero entropy at $T = 0$ (because the change in entropy that accompanies the formation of the compounds, like the entropy of all transformations at that temperature, is zero). This conclusion is summarized by the **Third Law of thermodynamics**:

The entropy of all perfect crystalline substances is zero at $T = 0$.

As far as thermodynamics is concerned, choosing this common value as zero is then a matter of convenience. The molecular interpretation of entropy, however, justifies the value $S = 0$ at $T = 0$.

Molecular interpretation 3.3 *The statistical view of the Third Law of thermodynamics*

We saw in *Molecular interpretation 3.1* that, according to the Boltzmann formula, the entropy is zero if there is only one accessible microstate ($W = 1$). In most cases, $W = 1$ at $T = 0$ because there is only one way of achieving the lowest total energy: put all the molecules into the same, lowest state. Therefore, $S = 0$ at $T = 0$, in accord with the Third Law of thermodynamics. In certain cases, though, W may differ from 1 at $T = 0$. This is the case if there is no energy advantage in adopting a particular orientation even at absolute zero. For instance, for a diatomic molecule AB there may be almost no energy difference between the arrangements . . . AB AB AB . . . and . . . BA AB BA . . . , so $W > 1$ even at $T = 0$. If $S > 0$ at $T = 0$ we say that the substance has a **residual entropy**. Ice has a residual entropy of $3.4 \text{ J K}^{-1} \text{ mol}^{-1}$. It stems from the arrangement of the hydrogen bonds between neighbouring water molecules: a given O atom has two short O—H bonds and two long O···H bonds to its neighbours, but there is a degree of randomness in which two bonds are short and which two are long.

(b) Third-Law entropies

Entropies reported on the basis that $S(0) = 0$ are called **Third-Law entropies** (and often just ‘entropies’). When the substance is in its standard state at the temperature T , the **standard (Third-Law) entropy** is denoted $S^\circ(T)$. A list of values at 298 K is given in Table 3.3.

The **standard reaction entropy**, $\Delta_r S^\circ$, is defined, like the standard reaction enthalpy, as the difference between the molar entropies of the pure, separated products and the pure, separated reactants, all substances being in their standard states at the specified temperature:

$$\Delta_r S^\circ = \sum_{\text{Products}} \nu S_m^\circ - \sum_{\text{Reactants}} \nu S_m^\circ \quad (3.21)$$

In this expression, each term is weighted by the appropriate stoichiometric coefficient. Standard reaction entropies are likely to be positive if there is a net formation of gas in a reaction, and are likely to be negative if there is a net consumption of gas.

Synoptic Table 3.3* Standard Third-Law entropies at 298 K

	$S_m^\circ / (\text{J K}^{-1} \text{ mol}^{-1})$
<i>Solids</i>	
Graphite, C(s)	5.7
Diamond, C(s)	2.4
Sucrose, $\text{C}_{12}\text{H}_{22}\text{O}_{11}(\text{s})$	360.2
Iodine, $\text{I}_2(\text{s})$	116.1
<i>Liquids</i>	
Benzene, $\text{C}_6\text{H}_6(\text{l})$	173.3
Water, $\text{H}_2\text{O}(\text{l})$	69.9
Mercury, $\text{Hg}(\text{l})$	76.0
<i>Gases</i>	
Methane, $\text{CH}_4(\text{g})$	186.3
Carbon dioxide, $\text{CO}_2(\text{g})$	213.7
Hydrogen, $\text{H}_2(\text{g})$	130.7
Helium, He	126.2
Ammonia, $\text{NH}_3(\text{g})$	126.2

* More values are given in the *Data section*.

Illustration 3.6 Calculating a standard reaction entropy

To calculate the standard reaction entropy of $\text{H}_2(\text{g}) + \frac{1}{2} \text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\text{l})$ at 25°C , we use the data in Table 2.7 of the *Data Section* to write

$$\begin{aligned}\Delta_r S^\circ &= S^\circ_{\text{m}}(\text{H}_2\text{O}, \text{l}) - \{S^\circ_{\text{m}}(\text{H}_2, \text{g}) + \tfrac{1}{2}S^\circ_{\text{m}}(\text{O}_2, \text{g})\} \\ &= 69.9 \text{ J K}^{-1} \text{ mol}^{-1} - \{130.7 + \tfrac{1}{2}(205.0)\} \text{ J K}^{-1} \text{ mol}^{-1} \\ &= -163.4 \text{ J K}^{-1} \text{ mol}^{-1}\end{aligned}$$

The negative value is consistent with the conversion of two gases to a compact liquid.

A note on good practice Do not make the mistake of setting the standard molar entropies of elements equal to zero: they have non-zero values (provided $T > 0$), as we have already discussed.

Self-test 3.6 Calculate the standard reaction entropy for the combustion of methane to carbon dioxide and liquid water at 25°C . [$-243 \text{ J K}^{-1} \text{ mol}^{-1}$]

Just as in the discussion of enthalpies in Section 2.8, where we acknowledged that solutions of cations cannot be prepared in the absence of anions, the standard molar entropies of ions in solution are reported on a scale in which the standard entropy of the H^+ ions in water is taken as zero at all temperatures:

$$S^\circ(\text{H}^+, \text{aq}) = 0 \quad [3.22]$$

The values based on this choice are listed in Table 2.7 in the *Data section*.⁵ Because the entropies of ions in water are values relative to the hydrogen ion in water, they may be either positive or negative. A positive entropy means that an ion has a higher molar entropy than H^+ in water and a negative entropy means that the ion has a lower molar entropy than H^+ in water. For instance, the standard molar entropy of $\text{Cl}^-(\text{aq})$ is $+57 \text{ J K}^{-1} \text{ mol}^{-1}$ and that of $\text{Mg}^{2+}(\text{aq})$ is $-128 \text{ J K}^{-1} \text{ mol}^{-1}$. Ion entropies vary as expected on the basis that they are related to the degree to which the ions order the water molecules around them in the solution. Small, highly charged ions induce local structure in the surrounding water, and the disorder of the solution is decreased more than in the case of large, singly charged ions. The absolute, Third-Law standard molar entropy of the proton in water can be estimated by proposing a model of the structure it induces, and there is some agreement on the value $-21 \text{ J K}^{-1} \text{ mol}^{-1}$. The negative value indicates that the proton induces order in the solvent.

Concentrating on the system

Entropy is the basic concept for discussing the direction of natural change, but to use it we have to analyse changes in both the system and its surroundings. We have seen that it is always very simple to calculate the entropy change in the surroundings, and we shall now see that it is possible to devise a simple method for taking that contribution into account automatically. This approach focuses our attention on the system

⁵ In terms of the language to be introduced in Section 5.1, the entropies of ions in solution are actually *partial molar entropies*, for their values include the consequences of their presence on the organization of the solvent molecules around them.

and simplifies discussions. Moreover, it is the foundation of all the applications of chemical thermodynamics that follow.

3.5 The Helmholtz and Gibbs energies

Consider a system in thermal equilibrium with its surroundings at a temperature T . When a change in the system occurs and there is a transfer of energy as heat between the system and the surroundings, the Clausius inequality, eqn 3.12, reads

$$dS - \frac{dq}{T} \geq 0 \quad (3.23)$$

We can develop this inequality in two ways according to the conditions (of constant volume or constant pressure) under which the process occurs.

(a) Criteria for spontaneity

First, consider heating at constant volume. Then, in the absence of non-expansion work, we can write $dq_V = dU$; consequently

$$dS - \frac{dU}{T} \geq 0 \quad (3.24)$$

The importance of the inequality in this form is that it expresses the criterion for spontaneous change solely in terms of the state functions of the system. The inequality is easily rearranged to

$$TdS \geq dU \quad (\text{constant } V, \text{ no additional work})^6 \quad (3.25)$$

At either constant internal energy ($dU = 0$) or constant entropy ($dS = 0$), this expression becomes, respectively,

$$dS_{U,V} \geq 0 \quad dU_{S,V} \leq 0 \quad (3.26)$$

where the subscripts indicate the constant conditions.

Equation 3.26 expresses the criteria for spontaneous change in terms of properties relating to the system. The first inequality states that, in a system at constant volume and constant internal energy (such as an isolated system), the entropy increases in a spontaneous change. That statement is essentially the content of the Second Law. The second inequality is less obvious, for it says that, if the entropy and volume of the system are constant, then the internal energy must decrease in a spontaneous change. Do not interpret this criterion as a tendency of the system to sink to lower energy. It is a disguised statement about entropy, and should be interpreted as implying that, if the entropy of the system is unchanged, then there must be an increase in entropy of the surroundings, which can be achieved only if the energy of the system decreases as energy flows out as heat.

When energy is transferred as heat at constant pressure, and there is no work other than expansion work, we can write $dq_p = dH$ and obtain

$$TdS \geq dH \quad (\text{constant } p, \text{ no additional work}) \quad (3.27)$$

At either constant enthalpy or constant entropy this inequality becomes, respectively,

$$dS_{H,p} \geq 0 \quad dH_{S,p} \leq 0 \quad (3.28)$$

The interpretations of these inequalities are similar to those of eqn 3.26. The entropy of the system at constant pressure must increase if its enthalpy remains constant (for

⁶ Recall that 'additional work' is work other than expansion work.

there can then be no change in entropy of the surroundings). Alternatively, the enthalpy must decrease if the entropy of the system is constant, for then it is essential to have an increase in entropy of the surroundings.

Because eqns 3.25 and 3.27 have the forms $dU - TdS \leq 0$ and $dH - TdS \leq 0$, respectively, they can be expressed more simply by introducing two more thermodynamic quantities. One is the **Helmholtz energy**, A , which is defined as

$$A = U - TS \quad [3.29]$$

The other is the **Gibbs energy**, G :

$$G = H - TS \quad [3.30]$$

All the symbols in these two definitions refer to the system.

When the state of the system changes at constant temperature, the two properties change as follows:

$$(a) \quad dA = dU - TdS \quad (b) \quad dG = dH - TdS \quad [3.31]$$

When we introduce eqns 3.25 and 3.27, respectively, we obtain the criteria of spontaneous change as

$$(a) \quad dA_{T,V} \leq 0 \quad (b) \quad dG_{T,p} \leq 0 \quad [3.32]$$

These inequalities are the most important conclusions from thermodynamics for chemistry. They are developed in subsequent sections and chapters.

(b) Some remarks on the Helmholtz energy

A change in a system at constant temperature and volume is spontaneous if $dA_{T,V} \leq 0$. That is, a change under these conditions is spontaneous if it corresponds to a decrease in the Helmholtz energy. Such systems move spontaneously towards states of lower A if a path is available. The criterion of equilibrium, when neither the forward nor reverse process has a tendency to occur, is

$$dA_{T,V} = 0 \quad [3.33]$$

The expressions $dA = dU - TdS$ and $dA < 0$ are sometimes interpreted as follows. A negative value of dA is favoured by a negative value of dU and a positive value of TdS . This observation suggests that the tendency of a system to move to lower A is due to its tendency to move towards states of lower internal energy and higher entropy. However, this interpretation is false (even though it is a good rule of thumb for remembering the expression for dA) because the tendency to lower A is solely a tendency towards states of greater overall entropy. Systems change spontaneously if in doing so the total entropy of the system and its surroundings increases, not because they tend to lower internal energy. The form of dA may give the impression that systems favour lower energy, but that is misleading: dS is the entropy change of the system, $-dU/T$ is the entropy change of the surroundings (when the volume of the system is constant), and their total tends to a maximum.

(c) Maximum work

It turns out that A carries a greater significance than being simply a signpost of spontaneous change: *the change in the Helmholtz function is equal to the maximum work accompanying a process*:

$$dw_{\max} = dA \quad [3.34]$$

As a result, A is sometimes called the ‘maximum work function’, or the ‘work function’.⁷

⁷ *Arbeit* is the German word for work; hence the symbol A .

Justification 3.2 *Maximum work*

To demonstrate that maximum work can be expressed in terms of the changes in Helmholtz energy, we combine the Clausius inequality $dS \geq dq/T$ in the form $TdS \geq dq$ with the First Law, $dU = dq + dw$, and obtain

$$dU \leq TdS + dw$$

(dU is smaller than the term on the right because we are replacing dq by TdS , which in general is larger.) This expression rearranges to

$$dw \geq dU - TdS$$

It follows that the most negative value of dw , and therefore the maximum energy that can be obtained from the system as work, is given by

$$dw_{\max} = dU - TdS$$

and that this work is done only when the path is traversed reversibly (because then the equality applies). Because at constant temperature $dA = dU - TdS$, we conclude that $dw_{\max} = dA$.

When a macroscopic isothermal change takes place in the system, eqn 3.34 becomes

$$w_{\max} = \Delta A \quad (3.35)$$

with

$$\Delta A = \Delta U - T\Delta S \quad (3.36)$$

This expression shows that in some cases, depending on the sign of $T\Delta S$, not all the change in internal energy may be available for doing work. If the change occurs with a decrease in entropy (of the system), in which case $T\Delta S < 0$, then the right-hand side of this equation is not as negative as ΔU itself, and consequently the maximum work is less than ΔU . For the change to be spontaneous, some of the energy must escape as heat in order to generate enough entropy in the surroundings to overcome the reduction in entropy in the system (Fig. 3.15). In this case, Nature is demanding a tax on the internal energy as it is converted into work. This is the origin of the alternative name ‘Helmholtz free energy’ for A , because ΔA is that part of the change in internal energy that we are free to use to do work.

Fig. 3.15 In a system not isolated from its surroundings, the work done may be different from the change in internal energy. Moreover, the process is spontaneous if overall the entropy of the global, isolated system increases. In the process depicted here, the entropy of the system decreases, so that of the surroundings must increase in order for the process to be spontaneous, which means that energy must pass from the system to the surroundings as heat. Therefore, less work than ΔU can be obtained.

Molecular interpretation 3.4 *Maximum work and the Helmholtz energy*

Further insight into the relation between the work that a system can do and the Helmholtz energy is obtained by recalling that work is energy transferred to the surroundings as the uniform motion of atoms. We can interpret the expression $A = U - TS$ as showing that A is the total internal energy of the system, U , less a contribution that is stored as energy of thermal motion (the quantity TS). Because energy stored in random thermal motion cannot be used to achieve uniform motion in the surroundings, only the part of U that is not stored in that way, the quantity $U - TS$, is available for conversion into work.

If the change occurs with an increase of entropy of the system (in which case $T\Delta S > 0$), the right-hand side of the equation is more negative than ΔU . In this case, the maximum work that can be obtained from the system is greater than ΔU . The explanation of this apparent paradox is that the system is not isolated and energy may

Fig. 3.16 In this process, the entropy of the system increases; hence we can afford to lose some entropy of the surroundings. That is, some of their energy may be lost as heat to the system. This energy can be returned to them as work. Hence the work done can exceed ΔU .

flow in as heat as work is done. Because the entropy of the system increases, we can afford a reduction of the entropy of the surroundings yet still have, overall, a spontaneous process. Therefore, some energy (no more than the value of $T\Delta S$) may leave the surroundings as heat and contribute to the work the change is generating (Fig. 3.16). Nature is now providing a tax refund.

Example 3.4 Calculating the maximum available work

When 1.000 mol $\text{C}_6\text{H}_{12}\text{O}_6$ (glucose) is oxidized to carbon dioxide and water at 25°C according to the equation $\text{C}_6\text{H}_{12}\text{O}_6(\text{s}) + 6 \text{O}_2(\text{g}) \rightarrow 6 \text{CO}_2(\text{g}) + 6 \text{H}_2\text{O}(\text{l})$, calorimetric measurements give $\Delta_r U^\circ = -2808 \text{ kJ mol}^{-1}$ and $\Delta_r S = +182.4 \text{ J K}^{-1} \text{ mol}^{-1}$ at 25°C . How much of this energy change can be extracted as (a) heat at constant pressure, (b) work?

Method We know that the heat released at constant pressure is equal to the value of ΔH , so we need to relate $\Delta_r H^\circ$ to $\Delta_r U^\circ$, which is given. To do so, we suppose that all the gases involved are perfect, and use eqn 2.21 in the form $\Delta_r H = \Delta_r U + \Delta v_g RT$. For the maximum work available from the process we use eqn 3.34.

Answer (a) Because $\Delta v_g = 0$, we know that $\Delta_r H^\circ = \Delta_r U^\circ = -2808 \text{ kJ mol}^{-1}$. Therefore, at constant pressure, the energy available as heat is 2808 kJ mol^{-1} . (b) Because $T = 298 \text{ K}$, the value of $\Delta_r A^\circ$ is

$$\Delta_r A^\circ = \Delta_r U^\circ - T\Delta_r S^\circ = -2862 \text{ kJ mol}^{-1}$$

Therefore, the combustion of 1.000 mol $\text{C}_6\text{H}_{12}\text{O}_6$ can be used to produce up to 2862 kJ of work. The maximum work available is greater than the change in internal energy on account of the positive entropy of reaction (which is partly due to the generation of a large number of small molecules from one big one). The system can therefore draw in energy from the surroundings (so reducing their entropy) and make it available for doing work.

Self-test 3.7 Repeat the calculation for the combustion of 1.000 mol $\text{CH}_4(\text{g})$ under the same conditions, using data from Table 2.5. [$|q_p| = 890 \text{ kJ}$, $|w_{\max}| = 813 \text{ kJ}$]

(d) Some remarks on the Gibbs energy

The Gibbs energy (the ‘free energy’) is more common in chemistry than the Helmholtz energy because, at least in laboratory chemistry, we are usually more interested in changes occurring at constant pressure than at constant volume. The criterion $dG_{T,p} \leq 0$ carries over into chemistry as the observation that, *at constant temperature and pressure, chemical reactions are spontaneous in the direction of decreasing Gibbs energy*. Therefore, if we want to know whether a reaction is spontaneous, the pressure and temperature being constant, we assess the change in the Gibbs energy. If G decreases as the reaction proceeds, then the reaction has a spontaneous tendency to convert the reactants into products. If G increases, then the reverse reaction is spontaneous.

The existence of spontaneous endothermic reactions provides an illustration of the role of G . In such reactions, H increases, the system rises spontaneously to states of higher enthalpy, and $dH > 0$. Because the reaction is spontaneous we know that $dG < 0$ despite $dH > 0$; it follows that the entropy of the system increases so much that TdS outweighs dH in $dG = dH - TdS$. Endothermic reactions are therefore driven by the increase of entropy of the system, and this entropy change overcomes the reduction of entropy brought about in the surroundings by the inflow of heat into the system ($dS_{\text{sur}} = -dH/T$ at constant pressure).

(e) Maximum non-expansion work

The analogue of the maximum work interpretation of ΔA , and the origin of the name ‘free energy’, can be found for ΔG . In the *Justification* below, we show that, at constant temperature and pressure, the maximum additional (non-expansion) work, $w_{\text{add,max}}$, is given by the change in Gibbs energy:

$$dw_{\text{add,max}} = dG \quad (3.37)$$

The corresponding expression for a measurable change is

$$w_{\text{add,max}} = \Delta G \quad (3.38)$$

This expression is particularly useful for assessing the electrical work that may be produced by fuel cells and electrochemical cells, and we shall see many applications of it.

Justification 3.3 *Maximum non-expansion work*

Because $H = U + pV$, for a general change in conditions, the change in enthalpy is

$$dH = dq + dw + d(pV)$$

The corresponding change in Gibbs energy ($G = H - TS$) is

$$dG = dH - TdS - SdT = dq + dw + d(pV) - TdS - SdT$$

When the change is isothermal we can set $dT = 0$; then

$$dG = dq + dw + d(pV) - TdS$$

When the change is reversible, $dw = dw_{\text{rev}}$ and $dq = dq_{\text{rev}} = TdS$, so for a reversible, isothermal process

$$dG = TdS + dw_{\text{rev}} + d(pV) - TdS = dw_{\text{rev}} + d(pV)$$

The work consists of expansion work, which for a reversible change is given by $-pdV$, and possibly some other kind of work (for instance, the electrical work of pushing electrons through a circuit or of raising a column of liquid); this additional work we denote dw_{add} . Therefore, with $d(pV) = pdV + Vdp$,

$$dG = (-pdV + dw_{\text{add,rev}}) + pdV + Vdp = dw_{\text{add,rev}} + Vdp$$

If the change occurs at constant pressure (as well as constant temperature), we can set $dp = 0$ and obtain $dG = dw_{\text{add,rev}}$. Therefore, at constant temperature and pressure, $dw_{\text{add,rev}} = dG$. However, because the process is reversible, the work done must now have its maximum value, so eqn 3.37 follows.

Example 3.5 *Calculating the maximum non-expansion work of a reaction*

How much energy is available for sustaining muscular and nervous activity from the combustion of 1.00 mol of glucose molecules under standard conditions at 37°C (blood temperature)? The standard entropy of reaction is $+182.4 \text{ J K}^{-1} \text{ mol}^{-1}$.

Method The non-expansion work available from the reaction is equal to the change in standard Gibbs energy for the reaction ($\Delta_r G^\circ$, a quantity defined more fully below). To calculate this quantity, it is legitimate to ignore the temperature-dependence of the reaction enthalpy, to obtain $\Delta_r H^\circ$ from Table 2.5, and to substitute the data into $\Delta_r G^\circ = \Delta_r H^\circ - T\Delta_r S^\circ$.

Answer Because the standard reaction enthalpy is $-2808 \text{ kJ mol}^{-1}$, it follows that the standard reaction Gibbs energy is

$$\Delta_r G^\circ = -2808 \text{ kJ mol}^{-1} - (310 \text{ K}) \times (182.4 \text{ J K}^{-1} \text{ mol}^{-1}) = -2865 \text{ kJ mol}^{-1}$$

Therefore, $w_{\text{add,max}} = -2865 \text{ kJ}$ for the combustion of 1 mol glucose molecules, and the reaction can be used to do up to 2865 kJ of non-expansion work. To place this result in perspective, consider that a person of mass 70 kg needs to do 2.1 kJ of work to climb vertically through 3.0 m; therefore, at least 0.13 g of glucose is needed to complete the task (and in practice significantly more).

Self-test 3.8 How much non-expansion work can be obtained from the combustion of 1.00 mol $\text{CH}_4(\text{g})$ under standard conditions at 298 K? Use $\Delta_r S^\ominus = -243 \text{ J K}^{-1} \text{ mol}^{-1}$. [818 kJ]

3.6 Standard reaction Gibbs energies

Standard entropies and enthalpies of reaction can be combined to obtain the **standard Gibbs energy of reaction** (or ‘standard reaction Gibbs energy’), $\Delta_r G^\ominus$:

$$\Delta_r G^\ominus = \Delta_r H^\ominus - T\Delta_r S^\ominus \quad [3.39]$$

The standard Gibbs energy of reaction is the difference in standard molar Gibbs energies of the products and reactants in their standard states at the temperature specified for the reaction as written. As in the case of standard reaction enthalpies, it is convenient to define the **standard Gibbs energies of formation**, $\Delta_f G^\ominus$, the standard reaction Gibbs energy for the formation of a compound from its elements in their reference states.⁸ Standard Gibbs energies of formation of the elements in their reference states are zero, because their formation is a ‘null’ reaction. A selection of values for compounds is given in Table 3.4. From the values there, it is a simple matter to obtain the standard Gibbs energy of reaction by taking the appropriate combination:

$$\Delta_r G^\ominus = \sum_{\text{Products}} \nu \Delta_f G^\ominus - \sum_{\text{Reactants}} \nu \Delta_f G^\ominus \quad (3.40)$$

with each term weighted by the appropriate stoichiometric coefficient.

Illustration 3.7 Calculating a standard Gibbs energy of reaction

To calculate the standard Gibbs energy of the reaction $\text{CO}(\text{g}) + \frac{1}{2} \text{O}_2(\text{g}) \rightarrow \text{CO}_2(\text{g})$ at 25°C, we write

$$\begin{aligned} \Delta_r G^\ominus &= \Delta_f G^\ominus(\text{CO}_2, \text{g}) - \{\Delta_f G^\ominus(\text{CO}, \text{g}) + \tfrac{1}{2} \Delta_f G^\ominus(\text{O}_2, \text{g})\} \\ &= -394.4 \text{ kJ mol}^{-1} - \{(-137.2) + \tfrac{1}{2}(0)\} \text{ kJ mol}^{-1} \\ &= -257.2 \text{ kJ mol}^{-1} \end{aligned}$$

Self-test 3.9 Calculate the standard reaction Gibbs energy for the combustion of $\text{CH}_4(\text{g})$ at 298 K. [−818 kJ mol^{−1}]

Synoptic Table 3.4* Standard Gibbs energies of formation (at 298 K)

	$\Delta_f G^\ominus / (\text{kJ mol}^{-1})$
Diamond, C(s)	+2.9
Benzene, $\text{C}_6\text{H}_6(\text{l})$	+124.3
Methane, $\text{CH}_4(\text{g})$	−50.7
Carbon dioxide, $\text{CO}_2(\text{g})$	−394.4
Water, $\text{H}_2\text{O}(\text{l})$	−237.1
Ammonia, $\text{NH}_3(\text{g})$	−16.5
Sodium chloride, $\text{NaCl}(\text{s})$	−384.1

* More values are given in the Data section.

Just as we did in Section 2.8, where we acknowledged that solutions of cations cannot be prepared without their accompanying anions, we define one ion, conventionally the hydrogen ion, to have zero standard Gibbs energy of formation at all temperatures:

$$\Delta_f G^\ominus(\text{H}^+, \text{aq}) = 0 \quad [3.41]$$

⁸ The reference state of an element was defined in Section 2.7.

In essence, this definition adjusts the actual values of the Gibbs energies of formation of ions by a fixed amount, which is chosen so that the standard value for one of them, $\text{H}^+(\text{aq})$, has the value zero. Then for the reaction

we can write

$$\Delta_{\text{r}}G^{\ominus} = \Delta_{\text{f}}G^{\ominus}(\text{H}^+, \text{aq}) + \Delta_{\text{f}}G^{\ominus}(\text{Cl}^-, \text{aq}) = \Delta_{\text{f}}G^{\ominus}(\text{Cl}^-, \text{aq})$$

and hence identify $\Delta_{\text{f}}G^{\ominus}(\text{Cl}^-, \text{aq})$ as $-131.23 \text{ kJ mol}^{-1}$. All the Gibbs energies of formation of ions tabulated in the *Data section* were calculated in the same way.

Illustration 3.8 Calculating the standard Gibbs energy of formation of an ion

With the value of $\Delta_{\text{f}}G^{\ominus}(\text{Cl}^-, \text{aq})$ established, we can find the value of $\Delta_{\text{f}}G^{\ominus}(\text{Ag}^+, \text{aq})$ from

which leads to $\Delta_{\text{f}}G^{\ominus}(\text{Ag}^+, \text{aq}) = +77.11 \text{ kJ mol}^{-1}$.

The factors responsible for the magnitude of the Gibbs energy of formation of an ion in solution can be identified by analysing it in terms of a thermodynamic cycle. As an illustration, we consider the standard Gibbs energies of formation of Cl^- in water, which is -131 kJ mol^{-1} . We do so by treating the formation reaction

as the outcome of the sequence of steps shown in Fig. 3.17 (with values taken from the *Data section*). The sum of the Gibbs energies for all the steps around a closed cycle is zero, so

$$\Delta_{\text{f}}G^{\ominus}(\text{Cl}^-, \text{aq}) = 1272 \text{ kJ mol}^{-1} + \Delta_{\text{solv}}G^{\ominus}(\text{H}^+) + \Delta_{\text{solv}}G^{\ominus}(\text{Cl}^-)$$

Fig. 3.17 The thermodynamic cycles for the discussion of the Gibbs energies of solvation (hydration) and formation of (a) chloride ions, (b) iodide ions in aqueous solution. The sum of the changes in Gibbs energies around the cycle sum to zero because G is a state function.

Comment 3.2

The standard Gibbs energies of formation of the gas-phase ions are unknown. We have therefore used ionization energies (the energies associated with the removal of electrons from atoms or cations in the gas phase) or electron affinities (the energies associated with the uptake of electrons by atoms or anions in the gas phase) and have assumed that any differences from the Gibbs energies arising from conversion to enthalpy and the inclusion of entropies to obtain Gibbs energies in the formation of H^+ are cancelled by the corresponding terms in the electron gain of X . The conclusions from the cycles are therefore only approximate.

An important point to note is that the value of $\Delta_f G^\circ$ of an ion X is not determined by the properties of X alone but includes contributions from the dissociation, ionization, and hydration of hydrogen.

Gibbs energies of solvation of individual ions may be estimated from an equation derived by Max Born, who identified $\Delta_{\text{solv}} G^\circ$ with the electrical work of transferring an ion from a vacuum into the solvent treated as a continuous dielectric of relative permittivity ϵ_r . The resulting **Born equation**, which is derived in *Further information 3.1*, is

$$\Delta_{\text{solv}} G^\circ = -\frac{z_i^2 e^2 N_A}{8\pi\epsilon_0 r_i} \left(1 - \frac{1}{\epsilon_r}\right) \quad (3.42a)$$

where z_i is the charge number of the ion and r_i its radius (N_A is Avogadro's constant). Note that $\Delta_{\text{solv}} G^\circ < 0$, and that $\Delta_{\text{solv}} G^\circ$ is strongly negative for small, highly charged ions in media of high relative permittivity. For water at 25°C,

$$\Delta_{\text{solv}} G^\circ = -\frac{z_i^2}{(r_i/\text{pm})} \times (6.86 \times 10^4 \text{ kJ mol}^{-1}) \quad (3.42b)$$

Illustration 3.9 Using the Born equation

To see how closely the Born equation reproduces the experimental data, we calculate the difference in the values of $\Delta_f G^\circ$ for Cl^- and I^- in water, for which $\epsilon_r = 78.54$ at 25°C, given their radii as 181 pm and 220 pm (Table 20.3), respectively, is

$$\begin{aligned} \Delta_{\text{solv}} G^\circ(\text{Cl}^-) - \Delta_{\text{solv}} G^\circ(\text{I}^-) &= -\left(\frac{1}{181} - \frac{1}{220}\right) \times (6.86 \times 10^4 \text{ kJ mol}^{-1}) \\ &= -67 \text{ kJ mol}^{-1} \end{aligned}$$

This estimated difference is in good agreement with the experimental difference, which is -61 kJ mol^{-1} .

Self-test 3.10 Estimate the value of $\Delta_{\text{solv}} G^\circ(\text{Cl}^-, \text{aq}) - \Delta_{\text{solv}} G^\circ(\text{Br}^-, \text{aq})$ from experimental data and from the Born equation.

[-26 kJ mol^{-1} experimental; -29 kJ mol^{-1} calculated]

Comment 3.3

The *NIST WebBook* is a good source of links to online databases of thermochemical data.

Calorimetry (for ΔH directly, and for S via heat capacities) is only one of the ways of determining Gibbs energies. They may also be obtained from equilibrium constants and electrochemical measurements (Chapter 7), and for gases they may be calculated using data from spectroscopic observations (Chapter 17).

Combining the First and Second Laws

The First and Second Laws of thermodynamics are both relevant to the behaviour of matter, and we can bring the whole force of thermodynamics to bear on a problem by setting up a formulation that combines them.

3.7 The fundamental equation

We have seen that the First Law of thermodynamics may be written $dU = dq + dw$. For a reversible change in a closed system of constant composition, and in the absence of

any additional (non-expansion) work, we may set $dw_{\text{rev}} = -pdV$ and (from the definition of entropy) $dq_{\text{rev}} = TdS$, where p is the pressure of the system and T its temperature. Therefore, for a reversible change in a closed system,

$$dU = TdS - pdV \quad (3.43)$$

However, because dU is an exact differential, its value is independent of path. Therefore, the same value of dU is obtained whether the change is brought about irreversibly or reversibly. Consequently, *eqn 3.43 applies to any change—reversible or irreversible—of a closed system that does no additional (non-expansion) work*. We shall call this combination of the First and Second Laws the **fundamental equation**.

The fact that the fundamental equation applies to both reversible and irreversible changes may be puzzling at first sight. The reason is that only in the case of a reversible change may TdS be identified with dq and $-pdV$ with dw . When the change is irreversible, $TdS > dq$ (the Clausius inequality) and $-pdV > dw$. The sum of dw and dq remains equal to the sum of TdS and $-pdV$, provided the composition is constant.

3.8 Properties of the internal energy

Equation 3.43 shows that the internal energy of a closed system changes in a simple way when either S or V is changed ($dU \propto dS$ and $dU \propto dV$). These simple proportionalities suggest that U should be regarded as a function of S and V . We could regard U as a function of other variables, such as S and p or T and V , because they are all interrelated; but the simplicity of the fundamental equation suggests that $U(S, V)$ is the best choice.

The *mathematical* consequence of U being a function of S and V is that we can express an infinitesimal change dU in terms of changes dS and dV by

$$dU = \left(\frac{\partial U}{\partial S} \right)_V dS + \left(\frac{\partial U}{\partial V} \right)_S dV \quad (3.44)$$

The two partial derivatives are the slopes of the plots of U against S and V , respectively. When this expression is compared to the *thermodynamic* relation, eqn 3.43, we see that, for systems of constant composition,

$$\left(\frac{\partial U}{\partial S} \right)_V = T \quad \left(\frac{\partial U}{\partial V} \right)_S = -p \quad (3.45)$$

The first of these two equations is a purely thermodynamic definition of temperature (a Zeroth-Law concept) as the ratio of the changes in the internal energy (a First-Law concept) and entropy (a Second-Law concept) of a constant-volume, closed, constant-composition system. We are beginning to generate relations between the properties of a system and to discover the power of thermodynamics for establishing unexpected relations.

(a) The Maxwell relations

An infinitesimal change in a function $f(x, y)$ can be written $df = gdx + hdy$ where g and h are functions of x and y . The mathematical criterion for df being an exact differential (in the sense that its integral is independent of path) is that

$$\left(\frac{\partial g}{\partial y} \right)_x = \left(\frac{\partial h}{\partial x} \right)_y \quad (3.46)$$

Because the fundamental equation, eqn 3.43, is an expression for an exact differential, the functions multiplying dS and dV (namely T and $-p$) must pass this test. Therefore, it must be the case that

Comment 3.4

Partial derivatives were introduced in *Comment 2.5* and are reviewed in *Appendix 2*. The type of result in eqn 3.44 was first obtained in Section 2.11, where we treated U as a function of T and V .

Comment 3.5

To illustrate the criterion set by eqn 3.46, let's test whether $df = 2xydx + x^2dy$ is an exact differential. We identify $g = 2xy$ and $h = x^2$ and form

$$\left(\frac{\partial g}{\partial y} \right)_x = \left(\frac{\partial(2xy)}{\partial y} \right)_x = 2x$$

$$\left(\frac{\partial h}{\partial x} \right)_y = \left(\frac{\partial x^2}{\partial x} \right)_y = 2x$$

Because these two coefficients are equal, df is exact.

Table 3.5 The Maxwell relations

From U :	$\left(\frac{\partial T}{\partial V}\right)_S = -\left(\frac{\partial p}{\partial S}\right)_V$
From H :	$\left(\frac{\partial T}{\partial p}\right)_S = \left(\frac{\partial V}{\partial S}\right)_p$
From A :	$\left(\frac{\partial p}{\partial T}\right)_V = \left(\frac{\partial S}{\partial V}\right)_T$
From G :	$\left(\frac{\partial V}{\partial T}\right)_p = -\left(\frac{\partial S}{\partial p}\right)_T$

$$\left(\frac{\partial T}{\partial V}\right)_S = -\left(\frac{\partial p}{\partial S}\right)_V \quad (3.47)$$

We have generated a relation between quantities that, at first sight, would not seem to be related.

Equation 3.47 is an example of a **Maxwell relation**. However, apart from being unexpected, it does not look particularly interesting. Nevertheless, it does suggest that there may be other similar relations that are more useful. Indeed, we can use the fact that H , G , and A are all state functions to derive three more Maxwell relations. The argument to obtain them runs in the same way in each case: because H , G , and A are state functions, the expressions for dH , dG , and dA satisfy relations like eqn 3.47. All four relations are listed in Table 3.5 and we put them to work later in the chapter.

(b) The variation of internal energy with volume

The quantity $\pi_T = (\partial U / \partial V)_T$, which represents how the internal energy changes as the volume of a system is changed isothermally, played a central role in the manipulation of the First Law, and in *Further information 2.2* we used the relation

$$\pi_T = T \left(\frac{\partial p}{\partial T}\right)_V - p \quad (3.48)$$

This relation is called a **thermodynamic equation of state** because it is an expression for pressure in terms of a variety of thermodynamic properties of the system. We are now ready to derive it by using a Maxwell relation.

Justification 3.4 The thermodynamic equation of state

We obtain an expression for the coefficient π_T by dividing both sides of eqn 3.43 by dV , imposing the constraint of constant temperature, which gives

$$\left(\frac{\partial U}{\partial V}\right)_T = \left(\frac{\partial U}{\partial S}\right)_V \left(\frac{\partial S}{\partial V}\right)_T + \left(\frac{\partial U}{\partial V}\right)_S$$

Next, we introduce the two relations in eqn 3.45 and the definition of π_T to obtain

$$\pi_T = T \left(\frac{\partial S}{\partial V}\right)_T - p$$

The third Maxwell relation in Table 3.5 turns $(\partial S / \partial V)_T$ into $(\partial p / \partial T)_V$, which completes the proof of eqn 3.48.

Example 3.6 Deriving a thermodynamic relation

Show thermodynamically that $\pi_T = 0$ for a perfect gas, and compute its value for a van der Waals gas.

Method Proving a result ‘thermodynamically’ means basing it entirely on general thermodynamic relations and equations of state, without drawing on molecular arguments (such as the existence of intermolecular forces). We know that for a perfect gas, $p = nRT/V$, so this relation should be used in eqn 3.48. Similarly, the van der Waals equation is given in Table 1.7, and for the second part of the question it should be used in eqn 3.48.

Answer For a perfect gas we write

$$\left(\frac{\partial p}{\partial T}\right)_V = \left(\frac{\partial(nRT/V)}{\partial T}\right)_V = \frac{nR}{V}$$

Then, eqn 3.48 becomes

$$\pi_T = \frac{nRT}{V} - p = 0$$

The equation of state of a van der Waals gas is

$$p = \frac{nRT}{V - nb} - a\frac{n^2}{V^2}$$

Because a and b are independent of temperature,

$$\left(\frac{\partial p}{\partial T}\right)_V = \frac{nR}{V - nb}$$

Therefore, from eqn 3.48,

$$\pi_T = \frac{nRT}{V - nb} - \frac{nRT}{V - nb} + a\frac{n^2}{V^2} = a\frac{n^2}{V^2}$$

This result for π_T implies that the internal energy of a van der Waals gas increases when it expands isothermally (that is, $(\partial U/\partial V)_T > 0$), and that the increase is related to the parameter a , which models the attractive interactions between the particles. A larger molar volume, corresponding to a greater average separation between molecules, implies weaker mean intermolecular attractions, so the total energy is greater.

Self-test 3.11 Calculate π_T for a gas that obeys the virial equation of state (Table 1.7). $[\pi_T = RT^2(\partial B/\partial T)_V/V_m^2 + \dots]$

3.9 Properties of the Gibbs energy

The same arguments that we have used for U can be used for the Gibbs energy $G = H - TS$. They lead to expressions showing how G varies with pressure and temperature that are important for discussing phase transitions and chemical reactions.

(a) General considerations

When the system undergoes a change of state, G may change because H , T , and S all change. As in *Justification 2.1*, we write for infinitesimal changes in each property

$$dG = dH - d(TS) = dH - TdS - SdT$$

Because $H = U + pV$, we know that

$$dH = dU + d(pV) = dU + pdV + Vdp$$

and therefore

$$dG = dU + pdV + Vdp - TdS - SdT$$

For a closed system doing no non-expansion work, we can replace dU by the fundamental equation $dU = TdS - pdV$ and obtain

$$dG = TdS - pdV + pdV + Vdp - TdS - SdT$$

Four terms now cancel on the right, and we conclude that, for a closed system in the absence of non-expansion work and at constant composition,

$$dG = Vdp - SdT \quad (3.49)$$

This expression, which shows that a change in G is proportional to a change in p or T , suggests that G may be best regarded as a function of p and T . It confirms that G is an important quantity in chemistry because the pressure and temperature are usually the variables under our control. In other words, G carries around the combined consequences of the First and Second Laws in a way that makes it particularly suitable for chemical applications.

The same argument that led to eqn 3.45, when applied to the exact differential $dG = Vdp - SdT$, now gives

$$\left(\frac{\partial G}{\partial T}\right)_p = -S \quad \left(\frac{\partial G}{\partial p}\right)_T = V \quad (3.50)$$

These relations show how the Gibbs energy varies with temperature and pressure (Fig. 3.18). The first implies that:

- Because $S > 0$ for all substances, G always *decreases* when the temperature is raised (at constant pressure and composition).
- Because $(\partial G/\partial T)_p$ becomes more negative as S increases, G decreases most sharply when the entropy of the system is large.

Therefore, the Gibbs energy of the gaseous phase of a substance, which has a high molar entropy, is more sensitive to temperature than its liquid and solid phases (Fig. 3.19). Similarly, the second relation implies that:

- Because $V > 0$ for all substances, G always *increases* when the pressure of the system is increased (at constant temperature and composition).

Fig. 3.18 The variation of the Gibbs energy of a system with (a) temperature at constant pressure and (b) pressure at constant temperature. The slope of the former is equal to the negative of the entropy of the system and that of the latter is equal to the volume.

Fig. 3.19 The variation of the Gibbs energy with the temperature is determined by the entropy. Because the entropy of the gaseous phase of a substance is greater than that of the liquid phase, and the entropy of the solid phase is smallest, the Gibbs energy changes most steeply for the gas phase, followed by the liquid phase, and then the solid phase of the substance.

• Because $(\partial G/\partial p)_T$ increases with V , G is more sensitive to pressure when the volume of the system is large.

Because the molar volume of the gaseous phase of a substance is greater than that of its condensed phases, the molar Gibbs energy of a gas is more sensitive to pressure than its liquid and solid phases (Fig. 3.20).

(b) The variation of the Gibbs energy with temperature

As we remarked in the introduction, because the equilibrium composition of a system depends on the Gibbs energy, to discuss the response of the composition to temperature we need to know how G varies with temperature.

The first relation in eqn 3.50, $(\partial G/\partial T)_p = -S$, is our starting point for this discussion. Although it expresses the variation of G in terms of the entropy, we can express it in terms of the enthalpy by using the definition of G to write $S = (H - G)/T$. Then

$$\left(\frac{\partial G}{\partial T}\right)_p = \frac{G - H}{T} \quad (3.51)$$

We shall see later that the equilibrium constant of a reaction is related to G/T rather than to G itself,⁹ and it is easy to deduce from the last equation (see the *Justification* below) that

$$\left(\frac{\partial}{\partial T} \frac{G}{T}\right)_p = -\frac{H}{T^2} \quad (3.52)$$

This expression is called the **Gibbs–Helmholtz equation**. It shows that if we know the enthalpy of the system, then we know how G/T varies with temperature.

Justification 3.5 The Gibbs–Helmholtz equation

First, we note that

$$\left(\frac{\partial}{\partial T} \frac{G}{T}\right)_p = \frac{1}{T} \left(\frac{\partial G}{\partial T}\right)_p + G \frac{d}{dT} \frac{1}{T} = \frac{1}{T} \left(\frac{\partial G}{\partial T}\right)_p - \frac{G}{T^2} = \frac{1}{T} \left\{ \left(\frac{\partial G}{\partial T}\right)_p - \frac{G}{T} \right\}$$

Then we use eqn 3.51 in the form

$$\left(\frac{\partial G}{\partial T}\right)_p - \frac{G}{T} = -\frac{H}{T}$$

It follows that

$$\left(\frac{\partial}{\partial T} \frac{G}{T}\right)_p = \frac{1}{T} \left\{ -\frac{H}{T} \right\} = -\frac{H}{T^2}$$

which is eqn 3.52.

The Gibbs–Helmholtz equation is most useful when it is applied to changes, including changes of physical state and chemical reactions at constant pressure. Then, because $\Delta G = G_f - G_i$ for the change of Gibbs energy between the final and initial states and because the equation applies to both G_f and G_i , we can write

Fig. 3.20 The variation of the Gibbs energy with the pressure is determined by the volume of the sample. Because the volume of the gaseous phase of a substance is greater than that of the same amount of liquid phase, and the entropy of the solid phase is smallest (for most substances), the Gibbs energy changes most steeply for the gas phase, followed by the liquid phase, and then the solid phase of the substance. Because the volumes of the solid and liquid phases of a substance are similar, their molar Gibbs energies vary by similar amounts as the pressure is changed.

Comment 3.6

For this step, we use the rule for differentiating a product of functions (which is valid for partial derivatives as well as ordinary derivatives):

$$\frac{d(uv)}{dx} = u \frac{dv}{dx} + v \frac{du}{dx}$$

For instance, to differentiate $x^2 e^{ax}$, we write

$$\begin{aligned} \frac{d(x^2 e^{ax})}{dx} &= x^2 \frac{de^{ax}}{dx} + e^{ax} \frac{dx^2}{dx} \\ &= ax^2 e^{ax} + 2xe^{ax} \end{aligned}$$

⁹ In Section 7.2b we derive the result that the equilibrium constant for a reaction is related to its standard reaction Gibbs energy by $\Delta_r G^\circ/T = -R \ln K$.

$$\left(\frac{\partial}{\partial T} \frac{\Delta G}{T} \right)_p = -\frac{\Delta H}{T^2} \quad (3.53)$$

This equation shows that, if we know the change in enthalpy of a system that is undergoing some kind of transformation (such as vaporization or reaction), then we know how the corresponding change in Gibbs energy varies with temperature. As we shall see, this is a crucial piece of information in chemistry.

(c) The variation of the Gibbs energy with pressure

To find the Gibbs energy at one pressure in terms of its value at another pressure, the temperature being constant, we set $dT = 0$ in eqn 3.49, which gives $dG = Vdp$, and integrate:

$$G(p_f) = G(p_i) + \int_{p_i}^{p_f} V dp \quad (3.54a)$$

For molar quantities,

$$G_m(p_f) = G_m(p_i) + \int_{p_i}^{p_f} V_m dp \quad (3.54b)$$

This expression is applicable to any phase of matter, but to evaluate it we need to know how the molar volume, V_m , depends on the pressure.

The molar volume of a condensed phase changes only slightly as the pressure changes (Fig. 3.21), so we can treat V_m as a constant and take it outside the integral:

$$G_m(p_f) = G_m(p_i) + V_m \int_{p_i}^{p_f} dp = G_m(p_i) + (p_f - p_i) V_m \quad (3.55)$$

Fig. 3.21 The difference in Gibbs energy of a solid or liquid at two pressures is equal to the rectangular area shown. We have assumed that the variation of volume with pressure is negligible.

Fig. 3.22 The difference in Gibbs energy for a perfect gas at two pressures is equal to the area shown below the perfect-gas isotherm.

Self-test 3.12 Calculate the change in G_m for ice at -10°C , with density 917 kg m^{-3} , when the pressure is increased from 1.0 bar to 2.0 bar. [+2.0 J mol⁻¹]

Under normal laboratory conditions $(p_f - p_i)V_m$ is very small and may be neglected. Hence, we may usually suppose that the Gibbs energies of solids and liquids are independent of pressure. However, if we are interested in geophysical problems, then because pressures in the Earth's interior are huge, their effect on the Gibbs energy cannot be ignored. If the pressures are so great that there are substantial volume changes over the range of integration, then we must use the complete expression, eqn 3.54.

Illustration 3.10 Gibbs energies at high pressures

Suppose that for a certain phase transition of a solid $\Delta_{\text{trs}}V = +1.0 \text{ cm}^3 \text{ mol}^{-1}$ independent of pressure. Then, for an increase in pressure to 3.0 Mbar ($3.0 \times 10^{11} \text{ Pa}$) from 1.0 bar ($1.0 \times 10^5 \text{ Pa}$), the Gibbs energy of the transition changes from $\Delta_{\text{trs}}G(1 \text{ bar})$ to

$$\begin{aligned} \Delta_{\text{trs}}G(3 \text{ Mbar}) &= \Delta_{\text{trs}}G(1 \text{ bar}) + (1.0 \times 10^{-6} \text{ m}^3 \text{ mol}^{-1}) \times (3.0 \times 10^{11} \text{ Pa} - 1.0 \times 10^5 \text{ Pa}) \\ &= \Delta_{\text{trs}}G(1 \text{ bar}) + 3.0 \times 10^2 \text{ kJ mol}^{-1} \end{aligned}$$

where we have used $1 \text{ Pa m}^3 = 1 \text{ J}$.

The molar volumes of gases are large, so the Gibbs energy of a gas depends strongly on the pressure. Furthermore, because the volume also varies markedly with the pressure, we cannot treat it as a constant in the integral in eqn 3.54b (Fig. 3.22).

For a perfect gas we substitute $V_m = RT/p$ into the integral, treat RT as a constant, and find

$$G_m(p_f) = G_m(p_i) + RT \int_{p_i}^{p_f} \frac{dp}{p} = G_m(p_i) + RT \ln \frac{p_f}{p_i} \quad (3.56)^\circ$$

This expression shows that when the pressure is increased tenfold at room temperature, the molar Gibbs energy increases by $RT \ln 10 \approx 6 \text{ kJ mol}^{-1}$. It also follows from this equation that, if we set $p_i = p^\circ$ (the standard pressure of 1 bar), then the molar Gibbs energy of a perfect gas at a pressure p (set $p_f = p$) is related to its standard value by

$$G_m(p) = G_m^\circ + RT \ln \frac{p}{p^\circ} \quad (3.57)^\circ$$

Fig. 3.23 The molar Gibbs energy potential of a perfect gas is proportional to $\ln p$, and the standard state is reached at p° . Note that, as $p \rightarrow 0$, the molar Gibbs energy becomes negatively infinite.

Exploration Show how the first derivative of G , $(\partial G/\partial p)_T$, varies with pressure, and plot the resulting expression over a pressure range. What is the physical significance of $(\partial G/\partial p)_T$?

Self-test 3.13 Calculate the change in the molar Gibbs energy of water vapour (treated as a perfect gas) when the pressure is increased isothermally from 1.0 bar to 2.0 bar at 298 K. Note that, whereas the change in molar Gibbs energy for a condensed phase (Self-test 3.12) is a few joules per mole, the answer you should get for a gas is of the order of kilojoules per mole. [+1.7 kJ mol⁻¹]

The logarithmic dependence of the molar Gibbs energy on the pressure predicted by eqn 3.57 is illustrated in Fig. 3.23. This very important expression, the consequences of which we unfold in the following chapters, applies to perfect gases (which is usually a good enough approximation). *Further information 3.2* describes how to take into account gas imperfections.

Checklist of key ideas

☐ 1. Kelvin statement of the Second Law of thermodynamics: No process is possible in which the sole result is the absorption of heat from a reservoir and its complete conversion into work. ☐ 2. The Second Law in terms of entropy: The entropy of an isolated system increases in the course of a spontaneous change: $\Delta S_{\text{tot}} > 0$. ☐ 3. The thermodynamic definition of entropy is $dS = dq_{\text{rev}}/T$. The statistical definition of entropy is given by the Boltzmann formula, $S = k \ln W$. ☐ 4. A Carnot cycle is a cycle composed of a sequence of isothermal and adiabatic reversible expansions and compressions. ☐ 5. The efficiency of a heat engine is $\varepsilon = w /q_h$. The Carnot efficiency is $\varepsilon_{\text{rev}} = 1 - T_c/T_h$. ☐ 6. The Kelvin scale is a thermodynamic temperature scale in which the triple point of water defines the point 273.16 K. ☐ 7. The Clausius inequality is $dS \geq dq/T$. ☐ 8. The normal transition temperature, T_{trs}, is the temperature at which two phases are in equilibrium at 1 atm. The entropy of transition at the transition temperature, $\Delta_{\text{trs}}S = \Delta_{\text{trs}}H/T_{\text{trs}}$.	☐ 9. Trouton's rule states that many normal liquids have approximately the same standard entropy of vaporization (about $85 \text{ J K}^{-1} \text{ mol}^{-1}$). ☐ 10. The variation of entropy with temperature is given by $S(T_f) = S(T_i) + \int_{T_i}^{T_f} (C_p/T) dT.$ ☐ 11. The entropy of a substance is measured from the area under a graph of C_p/T against T, using the Debye extrapolation at low temperatures, $C_p = aT^3$ as $T \rightarrow 0$. ☐ 12. The Nernst heat theorem states that the entropy change accompanying any physical or chemical transformation approaches zero as the temperature approaches zero: $\Delta S \rightarrow 0$ as $T \rightarrow 0$ provided all the substances involved are perfectly ordered. ☐ 13. Third Law of thermodynamics: The entropy of all perfect crystalline substances is zero at $T = 0$. ☐ 14. The standard reaction entropy is calculated from $\Delta_r S^\circ = \sum_{\text{Products}} \nu S_m^\circ - \sum_{\text{Reactants}} \nu S_m^\circ.$ ☐ 15. The standard molar entropies of ions in solution are reported on a scale in which $S^\circ(\text{H}^+, \text{aq}) = 0$ at all temperatures.

- 16. The Helmholtz energy is $A = U - TS$. The Gibbs energy is $G = H - TS$.
- 17. The criteria of spontaneity may be written as: (a) $dS_{U,V} \geq 0$ and $dU_{S,V} \leq 0$, or (b) $dA_{T,V} \leq 0$ and $dG_{T,p} \leq 0$.
- 18. The criterion of equilibrium at constant temperature and volume, $dA_{T,V} = 0$. The criterion of equilibrium at constant temperature and pressure, $dG_{T,p} = 0$.
- 19. The maximum work and the Helmholtz energy are related by $w_{\max} = \Delta A$. The maximum additional (non-expansion) work and the Gibbs energy are related by $w_{\text{add,max}} = \Delta G$.
- 20. The standard Gibbs energy of reaction is given by $\Delta_r G^\circ = \Delta_r H^\circ - T\Delta_r S^\circ = \sum_{\text{Products}} \nu G_m^\circ - \sum_{\text{Reactants}} \nu G_m^\circ$.
- 21. The standard Gibbs energy of formation ($\Delta_f G^\circ$) is the standard reaction Gibbs energy for the formation of a compound from its elements in their reference states.
- 22. The standard Gibbs energy of reaction may be expressed in terms of $\Delta_f G^\circ$, $\Delta_r G^\circ = \sum_{\text{Products}} \nu \Delta_f G^\circ - \sum_{\text{Reactants}} \nu \Delta_f G^\circ$.
- 23. The standard Gibbs energies of formation of ions are reported on a scale in which $\Delta_f G^\circ(\text{H}^+, \text{aq}) = 0$ at all temperatures.
- 24. The fundamental equation is $dU = TdS - pdV$.
- 25. The Maxwell relations are listed in Table 3.5.
- 26. A thermodynamic equation of state is an expression for pressure in terms of thermodynamic quantities, $\pi_T = T(\partial p / \partial T)_V - p$.
- 27. The Gibbs energy is best described as a function of pressure and temperature, $dG = Vdp - SdT$. The variation of Gibbs energy with pressure and temperature are, respectively, $(\partial G / \partial p)_T = V$ and $(\partial G / \partial T)_p = -S$.
- 28. The temperature dependence of the Gibbs energy is given by the Gibbs–Helmholtz equation, $(\partial(G/T) / \partial T)_p = -H/T^2$.
- 29. For a condensed phase, the Gibbs energy varies with pressure as $G(p_f) = G(p_i) + V_m \Delta p$. For a perfect gas, $G(p_f) = G(p_i) + nRT \ln(p_f/p_i)$.

Further information

Further information 3.1 The Born equation

The electrical concepts required in this derivation are reviewed in *Appendix 3*. The strategy of the calculation is to identify the Gibbs energy of solvation with the work of transferring an ion from a vacuum into the solvent. That work is calculated by taking the difference of the work of charging an ion when it is in the solution and the work of charging the same ion when it is in a vacuum.

The Coulomb interaction between two charges q_1 and q_2 separated by a distance r is described by the *Coulombic potential energy*:

$$V = \frac{q_1 q_2}{4\pi\epsilon r}$$

where ϵ is the medium's permittivity. The permittivity of vacuum is $\epsilon_0 = 8.854 \times 10^{-12} \text{ J}^{-1} \text{ C}^2 \text{ m}^{-1}$. The relative permittivity (formerly

called the 'dielectric constant') of a substance is defined as $\epsilon_r = \epsilon/\epsilon_0$. Ions do not interact as strongly in a solvent of high relative permittivity (such as water, with $\epsilon_r = 80$ at 293 K) as they do in a solvent of lower relative permittivity (such as ethanol, with $\epsilon_r = 25$ at 293 K). See Chapter 18 for more details. The potential energy of a charge q_1 in the presence of a charge q_2 can be expressed in terms of the *Coulomb potential*, ϕ :

$$V = q_1 \phi \quad \phi = \frac{q_2}{4\pi\epsilon r}$$

We model an ion as a sphere of radius r_i immersed in a medium of permittivity ϵ . It turns out that, when the charge of the sphere is q , the electric potential, ϕ , at its surface is the same as the potential due to a point charge at its centre, so we can use the last expression and write

¹⁰ See *Further reading* in Chapter 2 for additional articles, texts, and sources of thermochemical data.

$$\phi = \frac{q}{4\pi\epsilon r_i}$$

The work of bringing up a charge dq to the sphere is ϕdq . Therefore, the total work of charging the sphere from 0 to $z_i e$ is

$$w = \int_0^{z_i e} \phi dq = \frac{1}{4\pi\epsilon r_i} \int_0^{z_i e} q dq = \frac{z_i^2 e^2}{8\pi\epsilon r_i}$$

This electrical work of charging, when multiplied by Avogadro's constant, is the molar Gibbs energy for charging the ions.

The work of charging an ion in a vacuum is obtained by setting $\epsilon = \epsilon_0$, the vacuum permittivity. The corresponding value for charging the ion in a medium is obtained by setting $\epsilon = \epsilon_r \epsilon_0$, where ϵ_r is the relative permittivity of the medium. It follows that the change in molar Gibbs energy that accompanies the transfer of ions from a vacuum to a solvent is the difference of these two quantities:

$$\Delta_{\text{solv}} G^\ominus = \frac{z_i^2 e^2 N_A}{8\pi\epsilon r_i} - \frac{z_i^2 e^2 N_A}{8\pi\epsilon_0 r_i} = \frac{z_i^2 e^2 N_A}{8\pi\epsilon_r \epsilon_0 r_i} - \frac{z_i^2 e^2 N_A}{8\pi\epsilon_0 r_i} = -\frac{z_i^2 e^2 N_A}{8\pi\epsilon_0 r_i} \left(1 - \frac{1}{\epsilon_r}\right)$$

which is eqn 3.42.

Further information 3.2 Real gases: the fugacity

At various stages in the development of physical chemistry it is necessary to switch from a consideration of idealized systems to real systems. In many cases it is desirable to preserve the form of the expressions that have been derived for an idealized system. Then deviations from the idealized behaviour can be expressed most simply. For instance, the pressure-dependence of the molar Gibbs energy of a real gas might resemble that shown in Fig. 3.24. To adapt eqn 3.57 to this case, we replace the true pressure, p , by an effective pressure, called the **fugacity**,¹¹ f , and write

$$G_m = G_m^\ominus + RT \ln \frac{f}{p^\ominus} \quad [3.58]$$

The fugacity, a function of the pressure and temperature, is defined so that this relation is exactly true. Although thermodynamic expressions in terms of fugacities derived from this expression are exact, they are useful only if we know how to interpret fugacities in terms of actual pressures. To develop this relation we write the fugacity as

$$f = \phi p \quad [3.59]$$

where ϕ is the dimensionless **fugacity coefficient**, which in general depends on the temperature, the pressure, and the identity of the gas.

Equation 3.54b is true for all gases whether real or perfect.

Expressing it in terms of the fugacity by using eqn 3.58 turns it into

$$\begin{aligned} \int_{p'}^p V_m dp &= G_m(p) - G_m(p') = \left\{ G_m^\ominus + RT \ln \frac{f}{p^\ominus} \right\} - \left\{ G_m^\ominus + RT \ln \frac{f'}{p^\ominus} \right\} \\ &= RT \ln \frac{f}{f'} \end{aligned}$$

In this expression, f is the fugacity when the pressure is p and f' is the fugacity when the pressure is p' . If the gas were perfect, we would write

Fig. 3.24 The molar Gibbs energy of a real gas. As $p \rightarrow 0$, the molar Gibbs energy coincides with the value for a perfect gas (shown by the black line). When attractive forces are dominant (at intermediate pressures), the molar Gibbs energy is less than that of a perfect gas and the molecules have a lower ‘escaping tendency’. At high pressures, when repulsive forces are dominant, the molar Gibbs energy of a real gas is greater than that of a perfect gas. Then the ‘escaping tendency’ is increased.

$$\int_{p'}^p V_{\text{perfect, m}} dp = RT \ln \frac{p}{p'}$$

The difference between the two equations is

$$\begin{aligned} \int_{p'}^p (V_m - V_{\text{perfect, m}}) dp &= RT \left(\ln \frac{f}{f'} - \ln \frac{p}{p'} \right) = RT \ln \left(\frac{f/f'}{p/p'} \right) \\ &= RT \ln \left(\frac{f}{f'} \times \frac{p'}{p} \right) \end{aligned}$$

which can be rearranged into

$$\ln \left(\frac{f}{p} \times \frac{p'}{f'} \right) = \frac{1}{RT} \int_{p'}^p (V_m - V_{\text{perfect, m}}) dp$$

When $p' \rightarrow 0$, the gas behaves perfectly and f' becomes equal to the pressure, p' . Therefore, $f'/p' \rightarrow 1$ as $p' \rightarrow 0$. If we take this limit, which means setting $f'/p' = 1$ on the left and $p' = 0$ on the right, the last equation becomes

$$\ln \frac{f}{p} = \frac{1}{RT} \int_0^p (V_m - V_{\text{perfect, m}}) dp$$

Then, with $\phi = f/p$,

$$\ln \phi = \frac{1}{RT} \int_0^p (V_m - V_{\text{perfect, m}}) dp$$

For a perfect gas, $V_{\text{perfect, m}} = RT/p$. For a real gas, $V_m = RTZ/p$, where Z is the compression factor of the gas (Section 1.3). With these two substitutions, we obtain

¹¹ The name ‘fugacity’ comes from the Latin for ‘fleetness’ in the sense of ‘escaping tendency’; fugacity has the same dimensions as pressure.

Fig. 3.25 The fugacity coefficient of a van der Waals gas plotted using the reduced variables of the gas. The curves are labelled with the reduced temperature $T_r = T/T_c$.

Exploration Evaluate the fugacity coefficient as a function of the reduced volume of a van der Waals gas and plot the outcome for a selection of reduced temperatures over the range $0.8 \leq T_r \leq 3$.

$$\ln \phi = \int_0^p \frac{Z - 1}{p} dp \quad (3.60)$$

Provided we know how Z varies with pressure up to the pressure of interest, this expression enables us to determine the fugacity coefficient and hence, through eqn 3.59, to relate the fugacity to the pressure of the gas.

We see from Fig. 1.14 that for most gases $Z < 1$ up to moderate pressures, but that $Z > 1$ at higher pressures. If $Z < 1$ throughout the range of integration, then the integrand in eqn 3.60 is negative and $\phi < 1$. This value implies that $f < p$ (the molecules tend to stick together) and that the molar Gibbs energy of the gas is less than that of a perfect gas. At higher pressures, the range over which $Z > 1$ may dominate the range over which $Z < 1$. The integral is then positive, $\phi > 1$, and $f > p$ (the repulsive interactions are dominant and tend to drive the particles apart). Now the molar Gibbs energy of the gas is greater than that of the perfect gas at the same pressure.

Figure 3.25, which has been calculated using the full van der Waals equation of state, shows how the fugacity coefficient depends on the

Synoptic table 3.6* The fugacity of nitrogen at 273 K

p/atm	f/atm
1	0.999 55
10	9.9560
100	97.03
1000	1839

* More values are given in the *Data section*.

pressure in terms of the reduced variables (Section 1.5). Because critical constants are available in Table 1.6, the graphs can be used for quick estimates of the fugacities of a wide range of gases. Table 3.6 gives some explicit values for nitrogen.

Discussion questions

3.1 The evolution of life requires the organization of a very large number of molecules into biological cells. Does the formation of living organisms violate the Second Law of thermodynamics? State your conclusion clearly and present detailed arguments to support it.

3.2 You received an unsolicited proposal from a self-declared inventor who is seeking investors for the development of his latest idea: a device that uses heat extracted from the ground by a heat pump to boil water into steam that is used to heat a home and to power a steam engine that drives the heat pump. This procedure is potentially very lucrative because, after an initial extraction of energy from the ground, no fossil fuels would be required to keep the device running indefinitely. Would you invest in this idea? State your conclusion clearly and present detailed arguments to support it.

3.3 The following expressions have been used to establish criteria for spontaneous change: $\Delta S_{\text{tot}} > 0$, $dS_{U,V} \geq 0$ and $dU_{S,V} \leq 0$, $dA_{T,V} \leq 0$,

and $dG_{T,p} \leq 0$. Discuss the origin, significance, and applicability of each criterion.

3.4 The following expressions have been used to establish criteria for reversibility: $dA_{T,V} = 0$ and $dG_{T,p} = 0$. Discuss the origin, significance, and applicability of each criterion.

3.5 Discuss the physical interpretation of any one Maxwell relation.

3.6 Account for the dependence of π_r of a van der Waals gas in terms of the significance of the parameters a and b .

3.7 Suggest a physical interpretation of the dependence of the Gibbs energy on the pressure.

3.8 Suggest a physical interpretation of the dependence of the Gibbs energy on the temperature.

Exercises

Assume that all gases are perfect and that data refer to 298.15 K unless otherwise stated.

3.1(a) Calculate the change in entropy when 25 kJ of energy is transferred reversibly and isothermally as heat to a large block of iron at (a) 0°C, (b) 100°C.

3.1(b) Calculate the change in entropy when 50 kJ of energy is transferred reversibly and isothermally as heat to a large block of copper at (a) 0°C, (b) 70°C.

3.2(a) Calculate the molar entropy of a constant-volume sample of neon at 500 K given that it is $146.22 \text{ J K}^{-1} \text{ mol}^{-1}$ at 298 K.

3.2(b) Calculate the molar entropy of a constant-volume sample of argon at 250 K given that it is $154.84 \text{ J K}^{-1} \text{ mol}^{-1}$ at 298 K.

3.3(a) Calculate ΔS (for the system) when the state of 3.00 mol of perfect gas atoms, for which $C_{p,m} = \frac{5}{2}R$, is changed from 25°C and 1.00 atm to 125°C and 5.00 atm. How do you rationalize the sign of ΔS ?

3.3(b) Calculate ΔS (for the system) when the state of 2.00 mol diatomic perfect gas molecules, for which $C_{p,m} = \frac{7}{2}R$, is changed from 25°C and 1.50 atm to 135°C and 7.00 atm. How do you rationalize the sign of ΔS ?

3.4(a) A sample consisting of 3.00 mol of diatomic perfect gas molecules at 200 K is compressed reversibly and adiabatically until its temperature reaches 250 K. Given that $C_{v,m} = 27.5 \text{ J K}^{-1} \text{ mol}^{-1}$, calculate q , w , ΔU , ΔH , and ΔS .

3.4(b) A sample consisting of 2.00 mol of diatomic perfect gas molecules at 250 K is compressed reversibly and adiabatically until its temperature reaches 300 K. Given that $C_{v,m} = 27.5 \text{ J K}^{-1} \text{ mol}^{-1}$, calculate q , w , ΔU , ΔH , and ΔS .

3.5(a) Calculate ΔH and ΔS_{tot} when two copper blocks, each of mass 10.0 kg, one at 100°C and the other at 0°C, are placed in contact in an isolated container. The specific heat capacity of copper is $0.385 \text{ J K}^{-1} \text{ g}^{-1}$ and may be assumed constant over the temperature range involved.

3.5(b) Calculate ΔH and ΔS_{tot} when two iron blocks, each of mass 1.00 kg, one at 200°C and the other at 25°C, are placed in contact in an isolated container. The specific heat capacity of iron is $0.449 \text{ J K}^{-1} \text{ g}^{-1}$ and may be assumed constant over the temperature range involved.

3.6(a) Consider a system consisting of 2.0 mol $\text{CO}_2(\text{g})$, initially at 25°C and 10 atm and confined to a cylinder of cross-section 10.0 cm^2 . It is allowed to expand adiabatically against an external pressure of 1.0 atm until the piston has moved outwards through 20 cm. Assume that carbon dioxide may be considered a perfect gas with $C_{v,m} = 28.8 \text{ J K}^{-1} \text{ mol}^{-1}$ and calculate (a) q , (b) w , (c) ΔU , (d) ΔT , (e) ΔS .

3.6(b) Consider a system consisting of 1.5 mol $\text{CO}_2(\text{g})$, initially at 15°C and 9.0 atm and confined to a cylinder of cross-section 100.0 cm^2 . The sample is allowed to expand adiabatically against an external pressure of 1.5 atm until the piston has moved outwards through 15 cm. Assume that carbon dioxide may be considered a perfect gas with $C_{v,m} = 28.8 \text{ J K}^{-1} \text{ mol}^{-1}$, and calculate (a) q , (b) w , (c) ΔU , (d) ΔT , (e) ΔS .

3.7(a) The enthalpy of vaporization of chloroform (CHCl_3) is 29.4 kJ mol^{-1} at its normal boiling point of 334.88 K. Calculate (a) the entropy of vaporization of chloroform at this temperature and (b) the entropy change of the surroundings.

3.7(b) The enthalpy of vaporization of methanol is $35.27 \text{ kJ mol}^{-1}$ at its normal boiling point of 64.1°C. Calculate (a) the entropy of vaporization of methanol at this temperature and (b) the entropy change of the surroundings.

3.8(a) Calculate the standard reaction entropy at 298 K of

3.8(b) Calculate the standard reaction entropy at 298 K of

3.9(a) Combine the reaction entropies calculated in Exercise 3.8a with the reaction enthalpies, and calculate the standard reaction Gibbs energies at 298 K.

3.9(b) Combine the reaction entropies calculated in Exercise 3.8b with the reaction enthalpies, and calculate the standard reaction Gibbs energies at 298 K.

3.10(a) Use standard Gibbs energies of formation to calculate the standard reaction Gibbs energies at 298 K of the reactions in Exercise 3.8a.

3.10(b) Use standard Gibbs energies of formation to calculate the standard reaction Gibbs energies at 298 K of the reactions in Exercise 3.8b.

3.11(a) Calculate the standard Gibbs energy of the reaction $4 \text{HCl}(\text{g}) + \text{O}_2(\text{g}) \rightarrow 2 \text{Cl}_2(\text{g}) + 2 \text{H}_2\text{O}(\text{l})$ at 298 K, from the standard entropies and enthalpies of formation given in the *Data section*.

3.11(b) Calculate the standard Gibbs energy of the reaction $\text{CO}(\text{g}) + \text{CH}_3\text{OH}(\text{l}) \rightarrow \text{CH}_3\text{COOH}(\text{l})$ at 298 K, from the standard entropies and enthalpies of formation given in the *Data section*.

3.12(a) The standard enthalpy of combustion of solid phenol ($\text{C}_6\text{H}_5\text{OH}$) is $-3054 \text{ kJ mol}^{-1}$ at 298 K and its standard molar entropy is $144.0 \text{ J K}^{-1} \text{ mol}^{-1}$. Calculate the standard Gibbs energy of formation of phenol at 298 K.

3.12(b) The standard enthalpy of combustion of solid urea ($\text{CO}(\text{NH}_2)_2$) is -632 kJ mol^{-1} at 298 K and its standard molar entropy is $104.60 \text{ J K}^{-1} \text{ mol}^{-1}$. Calculate the standard Gibbs energy of formation of urea at 298 K.

3.13(a) Calculate the change in the entropies of the system and the surroundings, and the total change in entropy, when a sample of nitrogen gas of mass 14 g at 298 K and 1.00 bar doubles its volume in (a) an isothermal reversible expansion, (b) an isothermal irreversible expansion against $p_{\text{ex}} = 0$, and (c) an adiabatic reversible expansion.

3.13(b) Calculate the change in the entropies of the system and the surroundings, and the total change in entropy, when the volume of a sample of argon gas of mass 21 g at 298 K and 1.50 bar increases from 1.20 dm^3 to 4.60 dm^3 in (a) an isothermal reversible expansion, (b) an isothermal irreversible expansion against $p_{\text{ex}} = 0$, and (c) an adiabatic reversible expansion.

3.14(a) Calculate the maximum non-expansion work per mole that may be obtained from a fuel cell in which the chemical reaction is the combustion of methane at 298 K.

3.14(b) Calculate the maximum non-expansion work per mole that may be obtained from a fuel cell in which the chemical reaction is the combustion of propane at 298 K.

3.15(a) (a) Calculate the Carnot efficiency of a primitive steam engine operating on steam at 100°C and discharging at 60°C. (b) Repeat the calculation for a modern steam turbine that operates with steam at 300°C and discharges at 80°C.

3.15(b) A certain heat engine operates between 1000 K and 500 K. (a) What is the maximum efficiency of the engine? (b) Calculate the maximum work that can be done by for each 1.0 kJ of heat supplied by the hot source. (c) How much heat is discharged into the heat sink in a reversible process for each 1.0 kJ supplied by the hot source?

3.16(a) Suppose that 3.0 mmol $\text{N}_2(\text{g})$ occupies 36 cm^3 at 300 K and expands to 60 cm^3 . Calculate ΔG for the process.

3.16(b) Suppose that 2.5 mmol $\text{Ar}(\text{g})$ occupies 72 dm^3 at 298 K and expands to 100 dm^3 . Calculate ΔG for the process.

3.17(a) The change in the Gibbs energy of a certain constant-pressure process was found to fit the expression $\Delta G/J = -85.40 + 36.5(T/K)$. Calculate the value of ΔS for the process.

3.17(b) The change in the Gibbs energy of a certain constant-pressure process was found to fit the expression $\Delta G/J = -73.1 + 42.8(T/K)$. Calculate the value of ΔS for the process.

3.18(a) Calculate the change in Gibbs energy of 35 g of ethanol (mass density 0.789 g cm^{-3}) when the pressure is increased isothermally from 1 atm to 3000 atm.

3.18(b) Calculate the change in Gibbs energy of 25 g of methanol (mass density 0.791 g cm^{-3}) when the pressure is increased isothermally from 100 kPa to 100 MPa.

3.19(a) Calculate the change in chemical potential of a perfect gas when its pressure is increased isothermally from 1.8 atm to 29.5 atm at 40°C .

3.19(b) Calculate the change in chemical potential of a perfect gas when its pressure is increased isothermally from 92.0 kPa to 252.0 kPa at 50°C .

3.20(a) The fugacity coefficient of a certain gas at 200 K and 50 bar is 0.72. Calculate the difference of its molar Gibbs energy from that of a perfect gas in the same state.

3.20(b) The fugacity coefficient of a certain gas at 290 K and 2.1 MPa is 0.68. Calculate the difference of its molar Gibbs energy from that of a perfect gas in the same state.

3.21(a) Estimate the change in the Gibbs energy of 1.0 dm^3 of benzene when the pressure acting on it is increased from 1.0 atm to 100 atm.

3.21(b) Estimate the change in the Gibbs energy of 1.0 dm^3 of water when the pressure acting on it is increased from 100 kPa to 300 kPa.

3.22(a) Calculate the change in the molar Gibbs energy of hydrogen gas when its pressure is increased isothermally from 1.0 atm to 100.0 atm at 298 K.

3.22(b) Calculate the change in the molar Gibbs energy of oxygen when its pressure is increased isothermally from 50.0 kPa to 100.0 kPa at 500 K.

Problems*

Assume that all gases are perfect and that data refer to 298 K unless otherwise stated.

Numerical problems

3.1 Calculate the difference in molar entropy (a) between liquid water and ice at -5°C , (b) between liquid water and its vapour at 95°C and 1.00 atm. The differences in heat capacities on melting and on vaporization are $37.3 \text{ J K}^{-1} \text{ mol}^{-1}$ and $-41.9 \text{ J K}^{-1} \text{ mol}^{-1}$, respectively. Distinguish between the entropy changes of the sample, the surroundings, and the total system, and discuss the spontaneity of the transitions at the two temperatures.

3.2 The heat capacity of chloroform (trichloromethane, CHCl_3) in the range 240 K to 330 K is given by $C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1}) = 91.47 + 7.5 \times 10^{-2}(T/\text{K})$. In a particular experiment, 1.00 mol CHCl_3 is heated from 273 K to 300 K. Calculate the change in molar entropy of the sample.

3.3 A block of copper of mass 2.00 kg ($C_{p,m} = 24.44 \text{ J K}^{-1} \text{ mol}^{-1}$) and temperature 0°C is introduced into an insulated container in which there is 1.00 mol $\text{H}_2\text{O}(\text{g})$ at 100°C and 1.00 atm. (a) Assuming all the steam is condensed to water, what will be the final temperature of the system, the heat transferred from water to copper, and the entropy change of the water, copper, and the total system? (b) In fact, some water vapour is present at equilibrium. From the vapour pressure of water at the temperature calculated in (a), and assuming that the heat capacities of both gaseous and liquid water are constant and given by their values at that temperature, obtain an improved value of the final temperature, the heat transferred, and the various entropies. (Hint. You will need to make plausible approximations.)

3.4 Consider a perfect gas contained in a cylinder and separated by a frictionless adiabatic piston into two sections A and B. All changes in B isothermal; that is, a thermostat surrounds B to keep its temperature constant. There is 2.00 mol of the gas in each section. Initially, $T_A = T_B = 300 \text{ K}$, $V_A = V_B$

$= 2.00 \text{ dm}^3$. Energy is supplied as heat to Section A and the piston moves to the right reversibly until the final volume of Section B is 1.00 dm^3 . Calculate (a) ΔS_A and ΔS_B , (b) ΔA_A and ΔA_B , (c) ΔG_A and ΔG_B , (d) ΔS of the total system and its surroundings. If numerical values cannot be obtained, indicate whether the values should be positive, negative, or zero or are indeterminate from the information given. (Assume $C_{V,m} = 20 \text{ J K}^{-1} \text{ mol}^{-1}$.)

3.5 A Carnot cycle uses 1.00 mol of a monatomic perfect gas as the working substance from an initial state of 10.0 atm and 600 K. It expands isothermally to a pressure of 1.00 atm (Step 1), and then adiabatically to a temperature of 300 K (Step 2). This expansion is followed by an isothermal compression (Step 3), and then an adiabatic compression (Step 4) back to the initial state. Determine the values of q , w , ΔU , ΔH , ΔS , ΔS_{tot} , and ΔG for each stage of the cycle and for the cycle as a whole. Express your answer as a table of values.

3.6 1.00 mol of perfect gas molecules at 27°C is expanded isothermally from an initial pressure of 3.00 atm to a final pressure of 1.00 atm in two ways: (a) reversibly, and (b) against a constant external pressure of 1.00 atm. Determine the values of q , w , ΔU , ΔH , ΔS , ΔS_{sur} , ΔS_{tot} for each path.

3.7 The standard molar entropy of $\text{NH}_3(\text{g})$ is $192.45 \text{ J K}^{-1} \text{ mol}^{-1}$ at 298 K, and its heat capacity is given by eqn 2.25 with the coefficients given in Table 2.2. Calculate the standard molar entropy at (a) 100°C and (b) 500°C .

3.8 A block of copper of mass 500 g and initially at 293 K is in thermal contact with an electric heater of resistance $1.00 \text{ k}\Omega$ and negligible mass. A current of 1.00 A is passed for 15.0 s. Calculate the change in entropy of the copper, taking $C_{p,m} = 24.4 \text{ J K}^{-1} \text{ mol}^{-1}$. The experiment is then repeated with the copper immersed in a stream of water that maintains its temperature at 293 K. Calculate the change in entropy of the copper and the water in this case.

3.9 Find an expression for the change in entropy when two blocks of the same substance and of equal mass, one at the temperature T_1 and the other at T_2 , are brought into thermal contact and allowed to reach equilibrium. Evaluate the

* Problems denoted with the symbol ‡ were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

change for two blocks of copper, each of mass 500 g, with $C_{p,m} = 24.4 \text{ J K}^{-1} \text{ mol}^{-1}$, taking $T_h = 500 \text{ K}$ and $T_c = 250 \text{ K}$.

3.10 A gaseous sample consisting of 1.00 mol molecules is described by the equation of state $pV_m = RT(1 + Bp)$. Initially at 373 K, it undergoes Joule–Thomson expansion from 100 atm to 1.00 atm. Given that $C_{p,m} = \frac{5}{2}R$, $\mu = 0.21 \text{ K atm}^{-1}$, $B = -0.525(\text{K}/T) \text{ atm}^{-1}$, and that these are constant over the temperature range involved, calculate ΔT and ΔS for the gas.

3.11 The molar heat capacity of lead varies with temperature as follows:

T/K	10	15	20	25	30	50
$C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$	2.8	7.0	10.8	14.1	16.5	21.4
T/K	70	100	150	200	250	298
$C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$	23.3	24.5	25.3	25.8	26.2	26.6

Calculate the standard Third-Law entropy of lead at (a) 0°C and (b) 25°C .

3.12 From standard enthalpies of formation, standard entropies, and standard heat capacities available from tables in the *Data section*, calculate the standard enthalpies and entropies at 298 K and 398 K for the reaction $\text{CO}_2(\text{g}) + \text{H}_2(\text{g}) \rightarrow \text{CO}(\text{g}) + \text{H}_2\text{O}(\text{g})$. Assume that the heat capacities are constant over the temperature range involved.

3.13 The heat capacity of anhydrous potassium hexacyanoferrate(II) varies with temperature as follows:

T/K	$C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$	T/K	$C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$
10	2.09	100	179.6
20	14.43	110	192.8
30	36.44	150	237.6
40	62.55	160	247.3
50	87.03	170	256.5
60	111.0	180	265.1
70	131.4	190	273.0
80	149.4	200	280.3
90	165.3		

Calculate the molar enthalpy relative to its value at $T = 0$ and the Third-Law entropy at each of these temperatures.

3.14 The compound 1,3,5-trichloro-2,4,6-trifluorobenzene is an intermediate in the conversion of hexachlorobenzene to hexafluorobenzene, and its thermodynamic properties have been examined by measuring its heat capacity over a wide temperature range (R.L. Andon and J.F. Martin, *J. Chem. Soc. Faraday Trans. I* 871 (1973)). Some of the data are as follows:

T/K	14.14	16.33	20.03	31.15	44.08	64.81
$C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$	9.492	12.70	18.18	32.54	46.86	66.36
T/K	100.90	140.86	183.59	225.10	262.99	298.06
$C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$	95.05	121.3	144.4	163.7	180.2	196.4

Calculate the molar enthalpy relative to its value at $T = 0$ and the Third-Law molar entropy of the compound at these temperatures.

3.15† Given that $S_m^\circ = 29.79 \text{ J K}^{-1} \text{ mol}^{-1}$ for bismuth at 100 K and the following tabulated heat capacities data (D.G. Archer, *J. Chem. Eng. Data* 40, 1015 (1995)), compute the standard molar entropy of bismuth at 200 K.

T/K	100	120	140	150	160	180	200
$C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$	23.00	23.74	24.25	24.44	24.61	24.89	25.11

Compare the value to the value that would be obtained by taking the heat capacity to be constant at $24.44 \text{ J K}^{-1} \text{ mol}^{-1}$ over this range.

3.16 Calculate $\Delta_r G^\circ(375 \text{ K})$ for the reaction $2 \text{CO}(\text{g}) + \text{O}_2(\text{g}) \rightarrow 2 \text{CO}_2(\text{g})$ from the value of $\Delta_r G^\circ(298 \text{ K})$, $\Delta_r H^\circ(298 \text{ K})$, and the Gibbs–Helmholtz equation.

3.17 Estimate the standard reaction Gibbs energy of $\text{N}_2(\text{g}) + 3 \text{H}_2(\text{g}) \rightarrow 2 \text{NH}_3(\text{g})$ at (a) 500 K, (b) 1000 K from their values at 298 K.

3.18 At 200 K, the compression factor of oxygen varies with pressure as shown below. Evaluate the fugacity of oxygen at this temperature and 100 atm.

p/atm	1.0000	4.00000	7.00000	10.0000	40.00	70.00	100.0
Z	0.9971	0.98796	0.97880	0.96956	0.8734	0.7764	0.6871

Theoretical problems

3.19 Represent the Carnot cycle on a temperature–entropy diagram and show that the area enclosed by the cycle is equal to the work done.

3.20 Prove that two reversible adiabatic paths can never cross. Assume that the energy of the system under consideration is a function of temperature only. (*Hint*. Suppose that two such paths can intersect, and complete a cycle with the two paths plus one isothermal path. Consider the changes accompanying each stage of the cycle and show that they conflict with the Kelvin statement of the Second Law.)

3.21 Prove that the perfect gas temperature scale and the thermodynamic temperature scale based on the Second Law of thermodynamics differ from each other by at most a constant numerical factor.

3.22 The molar Gibbs energy of a certain gas is given by $G_m = RT \ln p + A + Bp + \frac{1}{2}Cp^2 + \frac{1}{3}Dp^3$, where A , B , C , and D are constants. Obtain the equation of state of the gas.

3.23 Evaluate $(\partial S/\partial V)_T$ for (a) a van der Waals gas, (b) a Dieterici gas (Table 1.7). For an isothermal expansion, for which kind of gas (and a perfect gas) will ΔS be greatest? Explain your conclusion.

3.24 Show that, for a perfect gas, $(\partial U/\partial S)_V = T$ and $(\partial U/\partial V)_S = -p$.

3.25 Two of the four Maxwell relations were derived in the text, but two were not. Complete their derivation by showing that $(\partial S/\partial T)_V = (\partial p/\partial T)_V$ and $(\partial T/\partial p)_S = (\partial V/\partial S)_p$.

3.26 Use the Maxwell relations to express the derivatives (a) $(\partial S/\partial V)_T$ and $(\partial V/\partial S)_p$ and (b) $(\partial p/\partial S)_V$ and $(\partial V/\partial S)_p$ in terms of the heat capacities, the expansion coefficient α , and the isothermal compressibility, κ_T .

3.27 Use the Maxwell relations to show that the entropy of a perfect gas depends on the volume as $S \propto R \ln V$.

3.28 Derive the thermodynamic equation of state

$$\left(\frac{\partial H}{\partial p}\right)_T = V - T \left(\frac{\partial V}{\partial T}\right)_p$$

Derive an expression for $(\partial H/\partial p)_T$ for (a) a perfect gas and (b) a van der Waals gas. In the latter case, estimate its value for 1.0 mol Ar(g) at 298 K and 10 atm. By how much does the enthalpy of the argon change when the pressure is increased isothermally to 11 atm?

3.29 Show that if $B(T)$ is the second virial coefficient of a gas, and $\Delta B = B(T'') - B(T')$, $\Delta T = T'' - T'$, and T is the mean of T'' and T' , then $\pi_T \approx RT^2 \Delta B/V_m^2 \Delta T$. Estimate π_T for argon given that $B(250 \text{ K}) = -28.0 \text{ cm}^3 \text{ mol}^{-1}$ and $B(300 \text{ K}) = -15.6 \text{ cm}^3 \text{ mol}^{-1}$ at 275 K at (a) 1.0 atm, (b) 10.0 atm.

3.30 The Joule coefficient, μ_J , is defined as $\mu_J = (\partial T/\partial V)_U$. Show that $\mu_J C_V = p - \alpha T/\kappa_T$.

3.31 Evaluate π_T for a Dieterici gas (Table 1.7). Justify physically the form of the expression obtained.

3.32 The adiabatic compressibility, κ_S , is defined like κ_T (eqn 2.44) but at constant entropy. Show that for a perfect gas $p\gamma\kappa_S = 1$ (where γ is the ratio of heat capacities).

3.33 Suppose that S is regarded as a function of p and T . Show that $TdS = C_p dT - \alpha TV dp$. Hence, show that the energy transferred as heat when the pressure on an incompressible liquid or solid is increased by Δp is equal to $-\alpha TV \Delta p$. Evaluate q when the pressure acting on 100 cm³ of mercury at 0°C is increased by 1.0 kbar. ($\alpha = 1.82 \times 10^{-4} \text{ K}^{-1}$.)

3.34 Suppose that (a) the attractive interactions between gas particles can be neglected, (b) the attractive interaction is dominant in a van der Waals gas, and the pressure is low enough to make the approximation $4ap/(RT)^2 \ll 1$. Find expressions for the fugacity of a van der Waals gas in terms of the pressure and estimate its value for ammonia at 10.00 atm and 298.15 K in each case.

3.35 Find an expression for the fugacity coefficient of a gas that obeys the equation of state $pV_m = RT(1 + B/V_m + C/V_m^2)$. Use the resulting expression to estimate the fugacity of argon at 1.00 atm and 100 K using $B = -21.13 \text{ cm}^3 \text{ mol}^{-1}$ and $C = 1054 \text{ cm}^6 \text{ mol}^{-2}$.

Applications: to biology, environmental science, polymer science, and engineering

3.36 The protein lysozyme unfolds at a transition temperature of 75.5°C and the standard enthalpy of transition is 509 kJ mol⁻¹. Calculate the entropy of unfolding of lysozyme at 25.0°C, given that the difference in the constant-pressure heat capacities upon unfolding is 6.28 kJ K⁻¹ mol⁻¹ and can be assumed to be independent of temperature. *Hint.* Imagine that the transition at 25.0°C occurs in three steps: (i) heating of the folded protein from 25.0°C to the transition temperature, (ii) unfolding at the transition temperature, and (iii) cooling of the unfolded protein to 25.0°C. Because the entropy is a state function, the entropy change at 25.0°C is equal to the sum of the entropy changes of the steps.

3.37 At 298 K the standard enthalpy of combustion of sucrose is -5797 kJ mol⁻¹ and the standard Gibbs energy of the reaction is -6333 kJ mol⁻¹. Estimate the additional non-expansion work that may be obtained by raising the temperature to blood temperature, 37°C.

3.38 In biological cells, the energy released by the oxidation of foods (*Impact on Biology I2.2*) is stored in adenosine triphosphate (ATP or ATP⁴⁻). The essence of ATP's action is its ability to lose its terminal phosphate group by hydrolysis and to form adenosine diphosphate (ADP or ADP³⁻):

At pH = 7.0 and 37°C (310 K, blood temperature) the enthalpy and Gibbs energy of hydrolysis are $\Delta_r H = -20 \text{ kJ mol}^{-1}$ and $\Delta_r G = -31 \text{ kJ mol}^{-1}$, respectively. Under these conditions, the hydrolysis of 1 mol ATP⁴⁻(aq) results in the extraction of up to 31 kJ of energy that can be used to do non-expansion work, such as the synthesis of proteins from amino acids, muscular contraction, and the activation of neuronal circuits in our brains. (a) Calculate and account for the sign of the entropy of hydrolysis of ATP at pH = 7.0 and 310 K. (b) Suppose that the radius of a typical biological cell is 10 μm and that inside it 10⁶ ATP molecules are hydrolysed each second. What is the power density of the cell in watts per cubic metre (1 W = 1 J s⁻¹)? A computer battery delivers about 15 W and has a volume of 100 cm³. Which has the greater power density, the cell or the battery? (c) The formation of glutamine from glutamate and ammonium ions requires 14.2 kJ mol⁻¹ of energy input. It is driven by the hydrolysis of ATP to ADP mediated by the enzyme glutamine synthetase. How many moles of ATP must be hydrolysed to form 1 mol glutamine?

3.39† In 1995, the Intergovernmental Panel on Climate Change (IPCC) considered a global average temperature rise of 1.0–3.5°C likely by the year 2100, with 2.0°C its best estimate. Because water vapour is itself a greenhouse gas, the increase in water vapour content of the atmosphere is of some concern to climate change experts. Predict the relative increase in water

vapour in the atmosphere based on a temperature rise of 2.0 K, assuming that the relative humidity remains constant. (The present global mean temperature is 290 K, and the equilibrium vapour pressure of water at that temperature is 0.0189 bar.)

3.40† Nitric acid hydrates have received much attention as possible catalysts for heterogeneous reactions that bring about the Antarctic ozone hole. Worsnop *et al.* investigated the thermodynamic stability of these hydrates under conditions typical of the polar winter stratosphere (D. R. Worsnop, L. E. Fox, M. S. Zahniser, and S. C. Wofsy, *Science* **259**, 71 (1993)). They report thermodynamic data for the sublimation of mono-, di-, and trihydrates to nitric acid and water vapours, $\text{HNO}_3 \cdot n\text{H}_2\text{O}(\text{s}) \rightarrow \text{HNO}_3(\text{g}) + n\text{H}_2\text{O}(\text{g})$, for $n = 1, 2$, and 3. Given $\Delta_r G^\circ$ and $\Delta_r H^\circ$ for these reactions at 220 K, use the Gibbs–Helmholtz equation to compute $\Delta_r G^\circ$ at 190 K.

n	1	2	3
$\Delta_r G^\circ/(\text{kJ mol}^{-1})$	46.2	69.4	93.2
$\Delta_r H^\circ/(\text{kJ mol}^{-1})$	127	188	237

3.41† J. Gao and J. H. Weiner in their study of the origin of stress on the atomic level in dense polymer systems (*Science* **266**, 748 (1994)), observe that the tensile force required to maintain the length, l , of a long linear chain of N freely jointed links each of length a , can be interpreted as arising from an entropic spring. For such a chain, $S(l) = -3kl^2/2Na^2 + C$, where k is the Boltzmann constant and C is a constant. Using thermodynamic relations of this and previous chapters, show that the tensile force obeys Hooke's law, $f = -k_t l$, if we assume that the energy U is independent of l .

3.42 Suppose that an internal combustion engine runs on octane, for which the enthalpy of combustion is -5512 kJ mol⁻¹ and take the mass of 1 gallon of fuel as 3 kg. What is the maximum height, neglecting all forms of friction, to which a car of mass 1000 kg can be driven on 1.00 gallon of fuel given that the engine cylinder temperature is 2000°C and the exit temperature is 800°C?

3.43 The cycle involved in the operation of an internal combustion engine is called the *Otto cycle*. Air can be considered to be the working substance and can be assumed to be a perfect gas. The cycle consists of the following steps: (1) reversible adiabatic compression from A to B, (2) reversible constant-volume pressure increase from B to C due to the combustion of a small amount of fuel, (3) reversible adiabatic expansion from C to D, and (4) reversible and constant-volume pressure decrease back to state A. Determine the change in entropy (of the system and of the surroundings) for each step of the cycle and determine an expression for the efficiency of the cycle, assuming that the heat is supplied in Step 2. Evaluate the efficiency for a compression ratio of 10:1. Assume that, in state A, $V = 4.00 \text{ dm}^3$, $p = 1.00 \text{ atm}$, and $T = 300 \text{ K}$, that $V_A = 10V_B$, $p_C/p_B = 5$, and that $C_{p,m} = \frac{7}{2}R$.

3.44 To calculate the work required to lower the temperature of an object, we need to consider how the coefficient of performance changes with the temperature of the object. (a) Find an expression for the work of cooling an object from T_i to T_f when the refrigerator is in a room at a temperature T_h . *Hint.* Write $dw = dq/c(T)$, relate dq to dT through the heat capacity C_p , and integrate the resulting expression. Assume that the heat capacity is independent of temperature in the range of interest. (b) Use the result in part (a) to calculate the work needed to freeze 250 g of water in a refrigerator at 293 K. How long will it take when the refrigerator operates at 100 W?

3.45 The expressions that apply to the treatment of refrigerators also describe the behaviour of heat pumps, where warmth is obtained from the back of a refrigerator while its front is being used to cool the outside world. Heat pumps are popular home heating devices because they are very efficient. Compare heating of a room at 295 K by each of two methods: (a) direct conversion of 1.00 kJ of electrical energy in an electrical heater, and (b) use of 1.00 kJ of electrical energy to run a reversible heat pump with the outside at 260 K. Discuss the origin of the difference in the energy delivered to the interior of the house by the two methods.

Physical transformations of pure substances

4

The discussion of the phase transitions of pure substances is among the simplest applications of thermodynamics to chemistry. We shall see that a phase diagram is a map of the pressures and temperatures at which each phase of a substance is the most stable. First, we describe the interpretation of empirically determined phase diagrams for a selection of materials. Then we turn to a consideration of the factors that determine the positions and shapes of the boundaries between the regions on a phase diagram. The practical importance of the expressions we derive is that they show how the vapour pressure of a substance varies with temperature and how the melting point varies with pressure. We shall see that the transitions between phases can be classified by noting how various thermodynamic functions change when the transition occurs. This chapter also introduces the chemical potential, a property that is at the centre of discussions of phase transitions and chemical reactions.

Vaporization, melting, and the conversion of graphite to diamond are all examples of changes of phase without change of chemical composition. In this chapter we describe such processes thermodynamically, using as the guiding principle the tendency of systems at constant temperature and pressure to minimize their Gibbs energy.

Phase diagrams

One of the most succinct ways of presenting the physical changes of state that a substance can undergo is in terms of its phase diagram. We present the concept in this section.

4.1 The stabilities of phases

A **phase** of a substance is a form of matter that is uniform throughout in chemical composition and physical state. Thus, we speak of solid, liquid, and gas phases of a substance, and of its various solid phases, such as the white and black allotropes of phosphorus. A **phase transition**, the spontaneous conversion of one phase into another phase, occurs at a characteristic temperature for a given pressure. Thus, at 1 atm, ice is the stable phase of water below 0°C, but above 0°C liquid water is more stable. This difference indicates that below 0°C the Gibbs energy decreases as liquid water changes into ice and that above 0°C the Gibbs energy decreases as ice changes into liquid water. The **transition temperature**, T_{trs} , is the temperature at which the two phases are in equilibrium and the Gibbs energy is minimized at the prevailing pressure.

Problems

Fig. 4.1 The general regions of pressure and temperature where solid, liquid, or gas is stable (that is, has minimum molar Gibbs energy) are shown on this phase diagram. For example, the solid phase is the most stable phase at low temperatures and high pressures. In the following paragraphs we locate the precise boundaries between the regions.

Fig. 4.2 The vapour pressure of a liquid or solid is the pressure exerted by the vapour in equilibrium with the condensed phase.

Comment 4.1

The *NIST Chemistry WebBook* is a good source of links to online databases of data on phase transitions.

As we stressed at the beginning of Chapter 3, we must distinguish between the thermodynamic description of a phase transition and the rate at which the transition occurs. A transition that is predicted from thermodynamics to be spontaneous may occur too slowly to be significant in practice. For instance, at normal temperatures and pressures the molar Gibbs energy of graphite is lower than that of diamond, so there is a thermodynamic tendency for diamond to change into graphite. However, for this transition to take place, the C atoms must change their locations, which is an immeasurably slow process in a solid except at high temperatures. The discussion of the rate of attainment of equilibrium is a kinetic problem and is outside the range of thermodynamics. In gases and liquids the mobilities of the molecules allow phase transitions to occur rapidly, but in solids thermodynamic instability may be frozen in. Thermodynamically unstable phases that persist because the transition is kinetically hindered are called **metastable phases**. Diamond is a metastable phase of carbon under normal conditions.

4.2 Phase boundaries

The **phase diagram** of a substance shows the regions of pressure and temperature at which its various phases are thermodynamically stable (Fig. 4.1). The lines separating the regions, which are called **phase boundaries**, show the values of p and T at which two phases coexist in equilibrium.

Consider a liquid sample of a pure substance in a closed vessel. The pressure of a vapour in equilibrium with the liquid is called the **vapour pressure** of the substance (Fig. 4.2). Therefore, the liquid–vapour phase boundary in a phase diagram shows how the vapour pressure of the liquid varies with temperature. Similarly, the solid–vapour phase boundary shows the temperature variation of the **sublimation vapour pressure**, the vapour pressure of the solid phase. The vapour pressure of a substance increases with temperature because at higher temperatures more molecules have sufficient energy to escape from their neighbours.

(a) Critical points and boiling points

When a liquid is heated in an open vessel, the liquid vaporizes from its surface. At the temperature at which its vapour pressure would be equal to the external pressure, vaporization can occur throughout the bulk of the liquid and the vapour can expand freely into the surroundings. The condition of free vaporization throughout the liquid is called **boiling**. The temperature at which the vapour pressure of a liquid is equal to the external pressure is called the **boiling temperature** at that pressure. For the special case of an external pressure of 1 atm, the boiling temperature is called the **normal boiling point**, T_b . With the replacement of 1 atm by 1 bar as standard pressure, there is some advantage in using the **standard boiling point** instead: this is the temperature at which the vapour pressure reaches 1 bar. Because 1 bar is slightly less than 1 atm (1.00 bar = 0.987 atm), the standard boiling point of a liquid is slightly lower than its normal boiling point. The normal boiling point of water is 100.0°C; its standard boiling point is 99.6°C.

Boiling does not occur when a liquid is heated in a rigid, closed vessel. Instead, the vapour pressure, and hence the density of the vapour, rise as the temperature is raised (Fig. 4.3). At the same time, the density of the liquid decreases slightly as a result of its expansion. There comes a stage when the density of the vapour is equal to that of the remaining liquid and the surface between the two phases disappears. The temperature at which the surface disappears is the **critical temperature**, T_c , of the substance. We first encountered this property in Section 1.3d. The vapour pressure at the critical temperature is called the **critical pressure**, p_c . At and above the critical temperature, a single uniform phase called a **supercritical fluid** fills the container and an interface no

longer exists. That is, above the critical temperature, the liquid phase of the substance does not exist.

(b) Melting points and triple points

The temperature at which, under a specified pressure, the liquid and solid phases of a substance coexist in equilibrium is called the **melting temperature**. Because a substance melts at exactly the same temperature as it freezes, the melting temperature of a substance is the same as its **freezing temperature**. The freezing temperature when the pressure is 1 atm is called the **normal freezing point**, T_f , and its freezing point when the pressure is 1 bar is called the **standard freezing point**. The normal and standard freezing points are negligibly different for most purposes. The normal freezing point is also called the **normal melting point**.

There is a set of conditions under which three different phases of a substance (typically solid, liquid, and vapour) all simultaneously coexist in equilibrium. These conditions are represented by the **triple point**, a point at which the three phase boundaries meet. The temperature at the triple point is denoted T_3 . The triple point of a pure substance is outside our control: it occurs at a single definite pressure and temperature characteristic of the substance. The triple point of water lies at 273.16 K and 611 Pa (6.11 mbar, 4.58 Torr), and the three phases of water (ice, liquid water, and water vapour) coexist in equilibrium at no other combination of pressure and temperature. This invariance of the triple point is the basis of its use in the definition of the thermodynamic temperature scale (Section 3.2c).

As we can see from Fig. 4.1, the triple point marks the lowest pressure at which a liquid phase of a substance can exist. If (as is common) the slope of the solid–liquid phase boundary is as shown in the diagram, then the triple point also marks the lowest temperature at which the liquid can exist; the critical temperature is the upper limit.

Fig. 4.3 (a) A liquid in equilibrium with its vapour. (b) When a liquid is heated in a sealed container, the density of the vapour phase increases and that of the liquid decreases slightly. There comes a stage, (c), at which the two densities are equal and the interface between the fluids disappears. This disappearance occurs at the critical temperature. The container needs to be strong: the critical temperature of water is 374°C and the vapour pressure is then 218 atm.

IMPACT ON CHEMICAL ENGINEERING AND TECHNOLOGY

14.1 Supercritical fluids

Supercritical carbon dioxide, scCO_2 , is the centre of attention for an increasing number of solvent-based processes. The critical temperature of CO_2 , 304.2 K (31.0°C) and its critical pressure, 72.9 atm, are readily accessible, it is cheap, and it can readily be recycled. The density of scCO_2 at its critical point is 0.45 g cm^{-3} . However, the transport properties of any supercritical fluid depend strongly on its density, which in turn is sensitive to the pressure and temperature. For instance, densities may be adjusted from a gas-like 0.1 g cm^{-3} to a liquid-like 1.2 g cm^{-3} . A useful rule of thumb is that the solubility of a solute is an exponential function of the density of the supercritical fluid, so small increases in pressure, particularly close to the critical point, can have very large effects on solubility.

A great advantage of scCO_2 is that there are no noxious residues once the solvent has been allowed to evaporate, so, coupled with its low critical temperature, scCO_2 is ideally suited to food processing and the production of pharmaceuticals. It is used, for instance, to remove caffeine from coffee. The supercritical fluid is also increasingly being used for dry cleaning, which avoids the use of carcinogenic and environmentally deleterious chlorinated hydrocarbons.

Supercritical CO_2 has been used since the 1960s as a mobile phase in *supercritical fluid chromatography* (SFC), but it fell out of favour when the more convenient technique of high-performance liquid chromatography (HPLC) was introduced. However, interest in SFC has returned, and there are separations possible in SFC that cannot easily be achieved by HPLC, such as the separation of lipids and of phospholipids. Samples as small as 1 pg can be analysed. The essential advantage of SFC is that diffusion coefficients in supercritical fluids are an order of magnitude greater than in

liquids, so there is less resistance to the transfer of solutes through the column, with the result that separations may be effected rapidly or with high resolution.

The principal problem with scCO_2 , though, is that the fluid is not a very good solvent and surfactants are needed to induce many potentially interesting solutes to dissolve. Indeed, scCO_2 -based dry cleaning depends on the availability of cheap surfactants; so too does the use of scCO_2 as a solvent for homogeneous catalysts, such as metal complexes. There appear to be two principal approaches to solving the solubilization problem. One solution is to use fluorinated and siloxane-based polymeric stabilizers, which allow polymerization reactions to proceed in scCO_2 . The disadvantage of these stabilizers for commercial use is their great expense. An alternative and much cheaper approach is poly(ether-carbonate) copolymers. The copolymers can be made more soluble in scCO_2 by adjusting the ratio of ether and carbonate groups.

The critical temperature of water is 374°C and its pressure is 218 atm. The conditions for using scH_2O are therefore much more demanding than for scCO_2 and the properties of the fluid are highly sensitive to pressure. Thus, as the density of scH_2O decreases, the characteristics of a solution change from those of an aqueous solution through those of a non-aqueous solution and eventually to those of a gaseous solution. One consequence is that reaction mechanisms may change from those involving ions to those involving radicals.

4.3 Three typical phase diagrams

We shall now see how these general features appear in the phase diagrams of pure substances.

(a) Carbon dioxide

The phase diagram for carbon dioxide is shown in Fig. 4.4. The features to notice include the positive slope of the solid–liquid boundary (the direction of this line is characteristic of most substances), which indicates that the melting temperature of solid carbon dioxide rises as the pressure is increased. Notice also that, as the triple point lies above 1 atm, the liquid cannot exist at normal atmospheric pressures whatever the temperature, and the solid sublimes when left in the open (hence the name ‘dry ice’). To obtain the liquid, it is necessary to exert a pressure of at least 5.11 atm. Cylinders of carbon dioxide generally contain the liquid or compressed gas; at 25°C that implies a vapour pressure of 67 atm if both gas and liquid are present in equilibrium. When the gas squirts through the throttle it cools by the Joule–Thomson effect, so when it emerges into a region where the pressure is only 1 atm, it condenses into a finely divided snow-like solid.

(b) Water

Figure 4.5 is the phase diagram for water. The liquid–vapour boundary in the phase diagram summarizes how the vapour pressure of liquid water varies with temperature. It also summarizes how the boiling temperature varies with pressure: we simply read off the temperature at which the vapour pressure is equal to the prevailing atmospheric pressure. The solid–liquid boundary shows how the melting temperature varies with the pressure. Its very steep slope indicates that enormous pressures are needed to bring about significant changes. Notice that the line has a negative slope up to 2 kbar, which means that the melting temperature falls as the pressure is raised. The reason for this almost unique behaviour can be traced to the decrease in volume that occurs on melting, and hence it being more favourable for the solid to transform into the liquid as the pressure is raised. The decrease in volume is a result of the very

Fig. 4.4 The experimental phase diagram for carbon dioxide. Note that, as the triple point lies at pressures well above atmospheric, liquid carbon dioxide does not exist under normal conditions (a pressure of at least 5.11 atm must be applied).

Fig. 4.5 The experimental phase diagram for water showing the different solid phases.

open molecular structure of ice: as shown in Fig 4.6, the water molecules are held apart, as well as together, by the hydrogen bonds between them but the structure partially collapses on melting and the liquid is denser than the solid.

Figure 4.5 shows that water has one liquid phase but many different solid phases other than ordinary ice ('ice I', shown in Fig. 4.5). Some of these phases melt at high temperatures. Ice VII, for instance, melts at 100°C but exists only above 25 kbar. Note that five more triple points occur in the diagram other than the one where vapour, liquid, and ice I coexist. Each one occurs at a definite pressure and temperature that cannot be changed. The solid phases of ice differ in the arrangement of the water molecules: under the influence of very high pressures, hydrogen bonds buckle and the H_2O molecules adopt different arrangements. These **polymorphs**, or different solid phases, of ice may be responsible for the advance of glaciers, for ice at the bottom of glaciers experiences very high pressures where it rests on jagged rocks.

(c) Helium

Figure 4.7 shows the phase diagram of helium. Helium behaves unusually at low temperatures. For instance, the solid and gas phases of helium are never in equilibrium however low the temperature: the atoms are so light that they vibrate with a large-amplitude motion even at very low temperatures and the solid simply shakes itself apart. Solid helium can be obtained, but only by holding the atoms together by applying pressure.

When considering helium at low temperatures it is necessary to distinguish between the isotopes ^3He and ^4He . Pure helium-4 has two liquid phases. The phase marked He-I in the diagram behaves like a normal liquid; the other phase, He-II, is a **superfluid**;

Fig. 4.6 A fragment of the structure of ice (ice-I). Each O atom is linked by two covalent bonds to H atoms and by two hydrogen bonds to a neighbouring O atom, in a tetrahedral array.

Fig. 4.7 The phase diagram for helium (^4He). The λ -line marks the conditions under which the two liquid phases are in equilibrium. Helium-II is the superfluid phase. Note that a pressure of over 20 bar must be exerted before solid helium can be obtained. The labels hcp and bcc denote different solid phases in which the atoms pack together differently: hcp denotes hexagonal closed packing and bcc denotes body-centred cubic (see Section 20.1 for a description of these structures).

Fig. 4.8 When two or more phases are in equilibrium, the chemical potential of a substance (and, in a mixture, a component) is the same in each phase and is the same at all points in each phase.

it is so called because it flows without viscosity.¹ Provided we discount the liquid crystalline substances discussed in Section 6.6, helium is the only known substance with a liquid–liquid boundary, shown as the **λ -line** (lambda line) in Fig. 4.7. The phase diagram of helium-3 differs from the phase diagram of helium-4, but it also possesses a superfluid phase. Helium-3 is unusual in that the entropy of the liquid is lower than that of the solid, and melting is exothermic.

Phase stability and phase transitions

We shall now see how thermodynamic considerations can account for the features of the phase diagrams we have just described. All our considerations will be based on the Gibbs energy of a substance, and in particular on its molar Gibbs energy, G_m . In fact, this quantity will play such an important role in this chapter and the rest of the text that we give it a special name and symbol, the **chemical potential**, μ (mu). For a one-component system, ‘molar Gibbs energy’ and ‘chemical potential’ are synonyms, so $\mu = G_m$, but in Chapter 5 we shall see that chemical potential has a broader significance and a more general definition. The name ‘chemical potential’ is also instructive: as we develop the concept, we shall see that μ is a measure of the potential that a substance has for undergoing change in a system. In this chapter, it reflects the potential of a substance to undergo physical change. In Chapter 7 we shall see that μ is the potential of a substance to undergo chemical change.

4.4 The thermodynamic criterion of equilibrium

We base our discussion on the following consequence of the Second Law: *at equilibrium, the chemical potential of a substance is the same throughout a sample, regardless of how many phases are present*. When the liquid and solid phases of a substance are in equilibrium, the chemical potential of the substance is the same throughout the system (Fig. 4.8).

To see the validity of this remark, consider a system in which the chemical potential of a substance is μ_1 at one location and μ_2 at another location. The locations may be in the same or in different phases. When an amount dn of the substance is transferred from one location to the other, the Gibbs energy of the system changes by $-\mu_1 dn$ when material is removed from location 1, and it changes by $+\mu_2 dn$ when that material is added to location 2. The overall change is therefore $dG = (\mu_2 - \mu_1)dn$. If the chemical potential at location 1 is higher than that at location 2, the transfer is accompanied by a decrease in G , and so has a spontaneous tendency to occur. Only if $\mu_1 = \mu_2$ is there no change in G , and only then is the system at equilibrium. We conclude that the transition temperature, T_{trs} , is the temperature at which the chemical potentials of two phases are equal.

4.5 The dependence of stability on the conditions

At low temperatures and provided the pressure is not too low, the solid phase of a substance has the lowest chemical potential and is therefore the most stable phase. However, the chemical potentials of different phases change with temperature in different ways, and above a certain temperature the chemical potential of another phase (perhaps another solid phase, a liquid, or a gas) may turn out to be the lowest. When that happens, a transition to the second phase is spontaneous and occurs if it is kinetically feasible to do so.

¹ Recent work has suggested that water may also have a superfluid liquid phase.

(a) The temperature dependence of phase stability

The temperature dependence of the Gibbs energy is expressed in terms of the entropy of the system by eqn 3.50 ($(\partial G/\partial T)_p = -S$). Because the chemical potential of a pure substance is just another name for its molar Gibbs energy, it follows that

$$\left(\frac{\partial \mu}{\partial T}\right)_p = -S_m \quad (4.1)$$

This relation shows that, as the temperature is raised, the chemical potential of a pure substance decreases: $S_m > 0$ for all substances, so the slope of a plot of μ against T is negative.

Equation 4.1 implies that the slope of a plot of μ against temperature is steeper for gases than for liquids, because $S_m(g) > S_m(l)$. The slope is also steeper for a liquid than the corresponding solid, because $S_m(l) > S_m(s)$ almost always. These features are illustrated in Fig. 4.9. The steep negative slope of $\mu(l)$ results in its falling below $\mu(s)$ when the temperature is high enough, and then the liquid becomes the stable phase: the solid melts. The chemical potential of the gas phase plunges steeply downwards as the temperature is raised (because the molar entropy of the vapour is so high), and there comes a temperature at which it lies lowest. Then the gas is the stable phase and vaporization is spontaneous.

(b) The response of melting to applied pressure

Most substances melt at a higher temperature when subjected to pressure. It is as though the pressure is preventing the formation of the less dense liquid phase. Exceptions to this behaviour include water, for which the liquid is denser than the solid. Application of pressure to water encourages the formation of the liquid phase. That is, water freezes at a lower temperature when it is under pressure.

We can rationalize the response of melting temperatures to pressure as follows. The variation of the chemical potential with pressure is expressed (from the second of eqn 3.50) by

$$\left(\frac{\partial \mu}{\partial p}\right)_T = V_m \quad (4.2)$$

This equation shows that the slope of a plot of chemical potential against pressure is equal to the molar volume of the substance. An increase in pressure raises the chemical potential of any pure substance (because $V_m > 0$). In most cases, $V_m(l) > V_m(s)$ and the equation predicts that an increase in pressure increases the chemical potential of the liquid more than that of the solid. As shown in Fig. 4.10a, the effect of pressure in such

Fig. 4.9 The schematic temperature dependence of the chemical potential of the solid, liquid, and gas phases of a substance (in practice, the lines are curved). The phase with the lowest chemical potential at a specified temperature is the most stable one at that temperature. The transition temperatures, the melting and boiling temperatures (T_f and T_b , respectively), are the temperatures at which the chemical potentials of the two phases are equal.

Fig. 4.10 The pressure dependence of the chemical potential of a substance depends on the molar volume of the phase. The lines show schematically the effect of increasing pressure on the chemical potential of the solid and liquid phases (in practice, the lines are curved), and the corresponding effects on the freezing temperatures. (a) In this case the molar volume of the solid is smaller than that of the liquid and $\mu(s)$ increases less than $\mu(l)$. As a result, the freezing temperature rises. (b) Here the molar volume is greater for the solid than the liquid (as for water), $\mu(s)$ increases more strongly than $\mu(l)$, and the freezing temperature is lowered.

a case is to raise the melting temperature slightly. For water, however, $V_{\text{m}}(\text{l}) < V_{\text{m}}(\text{s})$, and an increase in pressure increases the chemical potential of the solid more than that of the liquid. In this case, the melting temperature is lowered slightly (Fig. 4.10b).

Example 4.1 Assessing the effect of pressure on the chemical potential

Calculate the effect on the chemical potentials of ice and water of increasing the pressure from 1.00 bar to 2.00 bar at 0°C. The density of ice is 0.917 g cm^{-3} and that of liquid water is 0.999 g cm^{-3} under these conditions.

Method From eqn 4.2, we know that the change in chemical potential of an incompressible substance when the pressure is changed by Δp is $\Delta\mu = V_{\text{m}}\Delta p$. Therefore, to answer the question, we need to know the molar volumes of the two phases of water. These values are obtained from the mass density, ρ , and the molar mass, M , by using $V_{\text{m}} = M/\rho$. We therefore use the expression $\Delta\mu = M\Delta p/\rho$.

Answer The molar mass of water is 18.02 g mol^{-1} ($1.802 \times 10^{-2} \text{ kg mol}^{-1}$); therefore,

$$\Delta\mu(\text{ice}) = \frac{(1.802 \times 10^{-2} \text{ kg mol}^{-1}) \times (1.00 \times 10^5 \text{ Pa})}{917 \text{ kg m}^{-3}} = +1.97 \text{ J mol}^{-1}$$

$$\Delta\mu(\text{water}) = \frac{(1.802 \times 10^{-2} \text{ kg mol}^{-1}) \times (1.00 \times 10^5 \text{ Pa})}{999 \text{ kg m}^{-3}} = +1.80 \text{ J mol}^{-1}$$

We interpret the numerical results as follows: the chemical potential of ice rises more sharply than that of water, so if they are initially in equilibrium at 1 bar, then there will be a tendency for the ice to melt at 2 bar.

Self-test 4.1 Calculate the effect of an increase in pressure of 1.00 bar on the liquid and solid phases of carbon dioxide (of molar mass 44.0 g mol^{-1}) in equilibrium with densities 2.35 g cm^{-3} and 2.50 g cm^{-3} , respectively.

$[\Delta\mu(\text{l}) = +1.87 \text{ J mol}^{-1}, \Delta\mu(\text{s}) = +1.76 \text{ J mol}^{-1}; \text{solid forms}]$

Fig. 4.11 Pressure may be applied to a condensed phase either (a) by compressing the condensed phase or (b) by subjecting it to an inert pressurizing gas. When pressure is applied, the vapour pressure of the condensed phase increases.

(c) The effect of applied pressure on vapour pressure

When pressure is applied to a condensed phase, its vapour pressure rises: in effect, molecules are squeezed out of the phase and escape as a gas. Pressure can be exerted on the condensed phases mechanically or by subjecting it to the applied pressure of an inert gas (Fig. 4.11); in the latter case, the vapour pressure is the partial pressure of the vapour in equilibrium with the condensed phase, and we speak of the **partial vapour pressure** of the substance. One complication (which we ignore here) is that, if the condensed phase is a liquid, then the pressurizing gas might dissolve and change the properties of the liquid. Another complication is that the gas phase molecules might attract molecules out of the liquid by the process of **gas solvation**, the attachment of molecules to gas phase species.

As shown in the following *Justification*, the quantitative relation between the vapour pressure, p , when a pressure ΔP is applied and the vapour pressure, p^* , of the liquid in the absence of an additional pressure is

$$p = p^* e^{V_{\text{m}}(\text{l})\Delta P/RT} \quad (4.3)$$

This equation shows how the vapour pressure increases when the pressure acting on the condensed phase is increased.

Justification 4.1 *The vapour pressure of a pressurized liquid*

We calculate the vapour pressure of a pressurized liquid by using the fact that at equilibrium the chemical potentials of the liquid and its vapour are equal: $\mu(l) = \mu(g)$. It follows that, for any change that preserves equilibrium, the resulting change in $\mu(l)$ must be equal to the change in $\mu(g)$; therefore, we can write $d\mu(g) = d\mu(l)$. When the pressure P on the liquid is increased by dP , the chemical potential of the liquid changes by $d\mu(l) = V_m(l)dP$. The chemical potential of the vapour changes by $d\mu(g) = V_m(g)dp$ where dp is the change in the vapour pressure we are trying to find. If we treat the vapour as a perfect gas, the molar volume can be replaced by $V_m(g) = RT/p$, and we obtain

$$d\mu(g) = \frac{RTdp}{p}$$

Next, we equate the changes in chemical potentials of the vapour and the liquid:

$$\frac{RTdp}{p} = V_m(l)dP$$

We can integrate this expression once we know the limits of integration.

When there is no additional pressure acting on the liquid, P (the pressure experienced by the liquid) is equal to the normal vapour pressure p^* , so when $P = p^*$, $p = p^*$ too. When there is an additional pressure ΔP on the liquid, with the result that $P = p + \Delta P$, the vapour pressure is p (the value we want to find). Provided the effect of pressure on the vapour pressure is small (as will turn out to be the case) a good approximation is to replace the p in $p + \Delta P$ by p^* itself, and to set the upper limit of the integral to $p^* + \Delta P$. The integrations required are therefore as follows:

$$RT \int_{p^*}^p \frac{dp}{p} = \int_{p^*}^{p^*+\Delta P} V_m(l)dP$$

We now divide both sides by RT and assume that the molar volume of the liquid is the same throughout the small range of pressures involved:

$$\int_{p^*}^p \frac{dp}{p} = \frac{V_m(l)}{RT} \int_{p^*}^{p^*+\Delta P} dP$$

Then both integrations are straightforward, and lead to

$$\ln \frac{p}{p^*} = \frac{V_m(l)}{RT} \Delta P$$

which rearranges to eqn 4.3 because $e^{\ln x} = x$.

Illustration 4.1 *The effect of applied pressure on the vapour pressure of liquid water*

For water, which has density 0.997 g cm^{-3} at 25°C and therefore molar volume $18.1 \text{ cm}^3 \text{ mol}^{-1}$, when the pressure is increased by 10 bar (that is, $\Delta P = 1.0 \times 10^6 \text{ Pa}$)

$$\frac{V_m(l)\Delta P}{RT} = \frac{(1.81 \times 10^{-5} \text{ m}^3 \text{ mol}^{-1}) \times (1.0 \times 10^6 \text{ Pa})}{(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})} = \frac{1.81 \times 1.0 \times 10}{8.3145 \times 298}$$

where we have used $1 \text{ J} = 1 \text{ Pa m}^3$. It follows that $p = 1.0073p^*$, an increase of 0.73 per cent.

Self-test 4.2 Calculate the effect of an increase in pressure of 100 bar on the vapour pressure of benzene at 25°C , which has density 0.879 g cm^{-3} . [43 per cent]

Fig. 4.12 When pressure is applied to a system in which two phases are in equilibrium (at *a*), the equilibrium is disturbed. It can be restored by changing the temperature, so moving the state of the system to *b*. It follows that there is a relation between dp and dT that ensures that the system remains in equilibrium as either variable is changed.

Fig. 4.13 A typical solid–liquid phase boundary slopes steeply upwards. This slope implies that, as the pressure is raised, the melting temperature rises. Most substances behave in this way.

4.6 The location of phase boundaries

We can find the precise locations of the phase boundaries—the pressures and temperatures at which two phases can coexist—by making use of the fact that, when two phases are in equilibrium, their chemical potentials must be equal. Therefore, where the phases α and β are in equilibrium,

$$\mu_{\alpha}(p, T) = \mu_{\beta}(p, T) \quad (4.4)$$

By solving this equation for p in terms of T , we get an equation for the phase boundary.

(a) The slopes of the phase boundaries

It turns out to be simplest to discuss the phase boundaries in terms of their slopes, dp/dT . Let p and T be changed infinitesimally, but in such a way that the two phases α and β remain in equilibrium. The chemical potentials of the phases are initially equal (the two phases are in equilibrium). They remain equal when the conditions are changed to another point on the phase boundary, where the two phases continue to be in equilibrium (Fig. 4.12). Therefore, the changes in the chemical potentials of the two phases must be equal and we can write $d\mu_{\alpha} = d\mu_{\beta}$. Because, from eqn 3.49 ($dG = Vdp - SdT$), we know that $d\mu = -S_m dT + V_m dp$ for each phase, it follows that

$$-S_{\alpha,m} dT + V_{\alpha,m} dp = -S_{\beta,m} dT + V_{\beta,m} dp$$

where $S_{\alpha,m}$ and $S_{\beta,m}$ are the molar entropies of the phases and $V_{\alpha,m}$ and $V_{\beta,m}$ are their molar volumes. Hence

$$(V_{\beta,m} - V_{\alpha,m}) dp = (S_{\beta,m} - S_{\alpha,m}) dT \quad (4.5)$$

which rearranges into the **Clapeyron equation**:

$$\frac{dp}{dT} = \frac{\Delta_{\text{trs}} S}{\Delta_{\text{trs}} V} \quad (4.6)$$

In this expression $\Delta_{\text{trs}} S = S_{\beta,m} - S_{\alpha,m}$ and $\Delta_{\text{trs}} V = V_{\beta,m} - V_{\alpha,m}$ are the entropy and volume of transition, respectively. The Clapeyron equation is an exact expression for the slope of the phase boundary and applies to any phase equilibrium of any pure substance. It implies that we can use thermodynamic data to predict the appearance of phase diagrams and to understand their form. A more practical application is to the prediction of the response of freezing and boiling points to the application of pressure.

(b) The solid–liquid boundary

Melting (fusion) is accompanied by a molar enthalpy change $\Delta_{\text{fus}} H$ and occurs at a temperature T . The molar entropy of melting at T is therefore $\Delta_{\text{fus}} H/T$ (Section 3.3), and the Clapeyron equation becomes

$$\frac{dp}{dT} = \frac{\Delta_{\text{fus}} H}{T \Delta_{\text{fus}} V} \quad (4.7)$$

where $\Delta_{\text{fus}} V$ is the change in molar volume that occurs on melting. The enthalpy of melting is positive (the only exception is helium-3) and the volume change is usually positive and always small. Consequently, the slope dp/dT is steep and usually positive (Fig. 4.13).

We can obtain the formula for the phase boundary by integrating dp/dT , assuming that $\Delta_{\text{fus}} H$ and $\Delta_{\text{fus}} V$ change so little with temperature and pressure that they can be treated as constant. If the melting temperature is T^* when the pressure is p^* , and T when the pressure is p , the integration required is

$$\int_{p^*}^p dp = \frac{\Delta_{\text{fus}} H}{\Delta_{\text{fus}} V} \int_{T^*}^T \frac{dT}{T}$$

Therefore, the approximate equation of the solid–liquid boundary is

$$p \approx p^* + \frac{\Delta_{\text{fus}} H}{\Delta_{\text{fus}} V} \ln \frac{T}{T^*} \quad (4.8)$$

This equation was originally obtained by yet another Thomson—James, the brother of William, Lord Kelvin. When T is close to T^* , the logarithm can be approximated by using

$$\ln \frac{T}{T^*} = \ln \left(1 + \frac{T - T^*}{T^*} \right) \approx \frac{T - T^*}{T^*}$$

therefore,

$$p \approx p^* + \frac{\Delta_{\text{fus}} H}{T^* \Delta_{\text{fus}} V} (T - T^*) \quad (4.9)$$

This expression is the equation of a steep straight line when p is plotted against T (as in Fig. 4.13).

(c) The liquid–vapour boundary

The entropy of vaporization at a temperature T is equal to $\Delta_{\text{vap}} H/T$; the Clapeyron equation for the liquid–vapour boundary is therefore

$$\frac{dp}{dT} = \frac{\Delta_{\text{vap}} H}{T \Delta_{\text{vap}} V} \quad (4.10)$$

The enthalpy of vaporization is positive; $\Delta_{\text{vap}} V$ is large and positive. Therefore, dp/dT is positive, but it is much smaller than for the solid–liquid boundary. It follows that dT/dp is large, and hence that the boiling temperature is more responsive to pressure than the freezing temperature.

Comment 4.2

Calculations involving natural logarithms often become simpler if we note that, provided $-1 < x < 1$, $\ln(1+x) = x - \frac{1}{2}x^2 + \frac{1}{3}x^3 - \dots$. If $x \ll 1$, a good approximation is $\ln(1+x) \approx x$.

Example 4.2 Estimating the effect of pressure on the boiling temperature

Estimate the typical size of the effect of increasing pressure on the boiling point of a liquid.

Method To use eqn 4.10 we need to estimate the right-hand side. At the boiling point, the term $\Delta_{\text{vap}} H/T$ is Trouton's constant (Section 3.3b). Because the molar volume of a gas is so much greater than the molar volume of a liquid, we can write

$$\Delta_{\text{vap}} V = V_{\text{m}}(\text{g}) - V_{\text{m}}(\text{l}) \approx V_{\text{m}}(\text{g})$$

and take for $V_{\text{m}}(\text{g})$ the molar volume of a perfect gas (at low pressures, at least).

Answer Trouton's constant has the value $85 \text{ J K}^{-1} \text{ mol}^{-1}$. The molar volume of a perfect gas is about $25 \text{ dm}^3 \text{ mol}^{-1}$ at 1 atm and near but above room temperature. Therefore,

$$\frac{dp}{dT} \approx \frac{85 \text{ J K}^{-1} \text{ mol}^{-1}}{2.5 \times 10^{-2} \text{ m}^3 \text{ mol}^{-1}} = 3.4 \times 10^3 \text{ Pa K}^{-1}$$

Fig. 4.14 A typical liquid–vapour phase boundary. The boundary can be regarded as a plot of the vapour pressure against the temperature. Note that, in some depictions of phase diagrams in which a logarithmic pressure scale is used, the phase boundary has the opposite curvature (see Fig. 4.7). This phase boundary terminates at the critical point (not shown).

We have used $1 \text{ J} = 1 \text{ Pa m}^3$. This value corresponds to 0.034 atm K^{-1} , and hence to $dT/dp = 29 \text{ K atm}^{-1}$. Therefore, a change of pressure of $+0.1 \text{ atm}$ can be expected to change a boiling temperature by about $+3 \text{ K}$.

Self-test 4.3 Estimate dT/dp for water at its normal boiling point using the information in Table 3.2 and $V_m(\text{g}) = RT/p$. $[28 \text{ K atm}^{-1}]$

Because the molar volume of a gas is so much greater than the molar volume of a liquid, we can write $\Delta_{\text{vap}} V \approx V_m(\text{g})$ (as in *Example 4.2*). Moreover, if the gas behaves perfectly, $V_m(\text{g}) = RT/p$. These two approximations turn the exact Clapeyron equation into

$$\frac{dp}{dT} = \frac{\Delta_{\text{vap}} H}{T(RT/p)}$$

which rearranges into the **Clausius–Clapeyron equation** for the variation of vapour pressure with temperature:

$$\frac{d \ln p}{dT} = \frac{\Delta_{\text{vap}} H}{RT^2} \quad (4.11)^\circ$$

(We have used $dx/x = d \ln x$.) Like the Clapeyron equation, the Clausius–Clapeyron equation is important for understanding the appearance of phase diagrams, particularly the location and shape of the liquid–vapour and solid–vapour phase boundaries. It lets us predict how the vapour pressure varies with temperature and how the boiling temperature varies with pressure. For instance, if we also assume that the enthalpy of vaporization is independent of temperature, this equation can be integrated as follows:

$$\int_{\ln p^*}^{\ln p} d \ln p = \frac{\Delta_{\text{vap}} H}{R} \int_{T^*}^T \frac{dT}{T^2} = -\frac{\Delta_{\text{vap}} H}{R} \left(\frac{1}{T} - \frac{1}{T^*} \right)$$

where p^* is the vapour pressure when the temperature is T^* and p the vapour pressure when the temperature is T . Therefore, because the integral on the left evaluates to $\ln(p/p^*)$, the two vapour pressures are related by

$$p = p^* e^{-\chi} \quad \chi = \frac{\Delta_{\text{vap}} H}{R} \left(\frac{1}{T} - \frac{1}{T^*} \right) \quad (4.12)^\circ$$

Equation 4.12 is plotted as the liquid–vapour boundary in Fig. 4.14. The line does not extend beyond the critical temperature T_c , because above this temperature the liquid does not exist.

Illustration 4.2 The effect of temperature on the vapour pressure of a liquid

Equation 4.12 can be used to estimate the vapour pressure of a liquid at any temperature from its normal boiling point, the temperature at which the vapour pressure is 1.00 atm (101 kPa). Thus, because the normal boiling point of benzene is 80°C (353 K) and (from Table 2.3), $\Delta_{\text{vap}} H^\ominus = 30.8 \text{ kJ mol}^{-1}$, to calculate the vapour pressure at 20°C (293 K), we write

$$\chi = \frac{3.08 \times 10^4 \text{ J mol}^{-1}}{8.3145 \text{ J K}^{-1} \text{ mol}^{-1}} \left(\frac{1}{293 \text{ K}} - \frac{1}{353 \text{ K}} \right) = \frac{3.08 \times 10^4}{8.3145} \left(\frac{1}{293} - \frac{1}{353} \right)$$

and substitute this value into eqn 4.12 with $p^* = 101 \text{ kPa}$. The result is 12 kPa. The experimental value is 10 kPa.

A note on good practice Because exponential functions are so sensitive, it is good practice to carry out numerical calculations like this without evaluating the intermediate steps and using rounded values.

(d) The solid–vapour boundary

The only difference between this case and the last is the replacement of the enthalpy of vaporization by the enthalpy of sublimation, $\Delta_{\text{sub}}H$. Because the enthalpy of sublimation is greater than the enthalpy of vaporization ($\Delta_{\text{sub}}H = \Delta_{\text{fus}}H + \Delta_{\text{vap}}H$), the equation predicts a steeper slope for the sublimation curve than for the vaporization curve at similar temperatures, which is near where they meet at the triple point (Fig. 4.15).

4.7 The Ehrenfest classification of phase transitions

There are many different types of phase transition, including the familiar examples of fusion and vaporization and the less familiar examples of solid–solid, conducting–superconducting, and fluid–superfluid transitions. We shall now see that it is possible to use thermodynamic properties of substances, and in particular the behaviour of the chemical potential, to classify phase transitions into different types. The classification scheme was originally proposed by Paul Ehrenfest, and is known as the **Ehrenfest classification**.

Many familiar phase transitions, like fusion and vaporization, are accompanied by changes of enthalpy and volume. These changes have implications for the slopes of the chemical potentials of the phases at either side of the phase transition. Thus, at the transition from a phase α to another phase β ,

$$\left(\frac{\partial\mu_\beta}{\partial p}\right)_T - \left(\frac{\partial\mu_\alpha}{\partial p}\right)_T = V_{\beta,m} - V_{\alpha,m} = \Delta_{\text{trs}}V \quad (4.13)$$

$$\left(\frac{\partial\mu_\beta}{\partial T}\right)_p - \left(\frac{\partial\mu_\alpha}{\partial T}\right)_p = -S_{\beta,m} + S_{\alpha,m} = \Delta_{\text{trs}}S = \frac{\Delta_{\text{trs}}H}{T_{\text{trs}}}$$

Because $\Delta_{\text{trs}}V$ and $\Delta_{\text{trs}}H$ are non-zero for melting and vaporization, it follows that for such transitions the slopes of the chemical potential plotted against either pressure or temperature are different on either side of the transition (Fig. 4.16a). In other words, the first derivatives of the chemical potentials with respect to pressure and temperature are discontinuous at the transition.

A transition for which the first derivative of the chemical potential with respect to temperature is discontinuous is classified as a **first-order phase transition**. The constant-pressure heat capacity, C_p , of a substance is the slope of a plot of the enthalpy with respect to temperature. At a first-order phase transition, H changes by a finite amount for an infinitesimal change of temperature. Therefore, at the transition the heat capacity is infinite. The physical reason is that heating drives the transition rather than raising the temperature. For example, boiling water stays at the same temperature even though heat is being supplied.

Fig. 4.15 Near the point where they coincide (at the triple point), the solid–gas boundary has a steeper slope than the liquid–gas boundary because the enthalpy of sublimation is greater than the enthalpy of vaporization and the temperatures that occur in the Clausius–Clapeyron equation for the slope have similar values.

Fig. 4.16 The changes in thermodynamic properties accompanying (a) first-order and (b) second-order phase transitions.

A **second-order phase transition** in the Ehrenfest sense is one in which the first derivative of μ with respect to temperature is continuous but its second derivative is discontinuous. A continuous slope of μ (a graph with the same slope on either side of the transition) implies that the volume and entropy (and hence the enthalpy) do not change at the transition (Fig. 4.16b). The heat capacity is discontinuous at the transition but does not become infinite there. An example of a second-order transition is the conducting–superconducting transition in metals at low temperatures.²

The term **λ -transition** is applied to a phase transition that is not first-order yet the heat capacity becomes infinite at the transition temperature. Typically, the heat capacity of a system that shows such a transition begins to increase well before the transition (Fig. 4.17), and the shape of the heat capacity curve resembles the Greek letter lambda. This type of transition includes order–disorder transitions in alloys, the onset of ferromagnetism, and the fluid–superfluid transition of liquid helium.

Fig. 4.17 The λ -curve for helium, where the heat capacity rises to infinity. The shape of this curve is the origin of the name λ -transition.

Molecular interpretation 4.1 Second-order phase transitions and λ -transitions

One type of second-order transition is associated with a change in symmetry of the crystal structure of a solid. Thus, suppose the arrangement of atoms in a solid is like that represented in Fig. 4.18a, with one dimension (technically, of the unit cell) longer than the other two, which are equal. Such a crystal structure is classified as tetragonal (see Section 20.1). Moreover, suppose the two shorter dimensions increase more than the long dimension when the temperature is raised. There may come a stage when the three dimensions become equal. At that point the crystal has cubic symmetry (Fig. 4.18b), and at higher temperatures it will expand equally in all three directions (because there is no longer any distinction between them). The tetragonal $\rightarrow$ cubic phase transition has occurred, but as it has not involved a discontinuity in the interaction energy between the atoms or the volume they occupy, the transition is not first-order.

² A metallic conductor is a substance with an electrical conductivity that decreases as the temperature increases. A superconductor is a solid that conducts electricity without resistance. See Chapter 20 for more details.

Fig. 4.18 One version of a second-order phase transition in which (a) a tetragonal phase expands more rapidly in two directions than a third, and hence becomes a cubic phase, which (b) expands uniformly in three directions as the temperature is raised. There is no rearrangement of atoms at the transition temperature, and hence no enthalpy of transition.

The order–disorder transition in β -brass (CuZn) is an example of a λ -transition. The low-temperature phase is an orderly array of alternating Cu and Zn atoms. The high-temperature phase is a random array of the atoms (Fig. 4.19). At $T = 0$ the order is perfect, but islands of disorder appear as the temperature is raised. The islands form because the transition is cooperative in the sense that, once two atoms have exchanged locations, it is easier for their neighbours to exchange their locations. The islands grow in extent, and merge throughout the crystal at the transition temperature (742 K). The heat capacity increases as the transition temperature is approached because the cooperative nature of the transition means that it is increasingly easy for the heat supplied to drive the phase transition rather than to be stored as thermal motion.

Fig. 4.19 An order–disorder transition. (a) At $T = 0$, there is perfect order, with different kinds of atoms occupying alternate sites. (b) As the temperature is increased, atoms exchange locations and islands of each kind of atom form in regions of the solid. Some of the original order survives. (c) At and above the transition temperature, the islands occur at random throughout the sample.

Checklist of key ideas

- ☐ 1. A phase is a form of matter that is uniform throughout in chemical composition and physical state.
- ☐ 2. A transition temperature is the temperature at which the two phases are in equilibrium.
- ☐ 3. A metastable phase is a thermodynamically unstable phase that persists because the transition is kinetically hindered.
- ☐ 4. A phase diagram is a diagram showing the regions of pressure and temperature at which its various phases are thermodynamically stable.
- ☐ 5. A phase boundary is a line separating the regions in a phase diagram showing the values of p and T at which two phases coexist in equilibrium.
- ☐ 6. The vapour pressure is the pressure of a vapour in equilibrium with the condensed phase.
- ☐ 7. Boiling is the condition of free vaporization throughout the liquid.
- ☐ 8. The boiling temperature is the temperature at which the vapour pressure of a liquid is equal to the external pressure.
- ☐ 9. The critical temperature is the temperature at which a liquid surface disappears and above which a liquid does not exist whatever the pressure. The critical pressure is the vapour pressure at the critical temperature.
- ☐ 10. A supercritical fluid is a dense fluid phase above the critical temperature.
- ☐ 11. The melting temperature (or freezing temperature) is the temperature at which, under a specified pressure, the liquid and solid phases of a substance coexist in equilibrium.
- ☐ 12. The triple point is a point on a phase diagram at which the three phase boundaries meet and all three phases are in mutual equilibrium.
- ☐ 13. The chemical potential μ of a pure substance is the molar Gibbs energy of the substance.

- ☐ 14. The chemical potential is uniform throughout a system at equilibrium.
- ☐ 15. The chemical potential varies with temperature as $(\partial\mu/\partial T)_p = -S_m$ and with pressure as $(\partial\mu/\partial p)_T = V_m$.
- ☐ 16. The vapour pressure in the presence of applied pressure is given by $p = p^* e^{V_m \Delta p / RT}$.
- ☐ 17. The temperature dependence of the vapour pressure is given by the Clapeyron equation, $dp/dT = \Delta_{\text{trs}} S / \Delta_{\text{trs}} V$.
- ☐ 18. The temperature dependence of the vapour pressure of a condensed phase is given by the Clausius–Clapeyron equation, $d \ln p / dT = \Delta_{\text{vap}} H / RT^2$.
- ☐ 19. The Ehrenfest classification is a classification of phase transitions based on the behaviour of the chemical potential.

Discussion questions

- 4.1** Discuss the implications for phase stability of the variation of chemical potential with temperature and pressure.
- 4.2** Suggest a physical interpretation of the phenomena of superheating and supercooling.
- 4.3** Discuss what would be observed as a sample of water is taken along a path that encircles and is close to its critical point.
- 4.4** Use the phase diagram in Fig. 4.4 to state what would be observed when a sample of carbon dioxide, initially at 1.0 atm and 298 K, is subjected to the following cycle: (a) isobaric (constant–pressure) heating to 320 K, (b) isothermal compression to 100 atm, (c) isobaric cooling to 210 K, (d) isothermal decompression to 1.0 atm, (e) isobaric heating to 298 K.
- 4.5** The use of supercritical fluids for the extraction of a component from a complicated mixture is not confined to the decaffeination of coffee. Consult library and internet resources and prepare a discussion of the principles, advantages, disadvantages, and current uses of supercritical fluid extraction technology.
- 4.6** Explain the significance of the Clapeyron equation and of the Clausius–Clapeyron equation.
- 4.7** Distinguish between a first-order phase transition, a second-order phase transition, and a λ -transition at both molecular and macroscopic levels.

Exercises

- 4.1(a)** The vapour pressure of dichloromethane at 24.1°C is 53.3 kPa and its enthalpy of vaporization is 28.7 kJ mol^{−1}. Estimate the temperature at which its vapour pressure is 70.0 kPa.
- 4.1(b)** The vapour pressure of a substance at 20.0°C is 58.0 kPa and its enthalpy of vaporization is 32.7 kJ mol^{−1}. Estimate the temperature at which its vapour pressure is 66.0 kPa.
- 4.2(a)** The molar volume of a certain solid is 161.0 cm³ mol^{−1} at 1.00 atm and 350.75 K, its melting temperature. The molar volume of the liquid at this temperature and pressure is 163.3 cm³ mol^{−1}. At 100 atm the melting temperature changes to 351.26 K. Calculate the enthalpy and entropy of fusion of the solid.
- 4.2(b)** The molar volume of a certain solid is 142.0 cm³ mol^{−1} at 1.00 atm and 427.15 K, its melting temperature. The molar volume of the liquid at this temperature and pressure is 152.6 cm³ mol^{−1}. At 1.2 MPa the melting temperature changes to 429.26 K. Calculate the enthalpy and entropy of fusion of the solid.
- 4.3(a)** The vapour pressure of a liquid in the temperature range 200 K to 260 K was found to fit the expression $\ln(p/\text{Torr}) = 16.255 - 2501.8/(T/\text{K})$. Calculate the enthalpy of vaporization of the liquid.
- 4.3(b)** The vapour pressure of a liquid in the temperature range 200 K to 260 K was found to fit the expression $\ln(p/\text{Torr}) = 18.361 - 3036.8/(T/\text{K})$. Calculate the enthalpy of vaporization of the liquid.

³ See *Further reading* in Chapter 2 for additional sources of thermochemical data.

4.4(a) The vapour pressure of benzene between 10°C and 30°C fits the expression $\log(p/\text{Torr}) = 7.960 - 1780/(T/K)$. Calculate (a) the enthalpy of vaporization and (b) the normal boiling point of benzene.

4.4(b) The vapour pressure of a liquid between 15°C and 35°C fits the expression $\log(p/\text{Torr}) = 8.750 - 1625/(T/K)$. Calculate (a) the enthalpy of vaporization and (b) the normal boiling point of the liquid.

4.5(a) When benzene freezes at 5.5°C its density changes from 0.879 g cm^{-3} to 0.891 g cm^{-3} . Its enthalpy of fusion is $10.59 \text{ kJ mol}^{-1}$. Estimate the freezing point of benzene at 1000 atm.

4.5(b) When a certain liquid freezes at -3.65°C its density changes from 0.789 g cm^{-3} to 0.801 g cm^{-3} . Its enthalpy of fusion is 8.68 kJ mol^{-1} . Estimate the freezing point of the liquid at 100 MPa.

4.6(a) In July in Los Angeles, the incident sunlight at ground level has a power density of 1.2 kW m^{-2} at noon. A swimming pool of area 50 m^2 is directly exposed to the sun. What is the maximum rate of loss of water? Assume that all the radiant energy is absorbed.

4.6(b) Suppose the incident sunlight at ground level has a power density of 0.87 kW m^{-2} at noon. What is the maximum rate of loss of water from a lake of area 1.0 ha ? ($1 \text{ ha} = 10^4 \text{ m}^2$.) Assume that all the radiant energy is absorbed.

4.7(a) An open vessel containing (a) water, (b) benzene, (c) mercury stands in a laboratory measuring $5.0 \text{ m} \times 5.0 \text{ m} \times 3.0 \text{ m}$ at 25°C . What mass of each

substance will be found in the air if there is no ventilation? (The vapour pressures are (a) 3.2 kPa, (b) 13.1 kPa, (c) 0.23 Pa.)

4.7(b) On a cold, dry morning after a frost, the temperature was -5°C and the partial pressure of water in the atmosphere fell to 0.30 kPa. Will the frost sublime? What partial pressure of water would ensure that the frost remained?

4.8(a) Naphthalene, C_{10}H_8 , melts at 80.2°C . If the vapour pressure of the liquid is 1.3 kPa at 85.8°C and 5.3 kPa at 119.3°C , use the Clausius–Clapeyron equation to calculate (a) the enthalpy of vaporization, (b) the normal boiling point, and (c) the enthalpy of vaporization at the boiling point.

4.8(b) The normal boiling point of hexane is 69.0°C . Estimate (a) its enthalpy of vaporization and (b) its vapour pressure at 25°C and 60°C .

4.9(a) Calculate the melting point of ice under a pressure of 50 bar. Assume that the density of ice under these conditions is approximately 0.92 g cm^{-3} and that of liquid water is 1.00 g cm^{-3} .

4.9(b) Calculate the melting point of ice under a pressure of 10 MPa. Assume that the density of ice under these conditions is approximately 0.915 g cm^{-3} and that of liquid water is 0.998 g cm^{-3} .

4.10(a) What fraction of the enthalpy of vaporization of water is spent on expanding the water vapour?

4.10(b) What fraction of the enthalpy of vaporization of ethanol is spent on expanding its vapour?

Problems*

Numerical problems

4.1 The temperature dependence of the vapour pressure of solid sulfur dioxide can be approximately represented by the relation $\log(p/\text{Torr}) = 10.5916 - 1871.2/(T/K)$ and that of liquid sulfur dioxide by $\log(p/\text{Torr}) = 8.3186 - 1425.7/(T/K)$. Estimate the temperature and pressure of the triple point of sulfur dioxide.

4.2 Prior to the discovery that freon-12 (CF_2Cl_2) was harmful to the Earth's ozone layer, it was frequently used as the dispersing agent in spray cans for hair spray, etc. Its enthalpy of vaporization at its normal boiling point of -29.2°C is $20.25 \text{ kJ mol}^{-1}$. Estimate the pressure that a can of hair spray using freon-12 had to withstand at 40°C , the temperature of a can that has been standing in sunlight. Assume that $\Delta_{\text{vap}}H$ is a constant over the temperature range involved and equal to its value at -29.2°C .

4.3 The enthalpy of vaporization of a certain liquid is found to be 14.4 kJ mol^{-1} at 180 K, its normal boiling point. The molar volumes of the liquid and the vapour at the boiling point are $115 \text{ cm}^3 \text{ mol}^{-1}$ and $14.5 \text{ dm}^3 \text{ mol}^{-1}$, respectively. (a) Estimate dp/dT from the Clapeyron equation and (b) the percentage error in its value if the Clausius–Clapeyron equation is used instead.

4.4 Calculate the difference in slope of the chemical potential against temperature on either side of (a) the normal freezing point of water and (b) the normal boiling point of water. (c) By how much does the chemical potential of water supercooled to -5.0°C exceed that of ice at that temperature?

4.5 Calculate the difference in slope of the chemical potential against pressure on either side of (a) the normal freezing point of water and (b) the normal

boiling point of water. The densities of ice and water at 0°C are 0.917 g cm^{-3} and 1.000 g cm^{-3} , and those of water and water vapour at 100°C are 0.958 g cm^{-3} and 0.598 g dm^{-3} , respectively. By how much does the chemical potential of water vapour exceed that of liquid water at 1.2 atm and 100°C ?

4.6 The enthalpy of fusion of mercury is $2.292 \text{ kJ mol}^{-1}$, and its normal freezing point is 234.3 K with a change in molar volume of $+0.517 \text{ cm}^3 \text{ mol}^{-1}$ on melting. At what temperature will the bottom of a column of mercury (density 13.6 g cm^{-3}) of height 10.0 m be expected to freeze?

4.7 50.0 dm^3 of dry air was slowly bubbled through a thermally insulated beaker containing 250 g of water initially at 25°C . Calculate the final temperature. (The vapour pressure of water is approximately constant at 3.17 kPa throughout, and its heat capacity is $75.5 \text{ J K}^{-1} \text{ mol}^{-1}$. Assume that the air is not heated or cooled and that water vapour is a perfect gas.)

4.8 The vapour pressure, p , of nitric acid varies with temperature as follows:

$\theta/^\circ\text{C}$	0	20	40	50	70	80	90	100
p/kPa	1.92	6.38	17.7	27.7	62.3	89.3	124.9	170.9

What are (a) the normal boiling point and (b) the enthalpy of vaporization of nitric acid?

4.9 The vapour pressure of the ketone carvone ($M = 150.2 \text{ g mol}^{-1}$), a component of oil of spearmint, is as follows:

$\theta/^\circ\text{C}$	57.4	100.4	133.0	157.3	203.5	227.5
p/Torr	1.00	10.0	40.0	100	400	760

What are (a) the normal boiling point and (b) the enthalpy of vaporization of carvone?

* Problems denoted by the symbol ‡ were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

4.10 Construct the phase diagram for benzene near its triple point at 36 Torr and 5.50°C using the following data: $\Delta_{\text{fus}}H = 10.6 \text{ kJ mol}^{-1}$, $\Delta_{\text{vap}}H = 30.8 \text{ kJ mol}^{-1}$, $\rho(\text{s}) = 0.891 \text{ g cm}^{-3}$, $\rho(\text{l}) = 0.879 \text{ g cm}^{-3}$.

4.11† In an investigation of thermophysical properties of toluene (R.D. Goodwin *J. Phys. Chem. Ref. Data* **18**, 1565 (1989)) presented expressions for two coexistence curves (phase boundaries). The solid–liquid coexistence curve is given by

$$p/\text{bar} = p_3/\text{bar} + 1000 \times (5.60 + 11.727x)x$$

where $x = T/T_3 - 1$ and the triple point pressure and temperature are $p_3 = 0.4362 \text{ μbar}$ and $T_3 = 178.15 \text{ K}$. The liquid–vapour curve is given by:

$$\ln(p/\text{bar}) = -10.418/y + 21.157 - 15.996y + 14.015y^2 - 5.0120y^3 + 4.7224(1-y)^{1.70}$$

where $y = T/T_c = T/(593.95 \text{ K})$. (a) Plot the solid–liquid and liquid–vapour phase boundaries. (b) Estimate the standard melting point of toluene. (c) Estimate the standard boiling point of toluene. (d) Compute the standard enthalpy of vaporization of toluene, given that the molar volumes of the liquid and vapour at the normal boiling point are $0.12 \text{ dm}^3 \text{ mol}^{-1}$ and $30.3 \text{ dm}^3 \text{ mol}^{-1}$, respectively.

4.12† In a study of the vapour pressure of chloromethane, A. Bah and N. Dupont-Pavlovsky (*J. Chem. Eng. Data* **40**, 869 (1995)) presented data for the vapour pressure over solid chloromethane at low temperatures. Some of that data is shown below:

T/K	145.94	147.96	149.93	151.94	153.97	154.94
p/Pa	13.07	18.49	25.99	36.76	50.86	59.56

Estimate the standard enthalpy of sublimation of chloromethane at 150 K. (Take the molar volume of the vapour to be that of a perfect gas, and that of the solid to be negligible.)

Theoretical problems

4.13 Show that, for a transition between two incompressible solid phases, ΔG is independent of the pressure.

4.14 The change in enthalpy is given by $dH = C_p dT + V dp$. The Clapeyron equation relates dp and dT at equilibrium, and so in combination the two equations can be used to find how the enthalpy changes along a phase boundary as the temperature changes and the two phases remain in equilibrium. Show that $d(\Delta H/T) = \Delta C_p d \ln T$.

4.15 In the ‘gas saturation method’ for the measurement of vapour pressure, a volume V of gas (as measured at a temperature T and a pressure p) is bubbled slowly through the liquid that is maintained at the temperature T , and a mass loss m is measured. Show that the vapour pressure, p , of the liquid is related to its molar mass, M , by $p = AmP/(1 + Am)$, where $A = RT/MPV$. The vapour pressure of geraniol ($M = 154.2 \text{ g mol}^{-1}$), which is a component of oil of roses, was measured at 110°C. It was found that, when 5.00 dm^3 of nitrogen at 760 Torr was passed slowly through the heated liquid, the loss of mass was 0.32 g. Calculate the vapour pressure of geraniol.

4.16 Combine the barometric formula (stated in *Impact II.1*) for the dependence of the pressure on altitude with the Clausius–Clapeyron equation, and predict how the boiling temperature of a liquid depends on the altitude and the ambient temperature. Take the mean ambient temperature as 20°C and predict the boiling temperature of water at 3000 m.

4.17 Figure 4.9 gives a schematic representation of how the chemical potentials of the solid, liquid, and gaseous phases of a substance vary with temperature. All have a negative slope, but it is unlikely that they are truly straight lines as indicated in the illustration. Derive an expression for the curvatures (specifically, the second derivatives with respect to temperature) of these lines. Is there a restriction on the curvature of these lines? Which state of matter shows the greatest curvature?

4.18 The Clapeyron equation does not apply to second-order phase transitions, but there are two analogous equations, the *Ehrenfest equations*, that do. They are:

$$\frac{dp}{dT} = \frac{\alpha_2 - \alpha_1}{\kappa_{T,2} - \kappa_{T,1}} \quad \frac{dp}{dT} = \frac{C_{p,m2} - C_{p,m1}}{TV_m(\alpha_2 - \alpha_1)}$$

where α is the expansion coefficient, κ_T the isothermal compressibility, and the subscripts 1 and 2 refer to two different phases. Derive these two equations. Why does the Clapeyron equation not apply to second-order transitions?

4.19 For a first-order phase transition, to which the Clapeyron equation does apply, prove the relation

$$C_S = C_P - \frac{\alpha V \Delta_{\text{trs}} H}{\Delta_{\text{trs}} V}$$

where $C_S = (\partial q / \partial T)_S$ is the heat capacity along the coexistence curve of two phases.

Applications: to biology and engineering

4.20 Proteins are *polypeptides*, polymers of amino acids that can exist in ordered structures stabilized by a variety of molecular interactions. However, when certain conditions are changed, the compact structure of a polypeptide chain may collapse into a random coil. This structural change may be regarded as a phase transition occurring at a characteristic transition temperature, the *melting temperature*, T_m , which increases with the strength and number of intermolecular interactions in the chain. A thermodynamic treatment allows predictions to be made of the temperature T_m for the unfolding of a helical polypeptide held together by hydrogen bonds into a random coil. If a polypeptide has n amino acids, $n - 4$ hydrogen bonds are formed to form an α -helix, the most common type of helix in naturally occurring proteins (see Chapter 19). Because the first and last residues in the chain are free to move, $n - 2$ residues form the compact helix and have restricted motion. Based on these ideas, the molar Gibbs energy of unfolding of a polypeptide with $n \geq 5$ may be written as

$$\Delta G_m = (n - 4)\Delta_{\text{hb}}H_m - (n - 2)\Delta_{\text{hb}}S_m$$

where $\Delta_{\text{hb}}H_m$ and $\Delta_{\text{hb}}S_m$ are, respectively, the molar enthalpy and entropy of dissociation of hydrogen bonds in the polypeptide. (a) Justify the form of the equation for the Gibbs energy of unfolding. That is, why are the enthalpy and entropy terms written as $(n - 4)\Delta_{\text{hb}}H_m$ and $(n - 2)\Delta_{\text{hb}}S_m$, respectively? (b) Show that T_m may be written as

$$T_m = \frac{(n - 4)\Delta_{\text{hb}}H_m}{(n - 2)\Delta_{\text{hb}}S_m}$$

(c) Plot $T_m / (\Delta_{\text{hb}}H_m / \Delta_{\text{hb}}S_m)$ for $5 \leq n \leq 20$. At what value of n does T_m change by less than 1% when n increases by one?

4.21† The use of supercritical fluids as mobile phases in SFC depends on their properties as nonpolar solvents. The solubility parameter, δ , is defined as $(\Delta U_{\text{cohesive}} / V_m)^{1/2}$, where $\Delta U_{\text{cohesive}}$ is the cohesive energy of the solvent, the energy per mole needed to increase the volume isothermally to an infinite value. Diethyl ether, carbon tetrachloride, and dioxane have solubility parameter ranges of 7–8, 8–9, and 10–11, respectively. (a) Derive a practical equation for the computation of the isotherms for the reduced internal energy change, $\Delta U_r(T_r, V_r)$ defined as

$$\Delta U_r(T_r, V_r) = \frac{U_r(T_r, V_r) - U_r(T_r, \infty)}{p_c V_c}$$

(b) Draw a graph of ΔU_r against p_r for the isotherms $T_r = 1, 1.2$, and 1.5 in the reduced pressure range for which $0.7 \leq V_r \leq 2$. (c) Draw a graph of δ against p_r for the carbon dioxide isotherms $T_r = 1$ and 1.5 in the reduced pressure range for which $1 \leq V_r \leq 3$. In what pressure range at $T_r = 1$ will carbon dioxide have

solvent properties similar to those of liquid carbon tetrachloride? *Hint.* Use mathematical software or a spreadsheet.

4.22† A substance as well-known as methane still receives research attention because it is an important component of natural gas, a commonly used fossil fuel. Friend *et al.* have published a review of thermophysical properties of methane (D.G. Friend, J.F. Ely, and H. Ingham, *J. Phys. Chem. Ref. Data* **18**, 583 (1989)), which included the following data describing the liquid–vapour phase boundary.

T/K	100	108	110	112	114	120	130	140	150	160	170	190
p/MPa	0.034	0.074	0.088	0.104	0.122	0.192	0.368	0.642	1.041	1.593	2.329	4.521

(a) Plot the liquid–vapour phase boundary. (b) Estimate the standard boiling point of methane. (c) Compute the standard enthalpy of vaporization of methane, given that the molar volumes of the liquid and vapour at the standard boiling point are 3.80×10^{-2} and $8.89 \text{ dm}^3 \text{ mol}^{-1}$, respectively.

4.23† Diamond, an allotrope of carbon, is the hardest substance and the best conductor of heat yet characterized. For these reasons, diamond is used widely in industrial applications that require a strong abrasive. Unfortunately, it is difficult to synthesize diamond from the more readily available allotropes of carbon, such as graphite. To illustrate this point, calculate the pressure required to convert graphite into diamond at 25°C . The following data apply to 25°C and 100 kPa. Assume the specific volume, V_s , and κ_T are constant with respect to pressure changes.

	Graphite	Diamond
$\Delta_f G^\circ/(\text{kJ mol}^{-1})$	0	+2.8678
$V_s/(\text{cm}^3 \text{ g}^{-1})$	0.444	0.284
κ_T/kPa	3.04×10^{-8}	0.187×10^{-8}

Problems

This chapter begins by developing the concept of chemical potential to show that it is a particular case of a class of properties called partial molar quantities. Then it explores how to use the chemical potential of a substance to describe the physical properties of mixtures. The underlying principle to keep in mind is that at equilibrium the chemical potential of a species is the same in every phase. We see, by making use of the experimental observations known as Raoult's and Henry's laws, how to express the chemical potential of a substance in terms of its mole fraction in a mixture. With this result established, we can calculate the effect of a solute on certain thermodynamic properties of a solution. These properties include the lowering of vapour pressure of the solvent, the elevation of its boiling point, the depression of its freezing point, and the origin of osmotic pressure. Finally, we see how to express the chemical potential of a substance in a real mixture in terms of a property known as the activity. We see how the activity may be measured, and conclude with a discussion of how the standard states of solutes and solvents are defined and how ion–ion interactions are taken into account in electrolyte solutions.

Chemistry deals with mixtures, including mixtures of substances that can react together. Therefore, we need to generalize the concepts introduced so far to deal with substances that are mingled together. As a first step towards dealing with chemical reactions (which are treated in Chapter 7), here we consider mixtures of substances that do not react together. At this stage we deal mainly with *binary mixtures*, which are mixtures of two components, A and B. We shall therefore often be able to simplify equations by making use of the relation $x_A + x_B = 1$.

The thermodynamic description of mixtures

We have already seen that the partial pressure, which is the contribution of one component to the total pressure, is used to discuss the properties of mixtures of gases. For a more general description of the thermodynamics of mixtures we need to introduce other analogous 'partial' properties.

5.1 Partial molar quantities

The easiest partial molar property to visualize is the 'partial molar volume', the contribution that a component of a mixture makes to the total volume of a sample.

(a) Partial molar volume

Imagine a huge volume of pure water at 25°C. When a further 1 mol H₂O is added, the volume increases by 18 cm³ and we can report that 18 cm³ mol^{−1} is the molar volume

of pure water. However, when we add 1 mol H_2O to a huge volume of pure ethanol, the volume increases by only 14 cm^3 . The reason for the different increase in volume is that the volume occupied by a given number of water molecules depends on the identity of the molecules that surround them. In the latter case there is so much ethanol present that each H_2O molecule is surrounded by ethanol molecules, and the packing of the molecules results in the H_2O molecules increasing the volume by only 14 cm^3 . The quantity $14 \text{ cm}^3 \text{ mol}^{-1}$ is the partial molar volume of water in pure ethanol. In general, the **partial molar volume** of a substance A in a mixture is the change in volume per mole of A added to a large volume of the mixture.

The partial molar volumes of the components of a mixture vary with composition because the environment of each type of molecule changes as the composition changes from pure A to pure B. It is this changing molecular environment, and the consequential modification of the forces acting between molecules, that results in the variation of the thermodynamic properties of a mixture as its composition is changed. The partial molar volumes of water and ethanol across the full composition range at 25°C are shown in Fig. 5.1.

The partial molar volume, V_J , of a substance J at some general composition is defined formally as follows:

$$V_J = \left(\frac{\partial V}{\partial n_J} \right)_{p, T, n'} \quad [5.1]$$

where the subscript n' signifies that the amounts of all other substances present are constant.¹ The partial molar volume is the slope of the plot of the total volume as the amount of J is changed, the pressure, temperature, and amount of the other components being constant (Fig. 5.2). Its value depends on the composition, as we saw for water and ethanol. The definition in eqn 5.1 implies that, when the composition of the mixture is changed by the addition of dn_A of A and dn_B of B, then the total volume of the mixture changes by

$$dV = \left(\frac{\partial V}{\partial n_A} \right)_{p, T, n_B} dn_A + \left(\frac{\partial V}{\partial n_B} \right)_{p, T, n_A} dn_B = V_A dn_A + V_B dn_B \quad (5.2)$$

Provided the composition is held constant as the amounts of A and B are increased, the final volume of a mixture can be calculated by integration. Because the partial molar volumes are constant (provided the composition is held constant throughout the integration) we can write

$$\begin{aligned} V &= \int_0^{n_A} V_A dn_A + \int_0^{n_B} V_B dn_B = V_A \int_0^{n_A} dn_A + V_B \int_0^{n_B} dn_B \\ &= V_A n_A + V_B n_B \end{aligned} \quad (5.3)$$

Although we have envisaged the two integrations as being linked (in order to preserve constant composition), because V is a state function the final result in eqn 5.3 is valid however the solution is in fact prepared.

Partial molar volumes can be measured in several ways. One method is to measure the dependence of the volume on the composition and to fit the observed volume to a function of the amount of the substance. Once the function has been found, its slope can be determined at any composition of interest by differentiation.

¹ The IUPAC recommendation is to denote a partial molar quantity by $\bar{X}$, but only when there is the possibility of confusion with the quantity X . For instance, the partial molar volume of NaCl in water could be written $\bar{V}(\text{NaCl}, \text{aq})$ to distinguish it from the volume of the solution, $V(\text{NaCl}, \text{aq})$.

Fig. 5.1 The partial molar volumes of water and ethanol at 25°C . Note the different scales (water on the left, ethanol on the right).

Fig. 5.2 The partial molar volume of a substance is the slope of the variation of the total volume of the sample plotted against the composition. In general, partial molar quantities vary with the composition, as shown by the different slopes at the compositions a and b . Note that the partial molar volume at b is negative: the overall volume of the sample decreases as A is added.

Fig. 5.3 The partial molar volume of ethanol as expressed by the polynomial in Illustration 5.1.

 **Exploration** Using the data from Illustration 5.1, determine the value of b at which V_E has a minimum value.

Fig. 5.4 The chemical potential of a substance is the slope of the total Gibbs energy of a mixture with respect to the amount of substance of interest. In general, the chemical potential varies with composition, as shown for the two values at a and b . In this case, both chemical potentials are positive.

Illustration 5.1 The determination of partial molar volume

A polynomial fit to measurements of the total volume of a water/ethanol mixture at 25°C that contains 1.000 kg of water is

$$v = 1002.93 + 54.6664x - 0.363\,94x^2 + 0.028\,256x^3$$

where $v = V/\text{cm}^3$, $x = n_E/\text{mol}$, and n_E is the amount of $\text{CH}_3\text{CH}_2\text{OH}$ present. The partial molar volume of ethanol, V_E , is therefore

$$V_E = \left(\frac{\partial V}{\partial n_E} \right)_{p,T,n_W} = \left(\frac{\partial (V/\text{cm}^3)}{\partial (n_E/\text{mol})} \right)_{p,T,n_W} \text{cm}^3 \text{mol}^{-1} = \left(\frac{\partial v}{\partial x} \right)_{p,T,n_W} \text{cm}^3 \text{mol}^{-1}$$

Then, because

$$\frac{dv}{dx} = 54.6664 - 2(0.36394)x + 3(0.028256)x^2$$

we can conclude that

$$V_E/(\text{cm}^3 \text{mol}^{-1}) = 54.6664 - 0.72788x + 0.084768x^2$$

Figure 5.3 is a graph of this function.

Self-test 5.1 At 25°C, the density of a 50 per cent by mass ethanol/water solution is 0.914 g cm^{-3} . Given that the partial molar volume of water in the solution is $17.4 \text{ cm}^3 \text{mol}^{-1}$, what is the partial molar volume of the ethanol?

[$56.4 \text{ cm}^3 \text{mol}^{-1}$]

Molar volumes are always positive, but partial molar quantities need not be. For example, the limiting partial molar volume of MgSO_4 in water (its partial molar volume in the limit of zero concentration) is $-1.4 \text{ cm}^3 \text{mol}^{-1}$, which means that the addition of 1 mol MgSO_4 to a large volume of water results in a decrease in volume of 1.4 cm^3 . The mixture contracts because the salt breaks up the open structure of water as the ions become hydrated, and it collapses slightly.

(b) Partial molar Gibbs energies

The concept of a partial molar quantity can be extended to any extensive state function. For a substance in a mixture, the chemical potential is *defined* as the partial molar Gibbs energy:

$$\mu_J = \left(\frac{\partial G}{\partial n_J} \right)_{p,T,n'} \quad [5.4]$$

That is, the chemical potential is the slope of a plot of Gibbs energy against the amount of the component J , with the pressure and temperature (and the amounts of the other substances) held constant (Fig. 5.4). For a pure substance we can write $G = n_J G_{J,m}$, and from eqn 5.4 obtain $\mu_J = G_{J,m}$; in this case, the chemical potential is simply the molar Gibbs energy of the substance, as we used in Chapter 4.

By the same argument that led to eqn 5.3, it follows that the total Gibbs energy of a binary mixture is

$$G = n_A \mu_A + n_B \mu_B \quad (5.5)$$

where μ_A and μ_B are the chemical potentials at the composition of the mixture. That is, the chemical potential of a substance in a mixture is the contribution of that

substance to the total Gibbs energy of the mixture. Because the chemical potentials depend on composition (and the pressure and temperature), the Gibbs energy of a mixture may change when these variables change, and for a system of components A, B, etc., the equation $dG = Vdp - SdT$ becomes

$$dG = Vdp - SdT + \mu_A dn_A + \mu_B dn_B + \cdots \quad (5.6)$$

This expression is the **fundamental equation of chemical thermodynamics**. Its implications and consequences are explored and developed in this and the next two chapters.

At constant pressure and temperature, eqn 5.6 simplifies to

$$dG = \mu_A dn_A + \mu_B dn_B + \cdots \quad (5.7)$$

We saw in Section 3.5e that under the same conditions $dG = dw_{\text{add,max}}$. Therefore, at constant temperature and pressure,

$$dw_{\text{add,max}} = \mu_A dn_A + \mu_B dn_B + \cdots \quad (5.8)$$

That is, additional (non-expansion) work can arise from the changing composition of a system. For instance, in an electrochemical cell, the chemical reaction is arranged to take place in two distinct sites (at the two electrodes). The electrical work the cell performs can be traced to its changing composition as products are formed from reactants.

(c) The wider significance of the chemical potential

The chemical potential does more than show how G varies with composition. Because $G = U + pV - TS$, and therefore $U = -pV + TS + G$, we can write a general infinitesimal change in U for a system of variable composition as

$$\begin{aligned} dU &= -pdV - Vdp + SdT + TdS + dG \\ &= -pdV - Vdp + SdT + TdS + (Vdp - SdT + \mu_A dn_A + \mu_B dn_B + \cdots) \\ &= -pdV + TdS + \mu_A dn_A + \mu_B dn_B + \cdots \end{aligned}$$

This expression is the generalization of eqn 3.43 (that $dU = TdS - pdV$) to systems in which the composition may change. It follows that at constant volume and entropy,

$$dU = \mu_A dn_A + \mu_B dn_B + \cdots \quad (5.9)$$

and hence that

$$\mu_J = \left(\frac{\partial U}{\partial n_J} \right)_{S,V,n'} \quad (5.10)$$

Therefore, not only does the chemical potential show how G changes when the composition changes, it also shows how the internal energy changes too (but under a different set of conditions). In the same way it is easy to deduce that

$$(a) \mu_J = \left(\frac{\partial H}{\partial n_J} \right)_{S,p,n'} \quad (b) \mu_J = \left(\frac{\partial A}{\partial n_J} \right)_{V,T,n'} \quad (5.11)$$

Thus we see that the μ_J shows how all the extensive thermodynamic properties U , H , A , and G depend on the composition. This is why the chemical potential is so central to chemistry.

(d) The Gibbs–Duhem equation

Because the total Gibbs energy of a binary mixture is given by eqn 5.5 and the chemical potentials depend on the composition, when the compositions are changed infinitesimally we might expect G of a binary system to change by

$$dG = \mu_A dn_A + \mu_B dn_B + n_A d\mu_A + n_B d\mu_B$$

However, we have seen that at constant pressure and temperature a change in Gibbs energy is given by eqn 5.7. Because G is a state function, these two equations must be equal, which implies that at constant temperature and pressure

$$n_A d\mu_A + n_B d\mu_B = 0 \quad (5.12a)$$

This equation is a special case of the **Gibbs–Duhem equation**:

$$\sum_j n_j d\mu_j = 0 \quad (5.12b)$$

The significance of the Gibbs–Duhem equation is that the chemical potential of one component of a mixture cannot change independently of the chemical potentials of the other components. In a binary mixture, if one partial molar quantity increases, then the other must decrease, with the two changes related by

$$d\mu_B = -\frac{n_A}{n_B} d\mu_A \quad (5.13)$$

The same line of reasoning applies to all partial molar quantities. We can see in Fig. 5.1, for example, that, where the partial molar volume of water increases, that of ethanol decreases. Moreover, as eqn 5.13 shows, and as we can see from Fig. 5.1, a small change in the partial molar volume of A corresponds to a large change in the partial molar volume of B if n_A/n_B is large, but the opposite is true when this ratio is small. In practice, the Gibbs–Duhem equation is used to determine the partial molar volume of one component of a binary mixture from measurements of the partial molar volume of the second component.

Comment 5.1

The *molar concentration* (colloquially, the ‘molarity’, $[J]$ or c_j) is the amount of solute divided by the volume of the solution and is usually expressed in moles per cubic decimetre (mol dm^{-3}). We write $c^\ominus = 1 \text{ mol dm}^{-3}$. The term *molality*, b , is the amount of solute divided by the mass of solvent and is usually expressed in moles per kilogram of solvent (mol kg^{-1}). We write $b^\ominus = 1 \text{ mol kg}^{-1}$.

Example 5.1 Using the Gibbs–Duhem equation

The experimental values of the partial molar volume of $\text{K}_2\text{SO}_4(\text{aq})$ at 298 K are found to fit the expression

$$v_B = 32.280 + 18.216x^{1/2}$$

where $v_B = V_{\text{K}_2\text{SO}_4}/(\text{cm}^3 \text{ mol}^{-1})$ and x is the numerical value of the molality of K_2SO_4 ($x = b/b^\ominus$; see *Comment 5.1*). Use the Gibbs–Duhem equation to derive an equation for the molar volume of water in the solution. The molar volume of pure water at 298 K is $18.079 \text{ cm}^3 \text{ mol}^{-1}$.

Method Let A denote H_2O , the solvent, and B denote K_2SO_4 , the solute. The Gibbs–Duhem equation for the partial molar volumes of two components is $n_A dV_A + n_B dV_B = 0$. This relation implies that $dv_A = -(n_B/n_A)dv_B$, and therefore that v_A can be found by integration:

$$v_A = v_A^* - \int \frac{n_B}{n_A} dv_B$$

where $v_A^* = V_A/(\text{cm}^3 \text{ mol}^{-1})$ is the numerical value of the molar volume of pure A. The first step is to change the variable v_B to $x = b/b^\ominus$ and then to integrate the right-hand side between $x = 0$ (pure B) and the molality of interest.

Answer It follows from the information in the question that, with $B = \text{K}_2\text{SO}_4$, $dv_B/dx = 9.108x^{-1/2}$. Therefore, the integration required is

$$v_B = v_B^* - 9.108 \int_0^{b/b^\ominus} \frac{n_B}{n_A} x^{-1/2} dx$$

However, the ratio of amounts of A (H_2O) and B (K_2SO_4) is related to the molality of B, $b = n_{\text{B}}/(1 \text{ kg water})$ and $n_{\text{A}} = (1 \text{ kg water})/M_{\text{A}}$ where M_{A} is the molar mass of water, by

$$\frac{n_{\text{B}}}{n_{\text{A}}} = \frac{n_{\text{B}}}{(1 \text{ kg})/M_{\text{A}}} = \frac{n_{\text{B}}M_{\text{A}}}{1 \text{ kg}} = bM_{\text{A}} = xb^{\circ}M_{\text{A}}$$

and hence

$$v_{\text{A}} = v_{\text{A}}^* - 9.108M_{\text{A}}b^{\circ} \int_0^{b/b^{\circ}} x^{1/2} dx = v_{\text{A}}^* - \frac{2}{3} \{9.108M_{\text{A}}b^{\circ}(b/b^{\circ})^{3/2}\}$$

It then follows, by substituting the data (including $M_{\text{A}} = 1.802 \times 10^{-2} \text{ kg mol}^{-1}$, the molar mass of water), that

$$V_{\text{A}}/(\text{cm}^3 \text{ mol}^{-1}) = 18.079 - 0.1094(b/b^{\circ})^{3/2}$$

The partial molar volumes are plotted in Fig. 5.5.

Self-test 5.2 Repeat the calculation for a salt B for which $V_{\text{B}}/(\text{cm}^3 \text{ mol}^{-1}) = 6.218 + 5.146b - 7.147b^2$. $[V_{\text{A}}/(\text{cm}^3 \text{ mol}^{-1}) = 18.079 - 0.0464b^2 + 0.0859b^3]$

Fig. 5.5 The partial molar volumes of the components of an aqueous solution of potassium sulfate.

5.2 The thermodynamics of mixing

The dependence of the Gibbs energy of a mixture on its composition is given by eqn 5.5, and we know that at constant temperature and pressure systems tend towards lower Gibbs energy. This is the link we need in order to apply thermodynamics to the discussion of spontaneous changes of composition, as in the mixing of two substances. One simple example of a spontaneous mixing process is that of two gases introduced into the same container. The mixing is spontaneous, so it must correspond to a decrease in G . We shall now see how to express this idea quantitatively.

(a) The Gibbs energy of mixing of perfect gases

Let the amounts of two perfect gases in the two containers be n_{A} and n_{B} ; both are at a temperature T and a pressure p (Fig. 5.6). At this stage, the chemical potentials of the two gases have their ‘pure’ values, which are obtained by applying the definition $\mu = G_{\text{m}}$ to eqn 3.57:

$$\mu = \mu^{\circ} + RT \ln \frac{p}{p^{\circ}} \quad (5.14a)^{\circ}$$

where μ° is the **standard chemical potential**, the chemical potential of the pure gas at 1 bar. It will be much simpler notationally if we agree to let p denote the pressure relative to p° ; that is, to replace p/p° by p , for then we can write

$$\mu = \mu^{\circ} + RT \ln p \quad (5.14b)^{\circ}$$

Equations for which this convention is used will be labelled {1}, {2}, ...; to use the equations, we have to remember to replace p by p/p° again. In practice, that simply means using the numerical value of p in bars. The Gibbs energy of the total system is then given by eqn 5.5 as

$$G_{\text{i}} = n_{\text{A}}\mu_{\text{A}} + n_{\text{B}}\mu_{\text{B}} = n_{\text{A}}(\mu_{\text{A}}^{\circ} + RT \ln p) + n_{\text{B}}(\mu_{\text{B}}^{\circ} + RT \ln p) \quad (5.15)^{\circ}$$

Fig. 5.6 The arrangement for calculating the thermodynamic functions of mixing of two perfect gases.

Fig. 5.7 The Gibbs energy of mixing of two perfect gases and (as discussed later) of two liquids that form an ideal solution. The Gibbs energy of mixing is negative for all compositions and temperatures, so perfect gases mix spontaneously in all proportions.

Exploration Draw graphs of $\Delta_{\text{mix}}G$ against x_A at different temperatures in the range 298 K to 500 K. For what value of x_A does $\Delta_{\text{mix}}G$ depend on temperature most strongly?

Fig. 5.8 The initial and final states considered in the calculation of the Gibbs energy of mixing of gases at different initial pressures.

After mixing, the partial pressures of the gases are p_A and p_B , with $p_A + p_B = p$. The total Gibbs energy changes to

$$G_f = n_A(\mu_A^\circ + RT \ln p_A) + n_B(\mu_B^\circ + RT \ln p_B) \quad \{5.16\}^\circ$$

The difference $G_f - G_i$, the **Gibbs energy of mixing**, $\Delta_{\text{mix}}G$, is therefore

$$\Delta_{\text{mix}}G = n_A RT \ln \frac{p_A}{p} + n_B RT \ln \frac{p_B}{p} \quad (5.17)^\circ$$

At this point we may replace n_j by $x_j n$, where n is the total amount of A and B, and use the relation between partial pressure and mole fraction (Section 1.2b) to write $p_j/p = x_j$ for each component, which gives

$$\Delta_{\text{mix}}G = nRT(x_A \ln x_A + x_B \ln x_B) \quad (5.18)^\circ$$

Because mole fractions are never greater than 1, the logarithms in this equation are negative, and $\Delta_{\text{mix}}G < 0$ (Fig. 5.7). The conclusion that $\Delta_{\text{mix}}G$ is negative for all compositions confirms that perfect gases mix spontaneously in all proportions. However, the equation extends common sense by allowing us to discuss the process quantitatively.

Example 5.2 Calculating a Gibbs energy of mixing

A container is divided into two equal compartments (Fig. 5.8). One contains 3.0 mol $\text{H}_2(\text{g})$ at 25°C ; the other contains 1.0 mol $\text{N}_2(\text{g})$ at 25°C . Calculate the Gibbs energy of mixing when the partition is removed. Assume perfect behaviour.

Method Equation 5.18 cannot be used directly because the two gases are initially at different pressures. We proceed by calculating the initial Gibbs energy from the chemical potentials. To do so, we need the pressure of each gas. Write the pressure of nitrogen as p ; then the pressure of hydrogen as a multiple of p can be found from the gas laws. Next, calculate the Gibbs energy for the system when the partition is removed. The volume occupied by each gas doubles, so its initial partial pressure is halved.

Answer Given that the pressure of nitrogen is p , the pressure of hydrogen is $3p$; therefore, the initial Gibbs energy is

$$G_i = (3.0 \text{ mol})\{\mu^\circ(\text{H}_2) + RT \ln 3p\} + (1.0 \text{ mol})\{\mu^\circ(\text{N}_2) + RT \ln p\}$$

When the partition is removed and each gas occupies twice the original volume, the partial pressure of nitrogen falls to $\frac{1}{2}p$ and that of hydrogen falls to $\frac{3}{2}p$. Therefore, the Gibbs energy changes to

$$G_f = (3.0 \text{ mol})\{\mu^\circ(\text{H}_2) + RT \ln \frac{3}{2}p\} + (1.0 \text{ mol})\{\mu^\circ(\text{N}_2) + RT \ln \frac{1}{2}p\}$$

The Gibbs energy of mixing is the difference of these two quantities:

$$\begin{aligned} \Delta_{\text{mix}}G &= (3.0 \text{ mol})RT \ln \left(\frac{\frac{3}{2}p}{3p} \right) + (1.0 \text{ mol})RT \ln \left(\frac{\frac{1}{2}p}{p} \right) \\ &= -(3.0 \text{ mol})RT \ln 2 - (1.0 \text{ mol})RT \ln 2 \\ &= -(4.0 \text{ mol})RT \ln 2 = -6.9 \text{ kJ} \end{aligned}$$

In this example, the value of $\Delta_{\text{mix}}G$ is the sum of two contributions: the mixing itself, and the changes in pressure of the two gases to their final total pressure, $2p$. When 3.0 mol H_2 mixes with 1.0 mol N_2 at the same pressure, with the volumes of the vessels adjusted accordingly, the change of Gibbs energy is -5.6 kJ .

Self-test 5.3 Suppose that 2.0 mol H_2 at 2.0 atm and 25°C and 4.0 mol N_2 at 3.0 atm and 25°C are mixed at constant volume. Calculate $\Delta_{\text{mix}}G$. What would be the value of $\Delta_{\text{mix}}G$ had the pressures been identical initially? $[-9.7 \text{ kJ}, -9.5 \text{ kJ}]$

(b) Other thermodynamic mixing functions

Because $(\partial G/\partial T)_{p,n} = -S$, it follows immediately from eqn 5.18 that, for a mixture of perfect gases initially at the same pressure, the entropy of mixing, $\Delta_{\text{mix}}S$, is

$$\Delta_{\text{mix}}S = \left(\frac{\partial \Delta_{\text{mix}}G}{\partial T} \right)_{p,n_A,n_B} = -nR(x_A \ln x_A + x_B \ln x_B) \quad (5.19)^\circ$$

Because $\ln x < 0$, it follows that $\Delta_{\text{mix}}S > 0$ for all compositions (Fig. 5.9). For equal amounts of gas, for instance, we set $x_A = x_B = \frac{1}{2}$, and obtain $\Delta_{\text{mix}}S = nR \ln 2$, with n the total amount of gas molecules. This increase in entropy is what we expect when one gas disperses into the other and the disorder increases.

We can calculate the isothermal, isobaric (constant pressure) **enthalpy of mixing**, $\Delta_{\text{mix}}H$, the enthalpy change accompanying mixing, of two perfect gases from $\Delta G = \Delta H - T\Delta S$. It follows from eqns 5.18 and 5.19 that

$$\Delta_{\text{mix}}H = 0 \quad (5.20)^\circ$$

The enthalpy of mixing is zero, as we should expect for a system in which there are no interactions between the molecules forming the gaseous mixture. It follows that the whole of the driving force for mixing comes from the increase in entropy of the system, because the entropy of the surroundings is unchanged.

5.3 The chemical potentials of liquids

To discuss the equilibrium properties of liquid mixtures we need to know how the Gibbs energy of a liquid varies with composition. To calculate its value, we use the fact that, at equilibrium, the chemical potential of a substance present as a vapour must be equal to its chemical potential in the liquid.

(a) Ideal solutions

We shall denote quantities relating to pure substances by a superscript $^\circ$, so the chemical potential of pure A is written μ_A° , and as $\mu_A^\circ(\text{l})$ when we need to emphasize that A is a liquid. Because the vapour pressure of the pure liquid is p_A° , it follows from eqn 5.14 that the chemical potential of A in the vapour (treated as a perfect gas) is $\mu_A^\circ + RT \ln p_A^\circ$ (with p_A° to be interpreted as the relative pressure p_A/p°). These two chemical potentials are equal at equilibrium (Fig. 5.10), so we can write

$$\mu_A^\circ = \mu_A^\circ + RT \ln p_A^\circ \quad \{5.21\}$$

If another substance, a solute, is also present in the liquid, the chemical potential of A in the liquid is changed to μ_A and its vapour pressure is changed to p_A . The vapour and solvent are still in equilibrium, so we can write

$$\mu_A = \mu_A^\circ + RT \ln p_A \quad \{5.22\}$$

Next, we combine these two equations to eliminate the standard chemical potential of the gas. To do so, we write eqn 5.21 as $\mu_A^\circ = \mu_A^\circ - RT \ln p_A^\circ$ and substitute this expression into eqn 5.22 to obtain

Fig. 5.9 The entropy of mixing of two perfect gases and (as discussed later) of two liquids that form an ideal solution. The entropy increases for all compositions and temperatures, so perfect gases mix spontaneously in all proportions. Because there is no transfer of heat to the surroundings when perfect gases mix, the entropy of the surroundings is unchanged. Hence, the graph also shows the total entropy of the system plus the surroundings when perfect gases mix.

Fig. 5.10 At equilibrium, the chemical potential of the gaseous form of a substance A is equal to the chemical potential of its condensed phase. The equality is preserved if a solute is also present. Because the chemical potential of A in the vapour depends on its partial vapour pressure, it follows that the chemical potential of liquid A can be related to its partial vapour pressure.

Fig. 5.11 The total vapour pressure and the two partial vapour pressures of an ideal binary mixture are proportional to the mole fractions of the components.

Fig. 5.12 Two similar liquids, in this case benzene and methylbenzene (toluene), behave almost ideally, and the variation of their vapour pressures with composition resembles that for an ideal solution.

$$\mu_A = \mu_A^* - RT \ln p_A^* + RT \ln p_A = \mu_A^* + RT \ln \frac{p_A}{p_A^*} \quad (5.23)$$

In the final step we draw on additional experimental information about the relation between the ratio of vapour pressures and the composition of the liquid. In a series of experiments on mixtures of closely related liquids (such as benzene and methylbenzene), the French chemist François Raoult found that the ratio of the partial vapour pressure of each component to its vapour pressure as a pure liquid, p_A/p_A^* , is approximately equal to the mole fraction of A in the liquid mixture. That is, he established what we now call **Raoult's law**:

$$p_A = x_A p_A^* \quad (5.24)^\circ$$

This law is illustrated in Fig. 5.11. Some mixtures obey Raoult's law very well, especially when the components are structurally similar (Fig. 5.12). Mixtures that obey the law throughout the composition range from pure A to pure B are called **ideal solutions**. When we write equations that are valid only for ideal solutions, we shall label them with a superscript $^\circ$, as in eqn 5.24.

For an ideal solution, it follows from eqns 5.23 and 5.24 that

$$\mu_A = \mu_A^* + RT \ln x_A \quad (5.25)^\circ$$

This important equation can be used as the *definition* of an ideal solution (so that it implies Raoult's law rather than stemming from it). It is in fact a better definition than eqn 5.24 because it does not assume that the vapour is a perfect gas.

Fig. 5.13 A pictorial representation of the molecular basis of Raoult's law. The large spheres represent solvent molecules at the surface of a solution (the uppermost line of spheres), and the small spheres are solute molecules. The latter hinder the escape of solvent molecules into the vapour, but do not hinder their return.

Molecular interpretation 5.1 The molecular origin of Raoult's law

The origin of Raoult's law can be understood in molecular terms by considering the rates at which molecules leave and return to the liquid. The law reflects the fact that the presence of a second component reduces the rate at which A molecules leave the surface of the liquid but does not inhibit the rate at which they return (Fig. 5.13).

The rate at which A molecules leave the surface is proportional to the number of them at the surface, which in turn is proportional to the mole fraction of A:

$$\text{rate of vaporization} = kx_A$$

where k is a constant of proportionality. The rate at which molecules condense is proportional to their concentration in the gas phase, which in turn is proportional to their partial pressure:

$$\text{rate of condensation} = k'p_A$$

At equilibrium, the rates of vaporization and condensation are equal, so $k'p_A = kx_A$. It follows that

$$p_A = \frac{k}{k'} x_A$$

For the pure liquid, $x_A = 1$; so in this special case $p_A^* = k/k'$. Equation 5.24 then follows by substitution of this relation into the line above.

Some solutions depart significantly from Raoult's law (Fig. 5.14). Nevertheless, even in these cases the law is obeyed increasingly closely for the component in excess (the solvent) as it approaches purity. The law is therefore a good approximation for the properties of the solvent if the solution is dilute.

(b) Ideal-dilute solutions

In ideal solutions the solute, as well as the solvent, obeys Raoult's law. However, the English chemist William Henry found experimentally that, for real solutions at low concentrations, although the vapour pressure of the solute is proportional to its mole fraction, the constant of proportionality is not the vapour pressure of the pure substance (Fig. 5.15). **Henry's law** is:

Fig. 5.14 Strong deviations from ideality are shown by dissimilar liquids (in this case carbon disulfide and acetone, propanone).

Fig. 5.15 When a component (the solvent) is nearly pure, it has a vapour pressure that is proportional to mole fraction with a slope p_B^* (Raoult's law). When it is the minor component (the solute) its vapour pressure is still proportional to the mole fraction, but the constant of proportionality is now K_B (Henry's law).

Fig. 5.16 In a dilute solution, the solvent molecules (the purple spheres) are in an environment that differs only slightly from that of the pure solvent. The solute particles, however, are in an environment totally unlike that of the pure solute.

Fig. 5.17 The experimental partial vapour pressures of a mixture of chloroform (trichloromethane) and acetone (propanone) based on the data in *Example 5.3*. The values of K are obtained by extrapolating the dilute solution vapour pressures as explained in the *Example*.

$$p_B = x_B K_B \quad (5.26)^\circ$$

In this expression x_B is the mole fraction of the solute and K_B is an empirical constant (with the dimensions of pressure) chosen so that the plot of the vapour pressure of B against its mole fraction is tangent to the experimental curve at $x_B = 0$.

Mixtures for which the solute obeys Henry's law and the solvent obeys Raoult's law are called **ideal-dilute solutions**. We shall also label equations with a superscript $^\circ$ when they have been derived from Henry's law. The difference in behaviour of the solute and solvent at low concentrations (as expressed by Henry's and Raoult's laws, respectively) arises from the fact that in a dilute solution the solvent molecules are in an environment very much like the one they have in the pure liquid (Fig. 5.16). In contrast, the solute molecules are surrounded by solvent molecules, which is entirely different from their environment when pure. Thus, the solvent behaves like a slightly modified pure liquid, but the solute behaves entirely differently from its pure state unless the solvent and solute molecules happen to be very similar. In the latter case, the solute also obeys Raoult's law.

Example 5.3 Investigating the validity of Raoult's and Henry's laws

The vapour pressures of each component in a mixture of propanone (acetone, A) and trichloromethane (chloroform, C) were measured at 35°C with the following results:

x_C	0	0.20	0.40	0.60	0.80	1
p_C/kPa	0	4.7	11	18.9	26.7	36.4
p_A/kPa	46.3	33.3	23.3	12.3	4.9	0

Confirm that the mixture conforms to Raoult's law for the component in large excess and to Henry's law for the minor component. Find the Henry's law constants.

Method Both Raoult's and Henry's laws are statements about the form of the graph of partial vapour pressure against mole fraction. Therefore, plot the partial vapour pressures against mole fraction. Raoult's law is tested by comparing the data with the straight line $p_j = x_j p_j^*$ for each component in the region in which it is in excess (and acting as the solvent). Henry's law is tested by finding a straight line $p_j = x_j K_j$ that is tangent to each partial vapour pressure at low x , where the component can be treated as the solute.

Answer The data are plotted in Fig. 5.17 together with the Raoult's law lines. Henry's law requires $K = 23.3$ kPa for propanone and $K = 22.0$ kPa for trichloromethane. Notice how the system deviates from both Raoult's and Henry's laws even for quite small departures from $x = 1$ and $x = 0$, respectively. We deal with these deviations in Section 5.5.

Self-test 5.4 The vapour pressure of chloromethane at various mole fractions in a mixture at 25°C was found to be as follows:

x	0.005	0.009	0.019	0.024
p/kPa	27.3	48.4	101	126

Estimate Henry's law constant.

[5 MPa]

For practical applications, Henry's law is expressed in terms of the molality, b , of the solute,

$$p_B = b_B K_B$$

Some Henry's law data for this convention are listed in Table 5.1. As well as providing a link between the mole fraction of solute and its partial pressure, the data in the table may also be used to calculate gas solubilities. A knowledge of Henry's law constants for gases in blood and fats is important for the discussion of respiration, especially when the partial pressure of oxygen is abnormal, as in diving and mountaineering, and for the discussion of the action of gaseous anaesthetics.

Synoptic Table 5.1* Henry's law constants for gases in water at 298 K

	$K/(\text{kPa kg mol}^{-1})$
CO_2	3.01×10^3
H_2	1.28×10^5
N_2	1.56×10^5
O_2	7.92×10^4

* More values are given in the *Data section*.

Illustration 5.2 Using Henry's law

To estimate the molar solubility of oxygen in water at 25°C and a partial pressure of 21 kPa, its partial pressure in the atmosphere at sea level, we write

$$b_{\text{O}_2} = \frac{p_{\text{O}_2}}{K_{\text{O}_2}} = \frac{21 \text{ kPa}}{7.9 \times 10^4 \text{ kPa kg mol}^{-1}} = 2.9 \times 10^{-4} \text{ mol kg}^{-1}$$

The molality of the saturated solution is therefore 0.29 mmol kg⁻¹. To convert this quantity to a molar concentration, we assume that the mass density of this dilute solution is essentially that of pure water at 25°C, or $\rho_{\text{H}_2\text{O}} = 0.99709 \text{ kg dm}^{-3}$. It follows that the molar concentration of oxygen is

$$[\text{O}_2] = b_{\text{O}_2} \times \rho_{\text{H}_2\text{O}} = 0.29 \text{ mmol kg}^{-1} \times 0.99709 \text{ kg dm}^{-3} = 0.29 \text{ mmol dm}^{-3}$$

A note on good practice The number of significant figures in the result of a calculation should not exceed the number in the data (only two in this case).

Self-test 5.5 Calculate the molar solubility of nitrogen in water exposed to air at 25°C; partial pressures were calculated in *Example 1.3*. [0.51 mmol dm⁻³]

IMPACT ON BIOLOGY

I5.1 Gas solubility and breathing

We inhale about 500 cm³ of air with each breath we take. The influx of air is a result of changes in volume of the lungs as the diaphragm is depressed and the chest expands, which results in a decrease in pressure of about 100 Pa relative to atmospheric pressure. Expiration occurs as the diaphragm rises and the chest contracts, and gives rise to a differential pressure of about 100 Pa above atmospheric pressure. The total volume of air in the lungs is about 6 dm³, and the additional volume of air that can be exhaled forcefully after normal expiration is about 1.5 dm³. Some air remains in the lungs at all times to prevent the collapse of the alveoli.

A knowledge of Henry's law constants for gases in fats and lipids is important for the discussion of respiration. The effect of gas exchange between blood and air inside the alveoli of the lungs means that the composition of the air in the lungs changes throughout the breathing cycle. Alveolar gas is in fact a mixture of newly inhaled air and air about to be exhaled. The concentration of oxygen present in arterial blood is equivalent to a partial pressure of about 40 Torr (5.3 kPa), whereas the partial pressure of freshly inhaled air is about 104 Torr (13.9 kPa). Arterial blood remains in the capillary passing through the wall of an alveolus for about 0.75 s, but such is the steepness of the pressure gradient that it becomes fully saturated with oxygen in about 0.25 s. If the lungs collect fluids (as in pneumonia), then the respiratory membrane thickens, diffusion is greatly slowed, and body tissues begin to suffer from oxygen starvation. Carbon dioxide moves in the opposite direction across the respiratory

Comment 5.2

The web site contains links to online databases of Henry's law constants.

tissue, but the partial pressure gradient is much less, corresponding to about 5 Torr (0.7 kPa) in blood and 40 Torr (5.3 kPa) in air at equilibrium. However, because carbon dioxide is much more soluble in the alveolar fluid than oxygen is, equal amounts of oxygen and carbon dioxide are exchanged in each breath.

A hyperbaric oxygen chamber, in which oxygen is at an elevated partial pressure, is used to treat certain types of disease. Carbon monoxide poisoning can be treated in this way as can the consequences of shock. Diseases that are caused by anaerobic bacteria, such as gas gangrene and tetanus, can also be treated because the bacteria cannot thrive in high oxygen concentrations.

In scuba diving (where *scuba* is an acronym formed from ‘self-contained underwater breathing apparatus’), air is supplied at a higher pressure, so that the pressure within the diver’s chest matches the pressure exerted by the surrounding water. The latter increases by about 1 atm for each 10 m of descent. One unfortunate consequence of breathing air at high pressures is that nitrogen is much more soluble in fatty tissues than in water, so it tends to dissolve in the central nervous system, bone marrow, and fat reserves. The result is *nitrogen narcosis*, with symptoms like intoxication. If the diver rises too rapidly to the surface, the nitrogen comes out of its lipid solution as bubbles, which causes the painful and sometimes fatal condition known as *the bends*. Many cases of scuba drowning appear to be consequences of arterial embolisms (obstructions in arteries caused by gas bubbles) and loss of consciousness as the air bubbles rise into the head.

The properties of solutions

In this section we consider the thermodynamics of mixing of liquids. First, we consider the simple case of mixtures of liquids that mix to form an ideal solution. In this way, we identify the thermodynamic consequences of molecules of one species mingling randomly with molecules of the second species. The calculation provides a background for discussing the deviations from ideal behaviour exhibited by real solutions.

5.4 Liquid mixtures

Thermodynamics can provide insight into the properties of liquid mixtures, and a few simple ideas can bring the whole field of study together.

(a) Ideal solutions

The Gibbs energy of mixing of two liquids to form an ideal solution is calculated in exactly the same way as for two gases (Section 5.2). The total Gibbs energy before liquids are mixed is

$$G_i = n_A \mu_A^* + n_B \mu_B^*$$

When they are mixed, the individual chemical potentials are given by eqn 5.25 and the total Gibbs energy is

$$G_f = n_A \{\mu_A^* + RT \ln x_A\} + n_B \{\mu_B^* + RT \ln x_B\}$$

Consequently, the Gibbs energy of mixing is

$$\Delta_{\text{mix}} G = nRT \{x_A \ln x_A + x_B \ln x_B\} \quad (5.27)^\circ$$

where $n = n_A + n_B$. As for gases, it follows that the ideal entropy of mixing of two liquids is

$$\Delta_{\text{mix}} S = -nR \{x_A \ln x_A + x_B \ln x_B\} \quad (5.28)^\circ$$

and, because $\Delta_{\text{mix}}H = \Delta_{\text{mix}}G + T\Delta_{\text{mix}}S = 0$, the ideal enthalpy of mixing is zero. The ideal volume of mixing, the change in volume on mixing, is also zero because it follows from eqn 3.50 $((\partial G/\partial p)_T = V)$ that $\Delta_{\text{mix}}V = (\partial \Delta_{\text{mix}}G/\partial p)_T$, but $\Delta_{\text{mix}}G$ in eqn 5.27 is independent of pressure, so the derivative with respect to pressure is zero.

Equation 5.27 is the same as that for two perfect gases and all the conclusions drawn there are valid here: the driving force for mixing is the increasing entropy of the system as the molecules mingle and the enthalpy of mixing is zero. It should be noted, however, that solution ideality means something different from gas perfection. In a perfect gas there are no forces acting between molecules. In ideal solutions there are interactions, but the average energy of A–B interactions in the mixture is the same as the average energy of A–A and B–B interactions in the pure liquids.² The variation of the Gibbs energy of mixing with composition is the same as that already depicted for gases in Fig. 5.7; the same is true of the entropy of mixing, Fig. 5.9.

Real solutions are composed of particles for which A–A, A–B, and B–B interactions are all different. Not only may there be enthalpy and volume changes when liquids mix, but there may also be an additional contribution to the entropy arising from the way in which the molecules of one type might cluster together instead of mingling freely with the others. If the enthalpy change is large and positive or if the entropy change is adverse (because of a reorganization of the molecules that results in an orderly mixture), then the Gibbs energy might be positive for mixing. In that case, separation is spontaneous and the liquids may be immiscible. Alternatively, the liquids might be **partially miscible**, which means that they are miscible only over a certain range of compositions.

(b) Excess functions and regular solutions

The thermodynamic properties of real solutions are expressed in terms of the **excess functions**, X^E , the difference between the observed thermodynamic function of mixing and the function for an ideal solution. The **excess entropy**, S^E , for example, is defined as

$$S^E = \Delta_{\text{mix}}S - \Delta_{\text{mix}}S^{\text{ideal}} \quad [5.29]$$

where $\Delta_{\text{mix}}S^{\text{ideal}}$ is given by eqn 5.28. The excess enthalpy and volume are both equal to the observed enthalpy and volume of mixing, because the ideal values are zero in each case.

Deviations of the excess energies from zero indicate the extent to which the solutions are nonideal. In this connection a useful model system is the **regular solution**, a solution for which $H^E \neq 0$ but $S^E = 0$. We can think of a regular solution as one in which the two kinds of molecules are distributed randomly (as in an ideal solution) but have different energies of interactions with each other. Figure 5.18 shows two examples of the composition dependence of molar excess functions.

We can make this discussion more quantitative by supposing that the excess enthalpy depends on composition as

$$H^E = n\beta RTx_Ax_B \quad (5.30)$$

where β is a dimensionless parameter that is a measure of the energy of AB interactions relative to that of the AA and BB interactions. The function given by eqn 5.30 is plotted in Fig. 5.19, and we see it resembles the experimental curve in Fig. 5.18. If $\beta < 0$, mixing is exothermic and the solute–solvent interactions are more favourable than the solvent–solvent and solute–solute interactions. If $\beta > 0$, then the mixing is

Fig. 5.18 Experimental excess functions at 25°C. (a) H^E for benzene/cyclohexane; this graph shows that the mixing is endothermic (because $\Delta_{\text{mix}}H = 0$ for an ideal solution). (b) The excess volume, V^E , for tetrachloroethene/cyclopentane; this graph shows that there is a contraction at low tetrachloroethane mole fractions, but an expansion at high mole fractions (because $\Delta_{\text{mix}}V = 0$ for an ideal mixture).

² It is on the basis of this distinction that the term ‘perfect gas’ is preferable to the more common ‘ideal gas’.

Fig. 5.19 The excess enthalpy according to a model in which it is proportional to $\beta x_A x_B$, for different values of the parameter β .

 **Exploration** Using the graph above, fix β and vary the temperature. For what value of x_A does the excess enthalpy depend on temperature most strongly?

Fig. 5.20 The Gibbs energy of mixing for different values of the parameter β .

 **Exploration** Using the graph above, fix β at 1.5 and vary the temperature. Is there a range of temperatures over which you observe phase separation?

endothermic. Because the entropy of mixing has its ideal value for a regular solution, the excess Gibbs energy is equal to the excess enthalpy, and the Gibbs energy of mixing is

$$\Delta_{\text{mix}}G = nRT\{x_A \ln x_A + x_B \ln x_B + \beta x_A x_B\} \quad (5.31)$$

Figure 5.20 shows how $\Delta_{\text{mix}}G$ varies with composition for different values of β . The important feature is that for $\beta > 2$ the graph shows two minima separated by a maximum. The implication of this observation is that, provided $\beta > 2$, then the system will separate spontaneously into two phases with compositions corresponding to the two minima, for that separation corresponds to a reduction in Gibbs energy. We develop this point in Sections 5.8 and 6.5.

5.5 Colligative properties

The properties we now consider are the lowering of vapour pressure, the elevation of boiling point, the depression of freezing point, and the osmotic pressure arising from the presence of a solute. In dilute solutions these properties depend only on the number of solute particles present, not their identity. For this reason, they are called **colligative properties** (denoting ‘depending on the collection’).

We assume throughout the following that the solute is not volatile, so it does not contribute to the vapour. We also assume that the solute does not dissolve in the solid solvent: that is, the pure solid solvent separates when the solution is frozen. The latter assumption is quite drastic, although it is true of many mixtures; it can be avoided at the expense of more algebra, but that introduces no new principles.

(a) The common features of colligative properties

All the colligative properties stem from the reduction of the chemical potential of the liquid solvent as a result of the presence of solute. For an ideal-dilute solution, the

reduction is from μ_A^* for the pure solvent to $\mu_A^* + RT \ln x_A$ when a solute is present ($\ln x_A$ is negative because $x_A < 1$). There is no direct influence of the solute on the chemical potential of the solvent vapour and the solid solvent because the solute appears in neither the vapour nor the solid. As can be seen from Fig. 5.21, the reduction in chemical potential of the solvent implies that the liquid–vapour equilibrium occurs at a higher temperature (the boiling point is raised) and the solid–liquid equilibrium occurs at a lower temperature (the freezing point is lowered).

Molecular interpretation 5.2 *The lowering of vapour pressure of a solvent in a mixture*

The molecular origin of the lowering of the chemical potential is not the energy of interaction of the solute and solvent particles, because the lowering occurs even in an ideal solution (for which the enthalpy of mixing is zero). If it is not an enthalpy effect, it must be an entropy effect.

The pure liquid solvent has an entropy that reflects the number of microstates available to its molecules. Its vapour pressure reflects the tendency of the solution towards greater entropy, which can be achieved if the liquid vaporizes to form a gas. When a solute is present, there is an additional contribution to the entropy of the liquid, even in an ideal solution. Because the entropy of the liquid is already higher than that of the pure liquid, there is a weaker tendency to form the gas (Fig. 5.22). The effect of the solute appears as a lowered vapour pressure, and hence a higher boiling point.

Similarly, the enhanced molecular randomness of the solution opposes the tendency to freeze. Consequently, a lower temperature must be reached before equilibrium between solid and solution is achieved. Hence, the freezing point is lowered.

The strategy for the quantitative discussion of the elevation of boiling point and the depression of freezing point is to look for the temperature at which, at 1 atm, one phase (the pure solvent vapour or the pure solid solvent) has the same chemical potential as the solvent in the solution. This is the new equilibrium temperature for the phase transition at 1 atm, and hence corresponds to the new boiling point or the new freezing point of the solvent.

(b) The elevation of boiling point

The heterogeneous equilibrium of interest when considering boiling is between the solvent vapour and the solvent in solution at 1 atm (Fig. 5.23). We denote the solvent by A and the solute by B. The equilibrium is established at a temperature for which

$$\mu_A^*(g) = \mu_A^*(l) + RT \ln x_A \quad (5.32)^\circ$$

(The pressure of 1 atm is the same throughout, and will not be written explicitly.) We show in the *Justification* below that this equation implies that the presence of a solute at a mole fraction x_B causes an increase in normal boiling point from T^* to $T^* + \Delta T$, where

$$\Delta T = Kx_B \quad K = \frac{RT^{*2}}{\Delta_{\text{vap}}H} \quad (5.33)^\circ$$

Fig. 5.21 The chemical potential of a solvent in the presence of a solute. The lowering of the liquid's chemical potential has a greater effect on the freezing point than on the boiling point because of the angles at which the lines intersect.

Fig. 5.22 The vapour pressure of a pure liquid represents a balance between the increase in disorder arising from vaporization and the decrease in disorder of the surroundings. (a) Here the structure of the liquid is represented highly schematically by the grid of squares. (b) When solute (the dark squares) is present, the disorder of the condensed phase is higher than that of the pure liquid, and there is a decreased tendency to acquire the disorder characteristic of the vapour.

Fig. 5.23 The heterogeneous equilibrium involved in the calculation of the elevation of boiling point is between A in the pure vapour and A in the mixture, A being the solvent and B an involatile solute.

Comment 5.3

The series expansion of a natural logarithm (see Appendix 2) is

$$\ln(1 - x) = -x - \frac{1}{2}x^2 - \frac{1}{3}x^3 \dots$$

provided that $-1 < x < 1$. If $x \ll 1$, then the terms involving x raised to a power greater than 1 are much smaller than x , so $\ln(1 - x) \approx -x$.

Fig. 5.24 The heterogeneous equilibrium involved in the calculation of the lowering of freezing point is between A in the pure solid and A in the mixture, A being the solvent and B a solute that is insoluble in solid A.

Justification 5.1 The elevation of the boiling point of a solvent

Equation 5.32 can be rearranged into

$$\ln x_A = \frac{\mu_A^*(g) - \mu_A^*(l)}{RT} = \frac{\Delta_{\text{vap}}G}{RT}$$

where $\Delta_{\text{vap}}G$ is the Gibbs energy of vaporization of the pure solvent (A). First, to find the relation between a change in composition and the resulting change in boiling temperature, we differentiate both sides with respect to temperature and use the Gibbs–Helmholtz equation (eqn 3.52, $(\partial(G/T)/\partial T)_p = -H/T^2$) to express the term on the right:

$$\frac{d \ln x_A}{dT} = \frac{1}{R} \frac{d(\Delta_{\text{vap}}G/T)}{dT} = -\frac{\Delta_{\text{vap}}H}{RT^2}$$

Now multiply both sides by dT and integrate from $x_A = 1$, corresponding to $\ln x_A = 0$ (and when $T = T^*$, the boiling point of pure A) to x_A (when the boiling point is T):

$$\int_0^{\ln x_A} d \ln x_A = -\frac{1}{R} \int_{T^*}^T \frac{\Delta_{\text{vap}}H}{T^2} dT$$

The left-hand side integrates to $\ln x_A$, which is equal to $\ln(1 - x_B)$. The right-hand side can be integrated if we assume that the enthalpy of vaporization is a constant over the small range of temperatures involved and can be taken outside the integral. Thus, we obtain

$$\ln(1 - x_B) = \frac{\Delta_{\text{vap}}H}{R} \left(\frac{1}{T} - \frac{1}{T^*} \right)$$

We now suppose that the amount of solute present is so small that $x_B \ll 1$. We can then write $\ln(1 - x_B) \approx -x_B$ and hence obtain

$$x_B = \frac{\Delta_{\text{vap}}H}{R} \left(\frac{1}{T^*} - \frac{1}{T} \right)$$

Finally, because $T \approx T^*$, it also follows that

$$\frac{1}{T^*} - \frac{1}{T} = \frac{T - T^*}{TT^*} \approx \frac{\Delta T}{T^{*2}}$$

with $\Delta T = T - T^*$. The previous equation then rearranges into eqn 5.33.

Because eqn 5.33 makes no reference to the identity of the solute, only to its mole fraction, we conclude that the elevation of boiling point is a colligative property. The value of ΔT does depend on the properties of the solvent, and the biggest changes occur for solvents with high boiling points.³ For practical applications of eqn 5.33, we note that the mole fraction of B is proportional to its molality, b , in the solution, and write

$$\Delta T = K_b b \quad (5.34)$$

where K_b is the empirical **boiling-point constant** of the solvent (Table 5.2).

(c) The depression of freezing point

The heterogeneous equilibrium now of interest is between pure solid solvent A and the solution with solute present at a mole fraction x_B (Fig. 5.24). At the freezing point, the chemical potentials of A in the two phases are equal:

³ By Trouton's rule (Section 3.3b), $\Delta_{\text{vap}}H/T^*$ is a constant; therefore eqn 5.33 has the form $\Delta T \propto T^*$ and is independent of $\Delta_{\text{vap}}H$ itself.

Synoptic Table 5.2* Freezing-point and boiling-point constants

	$K_f/(\text{K kg mol}^{-1})$	$K_b/(\text{K kg mol}^{-1})$
Benzene	5.12	2.53
Camphor	40	
Phenol	7.27	3.04
Water	1.86	0.51

* More values are given in the *Data section*.

$$\mu_A^*(s) = \mu_A^*(l) + RT \ln x_A \quad (5.35)^\circ$$

The only difference between this calculation and the last is the appearance of the solid's chemical potential in place of the vapour's. Therefore we can write the result directly from eqn 5.33:

$$\Delta T = K' x_B \quad K' = \frac{RT^{*2}}{\Delta_{\text{fus}} H} \quad (5.36)^\circ$$

where ΔT is the freezing point depression, $T^* - T$, and $\Delta_{\text{fus}} H$ is the enthalpy of fusion of the solvent. Larger depressions are observed in solvents with low enthalpies of fusion and high melting points. When the solution is dilute, the mole fraction is proportional to the molality of the solute, b , and it is common to write the last equation as

$$\Delta T = K_f b \quad (5.37)$$

where K_f is the empirical **freezing-point constant** (Table 5.2). Once the freezing-point constant of a solvent is known, the depression of freezing point may be used to measure the molar mass of a solute in the method known as **cryoscopy**; however, the technique is of little more than historical interest.

(d) Solubility

Although solubility is not strictly a colligative property (because solubility varies with the identity of the solute), it may be estimated by the same techniques as we have been using. When a solid solute is left in contact with a solvent, it dissolves until the solution is saturated. Saturation is a state of equilibrium, with the undissolved solute in equilibrium with the dissolved solute. Therefore, in a saturated solution the chemical potential of the pure solid solute, $\mu_B^*(s)$, and the chemical potential of B in solution, μ_B , are equal (Fig. 5.25). Because the latter is

$$\mu_B = \mu_B^*(l) + RT \ln x_B$$

we can write

$$\mu_B^*(s) = \mu_B^*(l) + RT \ln x_B \quad (5.38)^\circ$$

This expression is the same as the starting equation of the last section, except that the quantities refer to the solute B, not the solvent A. We now show in the following *Justification* that

$$\ln x_B = \frac{\Delta_{\text{fus}} H}{R} \left(\frac{1}{T_f} - \frac{1}{T} \right) \quad (5.39)^\circ$$

Fig. 5.25 The heterogeneous equilibrium involved in the calculation of the solubility is between pure solid B and B in the mixture.

Fig. 5.26 The variation of solubility (the mole fraction of solute in a saturated solution) with temperature (T^* is the freezing temperature of the solute). Individual curves are labelled with the value of $\Delta_{\text{fus}} H/RT^*$.

Exploration Derive an expression for the temperature coefficient of the solubility, dx_B/dT , and plot it as a function of temperature for several values of the enthalpy of fusion.

Fig. 5.27 The equilibrium involved in the calculation of osmotic pressure, Π , is between pure solvent A at a pressure p on one side of the semipermeable membrane and A as a component of the mixture on the other side of the membrane, where the pressure is $p + \Pi$.

Justification 5.2 The solubility of an ideal solute.

The starting point is the same as in *Justification 5.1* but the aim is different. In the present case, we want to find the mole fraction of B in solution at equilibrium when the temperature is T . Therefore, we start by rearranging eqn 5.38 into

$$\ln x_B = \frac{\mu_B^*(s) - \mu_B^*(l)}{RT} = -\frac{\Delta_{\text{fus}} G}{RT}$$

As in *Justification 5.1*, we relate the change in composition $d \ln x_B$ to the change in temperature by differentiation and use of the Gibbs–Helmholtz equation. Then we integrate from the melting temperature of B (when $x_B = 1$ and $\ln x_B = 0$) to the lower temperature of interest (when x_B has a value between 0 and 1):

$$\int_0^{\ln x_B} d \ln x_B = \frac{1}{R} \int_{T_i}^T \frac{\Delta_{\text{fus}} H}{T^2} dT$$

If we suppose that the enthalpy of fusion of B is constant over the range of temperatures of interest, it can be taken outside the integral, and we obtain eqn 5.39.

Equation 5.39 is plotted in Fig. 5.26. It shows that the solubility of B decreases exponentially as the temperature is lowered from its melting point. The illustration also shows that solutes with high melting points and large enthalpies of melting have low solubilities at normal temperatures. However, the detailed content of eqn 5.39 should not be treated too seriously because it is based on highly questionable approximations, such as the ideality of the solution. One aspect of its approximate character is that it fails to predict that solutes will have different solubilities in different solvents, for no solvent properties appear in the expression.

(e) Osmosis

The phenomenon of **osmosis** (from the Greek word for ‘push’) is the spontaneous passage of a pure solvent into a solution separated from it by a **semipermeable membrane**, a membrane permeable to the solvent but not to the solute (Fig. 5.27). The **osmotic pressure**, Π , is the pressure that must be applied to the solution to stop the influx of solvent. Important examples of osmosis include transport of fluids through cell membranes, dialysis and **osmometry**, the determination of molar mass by the measurement of osmotic pressure. Osmometry is widely used to determine the molar masses of macromolecules.

In the simple arrangement shown in Fig. 5.28, the opposing pressure arises from the head of solution that the osmosis itself produces. Equilibrium is reached when the hydrostatic pressure of the column of solution matches the osmotic pressure. The complicating feature of this arrangement is that the entry of solvent into the solution results in its dilution, and so it is more difficult to treat than the arrangement in Fig. 5.27, in which there is no flow and the concentrations remain unchanged.

The thermodynamic treatment of osmosis depends on noting that, at equilibrium, the chemical potential of the solvent must be the same on each side of the membrane. The chemical potential of the solvent is lowered by the solute, but is restored to its ‘pure’ value by the application of pressure. As shown in the *Justification* below, this equality implies that for dilute solutions the osmotic pressure is given by the **van ’t Hoff equation**:

$$\Pi = [B]RT \quad (5.40)^\circ$$

where $[B] = n_B/V$ is the molar concentration of the solute.

Justification 5.3 *The van 't Hoff equation*

On the pure solvent side the chemical potential of the solvent, which is at a pressure p , is $\mu_A^*(p)$. On the solution side, the chemical potential is lowered by the presence of the solute, which reduces the mole fraction of the solvent from 1 to x_A . However, the chemical potential of A is raised on account of the greater pressure, $p + \Pi$, that the solution experiences. At equilibrium the chemical potential of A is the same in both compartments, and we can write

$$\mu_A^*(p) = \mu_A(x_A, p + \Pi)$$

The presence of solute is taken into account in the normal way:

$$\mu_A(x_A, p + \Pi) = \mu_A^*(p + \Pi) + RT \ln x_A$$

We saw in Section 3.9c (eqn 3.54) how to take the effect of pressure into account:

$$\mu_A^*(p + \Pi) = \mu_A^*(p) + \int_p^{p+\Pi} V_m dp$$

where V_m is the molar volume of the pure solvent A. When these three equations are combined we get

$$-RT \ln x_A = \int_p^{p+\Pi} V_m dp$$

This expression enables us to calculate the additional pressure Π that must be applied to the solution to restore the chemical potential of the solvent to its 'pure' value and thus to restore equilibrium across the semipermeable membrane. For dilute solutions, $\ln x_A$ may be replaced by $\ln(1 - x_B) \approx -x_B$. We may also assume that the pressure range in the integration is so small that the molar volume of the solvent is a constant. That being so, V_m may be taken outside the integral, giving

$$RT x_B = \Pi V_m$$

When the solution is dilute, $x_B \approx n_B/n_A$. Moreover, because $n_A V_m = V$, the total volume of the solvent, the equation simplifies to eqn 5.40.

Because the effect of osmotic pressure is so readily measurable and large, one of the most common applications of osmometry is to the measurement of molar masses of macromolecules, such as proteins and synthetic polymers. As these huge molecules dissolve to produce solutions that are far from ideal, it is assumed that the van 't Hoff equation is only the first term of a virial-like expansion:⁴

$$\Pi = [J] RT \{1 + B[J] + \dots\} \quad (5.41)$$

The additional terms take the nonideality into account; the empirical constant B is called the **osmotic virial coefficient**.

Example 5.4 *Using osmometry to determine the molar mass of a macromolecule*

The osmotic pressures of solutions of poly(vinyl chloride), PVC, in cyclohexanone at 298 K are given below. The pressures are expressed in terms of the heights of solution (of mass density $\rho = 0.980 \text{ g cm}^{-3}$) in balance with the osmotic pressure. Determine the molar mass of the polymer.

$c/(\text{g dm}^{-3})$	1.00	2.00	4.00	7.00	9.00
h/cm	0.28	0.71	2.01	5.10	8.00

⁴ We have denoted the solute J to avoid too many different Bs in this expression.

Fig. 5.28 The plot involved in the determination of molar mass by osmometry. The molar mass is calculated from the intercept at $c = 0$; in Chapter 19 we shall see that additional information comes from the slope.

 **Exploration** Calculate the osmotic virial coefficient B from these data.

Method The osmotic pressure is measured at a series of mass concentrations, c , and a plot of Π/c against c is used to determine the molar mass of the polymer. We use eqn 5.41 with $[J] = c/M$ where c is the mass concentration of the polymer and M is its molar mass. The osmotic pressure is related to the hydrostatic pressure by $\Pi = \rho gh$ (Example 1.2) with $g = 9.81 \text{ m s}^{-2}$. With these substitutions, eqn 5.41 becomes

$$\frac{h}{c} = \frac{RT}{\rho g M} \left(1 + \frac{Bc}{M} + \dots \right) = \frac{RT}{\rho g M} + \left(\frac{RTB}{\rho g M^2} \right) c + \dots$$

Therefore, to find M , plot h/c against c , and expect a straight line with intercept $RT/\rho g M$ at $c = 0$.

Answer The data give the following values for the quantities to plot:

$c/(\text{g dm}^{-3})$	1.00	2.00	4.00	7.00	9.00
$(h/c)/(\text{cm g}^{-1} \text{ dm}^3)$	0.28	0.36	0.503	0.729	0.889

The points are plotted in Fig. 5.28. The intercept is at 0.21. Therefore,

$$\begin{aligned} M &= \frac{RT}{\rho g} \times \frac{1}{0.21 \text{ cm g}^{-1} \text{ dm}^3} \\ &= \frac{(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})}{(980 \text{ kg m}^{-3}) \times (9.81 \text{ m s}^{-2})} \times \frac{1}{2.1 \times 10^{-3} \text{ m}^4 \text{ kg}^{-1}} \\ &= 1.2 \times 10^2 \text{ kg mol}^{-1} \end{aligned}$$

where we have used $1 \text{ kg m}^2 \text{ s}^{-2} = 1 \text{ J}$. Molar masses of macromolecules are often reported in daltons (Da), with $1 \text{ Da} = 1 \text{ g mol}^{-1}$. The macromolecule in this example has a molar mass of about 120 kDa. Modern osmometers give readings of osmotic pressure in pascals, so the analysis of the data is more straightforward and eqn 5.41 can be used directly. As we shall see in Chapter 19, the value obtained from osmometry is the ‘number average molar mass’.

Self-test 5.6 Estimate the depression of freezing point of the most concentrated of these solutions, taking K_f as about $10 \text{ K}/(\text{mol kg}^{-1})$. [0.8 mK]

Fig. 5.29 In a simple version of the osmotic pressure experiment, A is at equilibrium on each side of the membrane when enough has passed into the solution to cause a hydrostatic pressure difference.

IMPACT ON BIOLOGY

I5.2 Osmosis in physiology and biochemistry

Osmosis helps biological cells maintain their structure. Cell membranes are semipermeable and allow water, small molecules, and hydrated ions to pass, while blocking the passage of biopolymers synthesized inside the cell. The difference in concentrations of solutes inside and outside the cell gives rise to an osmotic pressure, and water passes into the more concentrated solution in the interior of the cell, carrying small nutrient molecules. The influx of water also keeps the cell swollen, whereas dehydration causes the cell to shrink. These effects are important in everyday medical practice. To maintain the integrity of blood cells, solutions that are injected into the bloodstream for blood transfusions and intravenous feeding must be *isotonic* with the blood, meaning that they must have the same osmotic pressure as blood. If the injected solution is too dilute, or *hypotonic*, the flow of solvent into the cells, required to equalize the osmotic pressure, causes the cells to burst and die by a process called *haemolysis*. If the solution is too concentrated, or *hypertonic*, equalization of the osmotic pressure requires flow of solvent out of the cells, which shrink and die.

Osmosis also forms the basis of *dialysis*, a common technique for the removal of impurities from solutions of biological macromolecules and for the study of binding of small molecules to macromolecules, such as an inhibitor to an enzyme, an antibiotic to DNA, and any other instance of cooperation or inhibition by small molecules attaching to large ones. In a purification experiment, a solution of macromolecules containing impurities, such as ions or small molecules (including small proteins or nucleic acids), is placed in a bag made of a material that acts as a semipermeable membrane and the filled bag is immersed in a solvent. The membrane permits the passage of the small ions and molecules but not the larger macromolecules, so the former migrate through the membrane, leaving the macromolecules behind. In practice, purification of the sample requires several changes of solvent to coax most of the impurities out of the dialysis bag.

In a binding experiment, a solution of macromolecules and smaller ions or molecules is placed in a dialysis bag, which is then immersed in a solvent. Suppose the molar concentration of the macromolecule M is $[M]$ and the total concentration of the small molecule A in the bag is $[A]_{\text{in}}$. This total concentration is the sum of the concentrations of free A and bound A, which we write $[A]_{\text{free}}$ and $[A]_{\text{bound}}$, respectively. At equilibrium, the chemical potential of free A in the macromolecule solution is equal to the chemical potential of A in the solution on the other side of the membrane, where its concentration is $[A]_{\text{out}}$. We shall see in Section 5.7 that the equality $\mu_{A,\text{free}} = \mu_{A,\text{out}}$ implies that $[A]_{\text{free}} = [A]_{\text{out}}$, provided the activity coefficient of A is the same in both solutions. Therefore, by measuring the concentration of A in the ‘outside’ solution, we can find the concentration of unbound A in the macromolecule solution and, from the difference $[A]_{\text{in}} - [A]_{\text{free}}$, which is equal to $[A]_{\text{in}} - [A]_{\text{out}}$, the concentration of bound A. The average number of A molecules bound to M molecules, ν , is then the ratio

$$\nu = \frac{[A]_{\text{bound}}}{[M]} = \frac{[A]_{\text{in}} - [A]_{\text{out}}}{[M]}$$

The bound and unbound A molecules are in equilibrium, $M + A \rightleftharpoons MA$, so their concentrations are related by an equilibrium constant K , where

$$K = \frac{[MA]}{[M]_{\text{free}}[A]_{\text{free}}} = \frac{[A]_{\text{bound}}}{([M] - [A]_{\text{bound}})[A]_{\text{free}}}$$

We have used $[MA] = [A]_{\text{bound}}$ and $[M]_{\text{free}} = [M] - [MA] = [M] - [A]_{\text{bound}}$. On division by $[M]$, and replacement of $[A]_{\text{free}}$ by $[A]_{\text{out}}$, the last expression becomes

$$K = \frac{\nu}{(1 - \nu)[A]_{\text{out}}}$$

If there are N *identical* and *independent* binding sites on each macromolecule, each macromolecule behaves like N separate smaller macromolecules, with the same value of K for each site. The average number of A molecules per site is ν/N , so the last equation becomes

$$K = \frac{\nu/N}{\left(1 - \frac{\nu}{N}\right)[A]_{\text{out}}}$$

It then follows that

$$\frac{\nu}{[A]_{\text{out}}} = KN - K\nu$$

Fig. 5.30 A Scatchard plot of $v/[A]_{\text{out}}$ against v . The slope is $-K$ and the intercept at $v = 0$ is KN .

Exploration The following tasks will give you an idea of how graphical analysis can distinguish between systems with the same values of K or N . First, display on the same graph several Scatchard plots with varying K values but fixed N . Then repeat the process, this time varying N but fixing K .

This expression is the *Scatchard equation*. It implies that a plot of $v/[A]_{\text{out}}$ against v should be a straight line of slope $-K$ and intercept KN at $v = 0$ (see Fig. 5.30). From these two quantities, we can find the equilibrium constant for binding and the number of binding sites on each macromolecule. If a straight line is not obtained we can conclude that the binding sites are not equivalent or independent.

Activities

Now we see how to adjust the expressions developed earlier in the chapter to take into account deviations from ideal behaviour. In Chapter 3 (specifically, *Further information* 3.2) we remarked that a quantity called ‘fugacity’ takes into account the effects of gas imperfections in a manner that resulted in the least upset of the form of equations. Here we see how the expressions encountered in the treatment of ideal solutions can also be preserved almost intact by introducing the concept of ‘activity’. It is important to be aware of the different definitions of standard states and activities, and they are summarized in Table 5.3. We shall put them to work in the next few chapters, when we shall see that using them is much easier than defining them.

5.6 The solvent activity

The general form of the chemical potential of a real or ideal solvent is given by a straightforward modification of eqn 5.23 (that $\mu_A = \mu_A^* + RT \ln(p_A/p_A^*)$, where p_A^* is the vapour pressure of pure A and p_A is the vapour pressure of A when it is a component of a solution. For an ideal solution, as we have seen, the solvent obeys Raoult’s law at all concentrations and we can express this relation as eqn 5.25 (that is, as $\mu_A = \mu_A^* + RT \ln x_A$). The form of the this relation can be preserved when the solution does not obey Raoult’s law by writing

$$\mu_A = \mu_A^* + RT \ln a_A \quad [5.42]$$

The quantity a_A is the **activity** of A, a kind of ‘effective’ mole fraction, just as the fugacity is an effective pressure.

Because eqn 5.23 is true for both real and ideal solutions (the only approximation being the use of pressures rather than fugacities), we can conclude by comparing it with eqn 5.42 that

$$a_A = \frac{p_A}{p_A^*} \quad (5.43)$$

Table 5.3 Standard states

Component	Basis	Standard state	Activity	Limits
Solid or liquid		Pure	$a = 1$	
Solvent	Raoult	Pure solvent	$a = p/p^*, a = \gamma x$	$\gamma \rightarrow 1$ as $x \rightarrow 1$ (pure solvent)
Solute	Henry	(1) A hypothetical state of the pure solute	$a = p/K, a = \gamma x$	$\gamma \rightarrow 1$ as $x \rightarrow 0$
		(2) A hypothetical state of the solute at molality b°	$a = \gamma b/b^\circ$	$\gamma \rightarrow 1$ as $b \rightarrow 0$

In each case, $\mu = \mu^\circ + RT \ln a$.

We see that there is nothing mysterious about the activity of a solvent: it can be determined experimentally simply by measuring the vapour pressure and then using eqn 5.43.

Illustration 5.3 *Calculating the solvent activity*

The vapour pressure of 0.500 M $\text{KNO}_3(\text{aq})$ at 100°C is 99.95 kPa, so the activity of water in the solution at this temperature is

$$a_{\text{A}} = \frac{99.95 \text{ kPa}}{101.325 \text{ kPa}} = 0.9864$$

Because all solvents obey Raoult's law (that $p_{\text{A}}/p_{\text{A}}^* = x_{\text{A}}$) increasingly closely as the concentration of solute approaches zero, the activity of the solvent approaches the mole fraction as $x_{\text{A}} \rightarrow 1$:

$$a_{\text{A}} \rightarrow x_{\text{A}} \quad \text{as} \quad x_{\text{A}} \rightarrow 1 \quad (5.44)$$

A convenient way of expressing this convergence is to introduce the **activity coefficient**, γ , by the definition

$$a_{\text{A}} = \gamma_{\text{A}} x_{\text{A}} \quad \gamma_{\text{A}} \rightarrow 1 \quad \text{as} \quad x_{\text{A}} \rightarrow 1 \quad [5.45]$$

at all temperatures and pressures. The chemical potential of the solvent is then

$$\mu_{\text{A}} = \mu_{\text{A}}^* + RT \ln x_{\text{A}} + RT \ln \gamma_{\text{A}} \quad (5.46)$$

The standard state of the solvent, the pure liquid solvent at 1 bar, is established when $x_{\text{A}} = 1$.

5.7 The solute activity

The problem with defining activity coefficients and standard states for solutes is that they approach ideal-dilute (Henry's law) behaviour as $x_{\text{B}} \rightarrow 0$, not as $x_{\text{B}} \rightarrow 1$ (corresponding to pure solute). We shall show how to set up the definitions for a solute that obeys Henry's law exactly, and then show how to allow for deviations.

(a) Ideal-dilute solutions

A solute B that satisfies Henry's law has a vapour pressure given by $p_{\text{B}} = K_{\text{B}} x_{\text{B}}$, where K_{B} is an empirical constant. In this case, the chemical potential of B is

$$\mu_{\text{B}} = \mu_{\text{B}}^* + RT \ln \frac{p_{\text{B}}}{p_{\text{B}}^*} = \mu_{\text{B}}^* + RT \ln \frac{K_{\text{B}}}{p_{\text{B}}^*} + RT \ln x_{\text{B}}$$

Both K_{B} and p_{B}^* are characteristics of the solute, so the second term may be combined with the first to give a new standard chemical potential:

$$\mu_{\text{B}}^{\ominus} = \mu_{\text{B}}^* + RT \ln \frac{K_{\text{B}}}{p_{\text{B}}^*} \quad [5.47]$$

It then follows that the chemical potential of a solute in an ideal-dilute solution is related to its mole fraction by

$$\mu_{\text{B}} = \mu_{\text{B}}^{\ominus} + RT \ln x_{\text{B}} \quad (5.48)^{\circ}$$

If the solution is ideal, $K_{\text{B}} = p_{\text{B}}^*$ and eqn 5.47 reduces to $\mu_{\text{B}}^{\ominus} = \mu_{\text{B}}^*$, as we should expect.

(b) Real solutes

We now permit deviations from ideal-dilute, Henry's law behaviour. For the solute, we introduce a_B in place of x_B in eqn 5.48, and obtain

$$\mu_B = \mu_B^\ominus + RT \ln a_B \quad [5.49]$$

The standard state remains unchanged in this last stage, and all the deviations from ideality are captured in the activity a_B . The value of the activity at any concentration can be obtained in the same way as for the solvent, but in place of eqn 5.43 we use

$$a_B = \frac{p_B}{K_B} \quad (5.50)$$

As for the solvent, it is sensible to introduce an activity coefficient through

$$a_B = \gamma_B x_B \quad [5.51]$$

Now all the deviations from ideality are captured in the activity coefficient γ_B . Because the solute obeys Henry's law as its concentration goes to zero, it follows that

$$a_B \rightarrow x_B \quad \text{and} \quad \gamma_B \rightarrow 1 \quad \text{as} \quad x_B \rightarrow 0 \quad (5.52)$$

at all temperatures and pressures. Deviations of the solute from ideality disappear as zero concentration is approached.

Example 5.5 *Measuring activity*

Use the information in Example 5.3 to calculate the activity and activity coefficient of chloroform in acetone at 25°C, treating it first as a solvent and then as a solute. For convenience, the data are repeated here:

x_C	0	0.20	0.40	0.60	0.80	1
p_C/kPa	0	4.7	11	18.9	26.7	36.4
p_A/kPa	46.3	33.3	23.3	12.3	4.9	0

Method For the activity of chloroform as a solvent (the Raoult's law activity), form $a_C = p_C/p_C^*$ and $\gamma_C = a_C/x_C$. For its activity as a solute (the Henry's law activity), form $a_C = p_C/K_C$ and $\gamma_C = a_C/x_C$.

Answer Because $p_C^* = 36.4 \text{ kPa}$ and $K_C = 22.0 \text{ kPa}$, we can construct the following tables. For instance, at $x_C = 0.20$, in the Raoult's law case we find $a_C = (4.7 \text{ kPa})/(36.4 \text{ kPa}) = 0.13$ and $\gamma_C = 0.13/0.20 = 0.65$; likewise, in the Henry's law case, $a_C = (4.7 \text{ kPa})/(22.0 \text{ kPa}) = 0.21$ and $\gamma_C = 0.21/0.20 = 1.05$.

From Raoult's law (chloroform regarded as the solvent):

a_C	0	0.13	0.30	0.52	0.73	1.00
γ_C		0.65	0.75	0.87	0.91	1.00

From Henry's law (chloroform regarded as the solute):

a_C	0	0.21	0.50	0.86	1.21	1.65
γ_C	1	1.05	1.25	1.43	1.51	1.65

These values are plotted in Fig. 5.31. Notice that $\gamma_C \rightarrow 1$ as $x_C \rightarrow 1$ in the Raoult's law case, but that $\gamma_C \rightarrow 1$ as $x_C \rightarrow 0$ in the Henry's law case.

Self-test 5.7 Calculate the activities and activity coefficients for acetone according to the two conventions.

[At $x_A = 0.60$, for instance $a_R = 0.50$; $\gamma_R = 0.83$; $a_H = 1.00$, $\gamma_H = 1.67$]

Fig. 5.31 The variation of activity and activity coefficient of chloroform (trichloromethane) and acetone (propanone) with composition according to (a) Raoult's law, (b) Henry's law.

(c) Activities in terms of molalities

The selection of a standard state is entirely arbitrary, so we are free to choose one that best suits our purpose and the description of the composition of the system. In chemistry, compositions are often expressed as molalities, b , in place of mole fractions. It therefore proves convenient to write

$$\mu_B = \mu_B^\ominus + RT \ln b_B \quad \{5.53\}^\circ$$

where $\mu^\ominus$ has a different value from the standard values introduced earlier. According to this definition, the chemical potential of the solute has its standard value $\mu^\ominus$ when the molality of B is equal to $b^\ominus$ (that is, at 1 mol kg^{-1}). Note that as $b_B \rightarrow 0$, $\mu_B \rightarrow -\infty$; that is, as the solution becomes diluted, so the solute becomes increasingly stabilized. The practical consequence of this result is that it is very difficult to remove the last traces of a solute from a solution.

Now, as before, we incorporate deviations from ideality by introducing a dimensionless activity a_B , a dimensionless activity coefficient γ_B , and writing

$$a_B = \gamma_B \frac{b_B}{b^\ominus} \quad \text{where} \quad \gamma_B \rightarrow 1 \quad \text{as} \quad b_B \rightarrow 0 \quad [5.54]$$

at all temperatures and pressures. The standard state remains unchanged in this last stage and, as before, all the deviations from ideality are captured in the activity coefficient γ_B . We then arrive at the following succinct expression for the chemical potential of a real solute at any molality:

$$\mu = \mu^\ominus + RT \ln a \quad (5.55)$$

(d) The biological standard state

One important illustration of the ability to choose a standard state to suit the circumstances arises in biological applications. The conventional standard state of hydrogen ions (unit activity, corresponding to $\text{pH} = 0$)⁵ is not appropriate to normal biological conditions. Therefore, in biochemistry it is common to adopt the **biological standard state**, in which $\text{pH} = 7$ (an activity of 10^{-7} , neutral solution) and to label the corresponding standard thermodynamic functions as $G^\oplus$, $H^\oplus$, $\mu^\oplus$, and $S^\oplus$ (some texts use $X^{\oplus'}$).

⁵ Recall from introductory chemistry courses that $\text{pH} = -\log a_{\text{H}_3\text{O}^+}$.

To find the relation between the thermodynamic and biological standard values of the chemical potential of hydrogen ions we need to note from eqn 5.55 that

$$\mu_{\text{H}^+} = \mu_{\text{H}^+}^\ominus + RT \ln a_{\text{H}^+} = \mu_{\text{H}^+}^\ominus - (RT \ln 10) \times \text{pH}$$

It follows that

$$\mu_{\text{H}^+}^\oplus = \mu_{\text{H}^+}^\ominus - 7RT \ln 10 \quad (5.56)$$

At 298 K, $7RT \ln 10 = 39.96 \text{ kJ mol}^{-1}$, so the two standard values differ by about 40 kJ mol^{-1} .

5.8 The activities of regular solutions

The material on regular solutions presented in Section 5.4 gives further insight into the origin of deviations from Raoult's law and its relation to activity coefficients. The starting point is the expression for the Gibbs energy of mixing for a regular solution (eqn 5.31). We show in the following *Justification* that eqn 5.31 implies that the activity coefficients are given by expressions of the form

$$\ln \gamma_A = \beta x_B^2 \quad \ln \gamma_B = \beta x_A^2 \quad (5.57)$$

These relations are called the **Margules equations**.

Justification 5.4 The Margules equations

The Gibbs energy of mixing to form a nonideal solution is

$$\Delta_{\text{mix}} G = nRT \{x_A \ln a_A + x_B \ln a_B\}$$

This relation follows from the derivation of eqn 5.31 with activities in place of mole fractions. If each activity is replaced by γx , this expression becomes

$$\Delta_{\text{mix}} G = nRT \{x_A \ln x_A + x_B \ln x_B + x_A \ln \gamma_A + x_B \ln \gamma_B\}$$

Now we introduce the two expressions in eqn 5.57, and use $x_A + x_B = 1$, which gives

$$\begin{aligned} \Delta_{\text{mix}} G &= nRT \{x_A \ln x_A + x_B \ln x_B + \beta x_A x_B^2 + \beta x_B x_A^2\} \\ &= nRT \{x_A \ln x_A + x_B \ln x_B + \beta x_A x_B (x_A + x_B)\} \\ &= nRT \{x_A \ln x_A + x_B \ln x_B + \beta x_A x_B\} \end{aligned}$$

as required by eqn 5.31. Note, moreover, that the activity coefficients behave correctly for dilute solutions: $\gamma_A \rightarrow 1$ as $x_B \rightarrow 0$ and $\gamma_B \rightarrow 1$ as $x_A \rightarrow 0$.

At this point we can use the Margules equations to write the activity of A as

$$a_A = \gamma_A x_A = x_A e^{\beta x_B^2} = x_A e^{\beta(1-x_A)^2} \quad (5.58)$$

with a similar expression for a_B . The activity of A, though, is just the ratio of the vapour pressure of A in the solution to the vapour pressure of pure A (eqn 5.43), so we can write

$$p_A = \{x_A e^{\beta(1-x_A)^2}\} p_A^* \quad (5.59)$$

This function is plotted in Fig. 5.32. We see that $\beta = 0$, corresponding to an ideal solution, gives a straight line, in accord with Raoult's law (indeed, when $\beta = 0$, eqn 5.59 becomes $p_A = x_A p_A^*$, which is Raoult's law). Positive values of β (endothermic mixing, unfavourable solute–solvent interactions) give vapour pressures higher than ideal. Negative values of β (exothermic mixing, favourable solute–solvent interactions) give a lower vapour pressure. All the curves approach linearity and coincide with the Raoult's law line as $x_A \rightarrow 1$ and the exponential function in eqn 5.59 approaches 1. When $x_A \ll 1$, eqn 5.59 approaches

Fig. 5.32 The vapour pressure of a mixture based on a model in which the excess enthalpy is proportional to $\beta x_A x_B$. An ideal solution corresponds to $\beta = 0$ and gives a straight line, in accord with Raoult's law. Positive values of β give vapour pressures higher than ideal. Negative values of β give a lower vapour pressure.

Exploration Plot p_A/p_A^* against x_A with $\beta = 2.5$ by using eqn 5.24 and then eqn 5.59. Above what value of x_A do the values of p_A/p_A^* given by these equations differ by more than 10 per cent?

$$p_A = x_A e^{\beta} p_A^* \quad (5.60)$$

This expression has the form of Henry's law once we identify K with $e^{\beta} p_A^*$, which is different for each solute–solvent system.

5.9 The activities of ions in solution

Interactions between ions are so strong that the approximation of replacing activities by molalities is valid only in very dilute solutions (less than 10^{-3} mol kg $^{-1}$ in total ion concentration) and in precise work activities themselves must be used. We need, therefore, to pay special attention to the activities of ions in solution, especially in preparation for the discussion of electrochemical phenomena.

(a) Mean activity coefficients

If the chemical potential of a univalent cation M^+ is denoted μ_+ and that of a univalent anion X^- is denoted μ_- , the total molar Gibbs energy of the ions in the electrically neutral solution is the sum of these partial molar quantities. The molar Gibbs energy of an *ideal* solution is

$$G_m^{\text{ideal}} = \mu_+^{\text{ideal}} + \mu_-^{\text{ideal}} \quad (5.61)^{\circ}$$

However, for a *real* solution of M^+ and X^- of the same molality,

$$G_m = \mu_+ + \mu_- = \mu_+^{\text{ideal}} + \mu_-^{\text{ideal}} + RT \ln \gamma_+ + RT \ln \gamma_- = G_m^{\text{ideal}} + RT \ln \gamma_+ \gamma_- \quad (5.62)$$

All the deviations from ideality are contained in the last term.

There is no experimental way of separating the product $\gamma_+ \gamma_-$ into contributions from the cations and the anions. The best we can do experimentally is to assign responsibility for the nonideality equally to both kinds of ion. Therefore, for a 1,1-electrolyte, we introduce the **mean activity coefficient** as the geometric mean of the individual coefficients:

$$\gamma_{\pm} = (\gamma_+ \gamma_-)^{1/2} \quad [5.63]$$

and express the individual chemical potentials of the ions as

$$\mu_+ = \mu_+^{\text{ideal}} + RT \ln \gamma_{\pm} \quad \mu_- = \mu_-^{\text{ideal}} + RT \ln \gamma_{\pm} \quad (5.64)$$

The sum of these two chemical potentials is the same as before, eqn 5.62, but now the nonideality is shared equally.

We can generalize this approach to the case of a compound $M_p X_q$ that dissolves to give a solution of p cations and q anions from each formula unit. The molar Gibbs energy of the ions is the sum of their partial molar Gibbs energies:

$$G_m = p\mu_+ + q\mu_- = G_m^{\text{ideal}} + pRT \ln \gamma_+ + qRT \ln \gamma_- \quad (5.65)$$

If we introduce the mean activity coefficient

$$\gamma_{\pm} = (\gamma_+^p \gamma_-^q)^{1/s} \quad s = p + q \quad [5.66]$$

and write the chemical potential of each ion as

$$\mu_i = \mu_i^{\text{ideal}} + RT \ln \gamma_{\pm} \quad (5.67)$$

we get the same expression as in eqn 5.62 for G_m when we write

$$G = p\mu_+ + q\mu_- \quad (5.68)$$

However, both types of ion now share equal responsibility for the nonideality.

(b) The Debye–Hückel limiting law

The long range and strength of the Coulombic interaction between ions means that it is likely to be primarily responsible for the departures from ideality in ionic solutions

Comment 5.4

The geometric mean of x^p and y^q is $(x^p y^q)^{1/(p+q)}$. For example, the geometric mean of x^2 and y^{-3} is $(x^2 y^{-3})^{-1}$.

Fig. 5.33 The picture underlying the Debye–Hückel theory is of a tendency for anions to be found around cations, and of cations to be found around anions (one such local clustering region is shown by the circle). The ions are in ceaseless motion, and the diagram represents a snapshot of their motion. The solutions to which the theory applies are far less concentrated than shown here.

and to dominate all the other contributions to nonideality. This domination is the basis of the **Debye–Hückel theory** of ionic solutions, which was devised by Peter Debye and Erich Hückel in 1923. We give here a qualitative account of the theory and its principal conclusions. The calculation itself, which is a profound example of how a seemingly intractable problem can be formulated and then resolved by drawing on physical insight, is described in *Further information 5.1*.

Oppositely charged ions attract one another. As a result, anions are more likely to be found near cations in solution, and vice versa (Fig. 5.33). Overall, the solution is electrically neutral, but near any given ion there is an excess of counter ions (ions of opposite charge). Averaged over time, counter ions are more likely to be found near any given ion. This time-averaged, spherical haze around the central ion, in which counter ions outnumber ions of the same charge as the central ion, has a net charge equal in magnitude but opposite in sign to that on the central ion, and is called its **ionic atmosphere**. The energy, and therefore the chemical potential, of any given central ion is lowered as a result of its electrostatic interaction with its ionic atmosphere. This lowering of energy appears as the difference between the molar Gibbs energy G_m and the ideal value G_m^{ideal} of the solute, and hence can be identified with $RT \ln \gamma_{\pm}$. The stabilization of ions by their interaction with their ionic atmospheres is part of the explanation why chemists commonly use dilute solutions, in which the stabilization is less important, to achieve precipitation of ions from electrolyte solutions.

The model leads to the result that at very low concentrations the activity coefficient can be calculated from the **Debye–Hückel limiting law**

$$\log \gamma_{\pm} = -|z_+ z_-| A I^{1/2} \quad (5.69)$$

where $A = 0.509$ for an aqueous solution at 25°C and I is the dimensionless **ionic strength** of the solution:

$$I = \frac{1}{2} \sum_i z_i^2 (b_i / b^\ominus) \quad [5.70]$$

In this expression z_i is the charge number of an ion i (positive for cations and negative for anions) and b_i is its molality. The ionic strength occurs widely wherever ionic solutions are discussed, as we shall see. The sum extends over all the ions present in the solution. For solutions consisting of two types of ion at molalities b_+ and b_- ,

$$I = \frac{1}{2} (b_+ z_+^2 + b_- z_-^2) / b^\ominus \quad (5.71)$$

The ionic strength emphasizes the charges of the ions because the charge numbers occur as their squares. Table 5.4 summarizes the relation of ionic strength and molality in an easily usable form.

Table 5.4 Ionic strength and molality, $I = kb/b^\ominus$

k	X^-	X^{2-}	X^{3-}	X^{4-}
M^+	1	3	6	10
M^{2+}	3	4	15	12
M^{3+}	6	15	9	42
M^{4+}	10	12	42	16

For example, the ionic strength of an M_2X_3 solution of molality b , which is understood to give M^{3+} and X^{2-} ions in solution is $15b/b^\ominus$.

Illustration 5.4 Using the Debye–Hückel limiting law

The mean activity coefficient of $5.0 \times 10^{-3} \text{ mol kg}^{-1}$ KCl(aq) at 25°C is calculated by writing

$$I = \frac{1}{2} (b_+ + b_-) / b^\ominus = b / b^\ominus$$

where b is the molality of the solution (and $b_+ = b_- = b$). Then, from eqn 5.69,

$$\log \gamma_{\pm} = -0.509 \times (5.0 \times 10^{-3})^{1/2} = -0.036$$

Hence, $\gamma_{\pm} = 0.92$. The experimental value is 0.927.

Self-test 5.8 Calculate the ionic strength and the mean activity coefficient of $1.00 \text{ mmol kg}^{-1}$ CaCl_2 (aq) at 25°C. [3.00 mmol kg^{-1} , 0.880]

The name ‘limiting law’ is applied to eqn 5.69 because ionic solutions of moderate molalities may have activity coefficients that differ from the values given by this expression, yet all solutions are expected to conform as $b \rightarrow 0$. Table 5.5 lists some experimental values of activity coefficients for salts of various valence types. Figure 5.34 shows some of these values plotted against $I^{1/2}$, and compares them with the theoretical straight lines calculated from eqn 5.69. The agreement at very low molalities (less than about 1 mmol kg⁻¹, depending on charge type) is impressive, and convincing evidence in support of the model. Nevertheless, the departures from the theoretical curves above these molalities are large, and show that the approximations are valid only at very low concentrations.

(c) The extended Debye–Hückel law

When the ionic strength of the solution is too high for the limiting law to be valid, the activity coefficient may be estimated from the **extended Debye–Hückel law**:

$$\log \gamma_{\pm} = -\frac{A |z_+ z_-| I^{1/2}}{1 + BI^{1/2}} + CI \quad (5.72)$$

where B and C are dimensionless constants. Although B can be interpreted as a measure of the closest approach of the ions, it (like C) is best regarded as an adjustable empirical parameter. A curve drawn in this way is shown in Fig. 5.35. It is clear that

Synoptic Table 5.5* Mean activity coefficients in water at 298 K

b/b^*	KCl	CaCl ₂
0.001	0.966	0.888
0.01	0.902	0.732
0.1	0.770	0.524
1.0	0.607	0.725

* More values are given in the *Data section*.

Fig. 5.34 An experimental test of the Debye–Hückel limiting law. Although there are marked deviations for moderate ionic strengths, the limiting slopes as $I \rightarrow 0$ are in good agreement with the theory, so the law can be used for extrapolating data to very low molalities.

Fig. 5.35 The extended Debye–Hückel law gives agreement with experiment over a wider range of molalities (as shown here for a 1,1-electrolyte), but it fails at higher molalities.

Exploration Consider the plot of $\log \gamma_{\pm}$ against $I^{1/2}$ with $B = 1.50$ and $C = 0$ as a representation of experimental data for a certain 1,1-electrolyte. Over what range of ionic strengths does the application of the limiting law lead to an error in the value of the activity coefficient of less than 10 per cent of the value predicted by the extended law?

eqn 5.72 accounts for some activity coefficients over a moderate range of dilute solutions (up to about 0.1 mol kg^{-1}); nevertheless it remains very poor near 1 mol kg^{-1} .

Current theories of activity coefficients for ionic solutes take an indirect route. They set up a theory for the dependence of the activity coefficient of the solvent on the concentration of the solute, and then use the Gibbs–Duhem equation (eqn 5.12) to estimate the activity coefficient of the solute. The results are reasonably reliable for solutions with molalities greater than about 0.1 mol kg^{-1} and are valuable for the discussion of mixed salt solutions, such as sea water.

Checklist of key ideas

- ☐ 1. The partial molar volume is the change in volume per mole of A added to a large volume of the mixture: $V_j = (\partial V / \partial n_j)_{p,T,n'}$. The total volume of a mixture is $V = n_A V_A + n_B V_B$.
- ☐ 2. The chemical potential can be defined in terms of the partial molar Gibbs energy, $\mu_j = (\partial G / \partial n_j)_{p,T,n'}$. The total Gibbs energy of a mixture is $G = n_A \mu_A + n_B \mu_B$.
- ☐ 3. The fundamental equation of chemical thermodynamics relates the change in Gibbs energy to changes in pressure, temperature, and composition: $dG = V dp - S dT + \mu_A dn_A + \mu_B dn_B + \dots$.
- ☐ 4. The Gibbs–Duhem equation is $\sum_j n_j d\mu_j = 0$.
- ☐ 5. The chemical potential of a perfect gas is $\mu = \mu^\circ + RT \ln(p/p^\circ)$, where μ° is the standard chemical potential, the chemical potential of the pure gas at 1 bar.
- ☐ 6. The Gibbs energy of mixing of two perfect gases is given by $\Delta_{\text{mix}} G = nRT(x_A \ln x_A + x_B \ln x_B)$.
- ☐ 7. The entropy of mixing of two perfect gases is given by $\Delta_{\text{mix}} S = -nR(x_A \ln x_A + x_B \ln x_B)$.
- ☐ 8. The enthalpy of mixing is $\Delta_{\text{mix}} H = 0$ for perfect gases.
- ☐ 9. An ideal solution is a solution in which all components obeys Raoult's law ($p_A = x_A p_A^*$) throughout the composition range.
- ☐ 10. The chemical potential of a component of an ideal solution is given by $\mu_A = \mu_A^* + RT \ln x_A$.
- ☐ 11. An ideal-dilute solution is a solution for which the solute obeys Henry's law ($p_B = x_B K_B^*$) and the solvent obeys Raoult's law.
- ☐ 12. The Gibbs energy of mixing of two liquids that form an ideal solution is given by $\Delta_{\text{mix}} G = nRT(x_A \ln x_A + x_B \ln x_B)$.
- ☐ 13. The entropy of mixing of two liquids that form an ideal solution is given by $\Delta_{\text{mix}} S = -nR(x_A \ln x_A + x_B \ln x_B)$.
- ☐ 14. An excess function (X^E) is the difference between the observed thermodynamic function of mixing and the function for an ideal solution.
- ☐ 15. A regular solution is a solution for which $H^E \neq 0$ but $S^E = 0$.
- ☐ 16. A colligative property is a property that depends only on the number of solute particles present, not their identity.
- ☐ 17. The elevation of boiling point is given by $\Delta T = K_b b$, where K_b is the ebullioscopic constant. The depression of freezing point is given by $\Delta T = K_f b$, where K_f is the cryoscopic constant.
- ☐ 18. Osmosis is the spontaneous passage of a pure solvent into a solution separated from it by a semipermeable membrane, a membrane permeable to the solvent but not to the solute.
- ☐ 19. The osmotic pressure is the pressure that must be applied to the solution to stop the influx of solvent.
- ☐ 20. The van 't Hoff equation for the osmotic pressure is $\Pi = [B]RT$.
- ☐ 21. The activity is defined as $a_A = p_A/p_A^*$.
- ☐ 22. The solvent activity is related to its chemical potential by $\mu_A = \mu_A^* + RT \ln a_A$. The activity may be written in terms of the activity coefficient $\gamma_A = a_A/x_A$.
- ☐ 23. The chemical potential of a solute in an ideal-dilute solution is given by $\mu_B = \mu_B^\circ + RT \ln a_B$. The activity may be written in terms of the activity coefficient $\gamma_B = a_B/x_B$.
- ☐ 24. The biological standard state ($\text{pH} = 7$) is related to the thermodynamic standard state by $\mu_{\text{H}^+}^\oplus = \mu_{\text{H}^+}^\circ - 7RT \ln 10$.
- ☐ 25. The mean activity coefficient is the geometric mean of the individual coefficients: $\gamma_{\pm} = (\gamma_+^p \gamma_-^q)^{1/(p+q)}$.
- ☐ 26. The Debye–Hückel theory of activity coefficients of electrolyte solutions is based on the assumption that Coulombic interactions between ions are dominant; a key idea of the theory is that of an ionic atmosphere.
- ☐ 27. The Debye–Hückel limiting law is $\log \gamma_{\pm} = -|z_+ z_-| A I^{1/2}$ where I is the ionic strength, $I = \frac{1}{2} \sum_i z_i^2 (b_i/b^\circ)$.
- ☐ 28. The extended Debye–Hückel law is $\ln \gamma_{\pm} = -|z_+ z_-| A I^{1/2} / (1 + B I^{1/2}) + C I$.

Further information

Further information 5.1 The Debye–Hückel theory of ionic solutions

Imagine a solution in which all the ions have their actual positions, but in which their Coulombic interactions have been turned off. The difference in molar Gibbs energy between the ideal and real solutions is equal to w_e , the electrical work of charging the system in this arrangement. For a salt M_pX_q , we write

$$\begin{aligned} w_e &= \overbrace{(p\mu_+ + q\mu_-)}^{G_m} - \overbrace{(p\mu_+^{\text{ideal}} + q\mu_-^{\text{ideal}})}^{G_m^{\text{ideal}}} \\ &= p(\mu_+ - \mu_+^{\text{ideal}}) + q(\mu_- - \mu_-^{\text{ideal}}) \end{aligned}$$

From eqn 5.64 we write

$$\mu_+ - \mu_+^{\text{ideal}} = \mu_- - \mu_-^{\text{ideal}} = RT \ln \gamma_{\pm}$$

So it follows that

$$\ln \gamma_{\pm} = \frac{w_e}{sRT} \quad s = p + q \quad (5.73)$$

This equation tells us that we must first find the final distribution of the ions and then the work of charging them in that distribution.

The Coulomb potential at a distance r from an isolated ion of charge $z_i e$ in a medium of permittivity ϵ is

$$\phi_i = \frac{Z_i}{r} \quad Z_i = \frac{z_i e}{4\pi\epsilon} \quad (5.74)$$

The ionic atmosphere causes the potential to decay with distance more sharply than this expression implies. Such shielding is a familiar problem in electrostatics, and its effect is taken into account by replacing the Coulomb potential by the **shielded Coulomb potential**, an expression of the form

$$\phi_i = \frac{Z_i}{r} e^{-r/r_D} \quad (5.75)$$

where r_D is called the **Debye length**. When r_D is large, the shielded potential is virtually the same as the unshielded potential. When it is small, the shielded potential is much smaller than the unshielded potential, even for short distances (Fig. 5.36).

Fig. 5.36 The variation of the shielded Coulomb potential with distance for different values of the Debye length, r_D/a . The smaller the Debye length, the more sharply the potential decays to zero. In each case, a is an arbitrary unit of length.

Exploration Write an expression for the difference between the unshielded and shielded Coulomb potentials evaluated at r_D . Then plot this expression against r_D and provide a physical interpretation for the shape of the plot.

⁶ See *Further reading* in Chapter 2 for additional texts on chemical thermodynamics.

To calculate r_D , we need to know how the **charge density**, ρ_i , of the ionic atmosphere, the charge in a small region divided by the volume of the region, varies with distance from the ion. This step draws on another standard result of electrostatics, in which charge density and potential are related by **Poisson's equation** (see Appendix 3):

$$\nabla^2 \phi = -\frac{\rho}{\epsilon} \quad (5.76)$$

where $\nabla^2 = (\partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2)$ is called the *laplacian*. Because we are considering only a spherical ionic atmosphere, we can use a simplified form of this equation in which the charge density varies only with distance from the central ion:

$$\frac{1}{r^2} \frac{d}{dr} \left(r^2 \frac{d\phi_i}{dr} \right) = -\frac{\rho_i}{\epsilon}$$

Comment 5.5

For systems with spherical symmetry, it is best to work in spherical polar coordinates r , θ , and ϕ (see the illustration): $x = r \sin \theta \cos \phi$, $y = r \sin \theta \sin \phi$, and $z = r \cos \theta$. The laplacian in spherical polar coordinates is

$$\nabla^2 = \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial}{\partial r} \right) + \frac{1}{r^2 \sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial}{\partial \theta} \right) + \frac{1}{r^2 \sin^2 \theta} \frac{\partial^2}{\partial \phi^2}$$

When a function depends only on r , the derivatives in the second and third terms evaluate to zero and the laplacian takes the form

$$\nabla^2 = \frac{1}{r^2} \frac{d}{dr} \left(r^2 \frac{d}{dr} \right)$$

Substitution of the expression for the shielded potential, eqn 5.75, results in

$$r_D^2 = -\frac{\epsilon \phi_i}{\rho_i} \quad (5.77)$$

To solve this equation we need to relate ρ_i and ϕ_i .

For the next step we draw on the fact that the energy of an ion depends on its closeness to the central ion, and then use the Boltzmann distribution (see Section 16.1) to work out the probability that an ion will be found at each distance. The energy of an ion of charge $z_i e$ at a distance where it experiences the potential ϕ_i of the central ion i relative to its energy when it is far away in the bulk solution is its charge times the potential:

$$E = z_i e \phi_i$$

Therefore, according to the Boltzmann distribution, the ratio of the molar concentration, c_j , of ions at a distance r and the molar concentration in the bulk, c_j^o , where the energy is zero, is:

$$\frac{c_j}{c_j^o} = e^{-E/kT}$$

The charge density, ρ_i , at a distance r from the ion i is the molar concentration of each type of ion multiplied by the charge per mole of ions, $z_i e N_A$. The quantity $e N_A$, the magnitude of the charge per mole of electrons, is Faraday's constant, $F = 96.48 \text{ kC mol}^{-1}$. It follows that

$$\rho_i = c_+ z_+ F + c_- z_- F = c_+^o z_+ F e^{-z_+ e \phi_i / kT} + c_-^o z_- F e^{-z_- e \phi_i / kT} \quad (5.78)$$

At this stage we need to simplify the expression to avoid the awkward exponential terms. Because the average electrostatic interaction energy is small compared with kT we may write eqn 5.78 as

$$\begin{aligned} \rho_i &= c_+^o z_+ F \left(1 - \frac{z_+ e \phi_i}{kT} + \dots \right) + c_-^o z_- F \left(1 - \frac{z_- e \phi_i}{kT} + \dots \right) \\ &= (c_+^o z_+ + c_-^o z_-) F - (c_+^o z_+^2 + c_-^o z_-^2) F \frac{e \phi_i}{kT} + \dots \end{aligned}$$

Comment 5.6

The expansion of an exponential function used here is $e^{-x} = 1 - x + \frac{1}{2}x^2 - \dots$. If $x \ll 1$, then $e^{-x} \approx 1 - x$.

Replacing e by F/N_A and $N_A k$ by R results in the following expression:

$$\rho_i = (c_+^o z_+ + c_-^o z_-) F - (c_+^o z_+^2 + c_-^o z_-^2) \frac{F^2 \phi_i}{RT} + \dots \quad (5.79)$$

The first term in the expansion is zero because it is the charge density in the bulk, uniform solution, and the solution is electrically neutral. The unwritten terms are assumed to be too small to be significant.

The one remaining term can be expressed in terms of the ionic strength, eqn 5.70, by noting that in the dilute aqueous solutions we are considering there is little difference between molality and molar concentration, and $c \approx b\rho$, where ρ is the mass density of the solvent

$$c_+^o z_+^2 + c_-^o z_-^2 \approx (b_+^o z_+^2 + b_-^o z_-^2) \rho = 2Ib^o \rho$$

With these approximations, eqn 5.78 becomes

$$\rho_i = -\frac{2\rho F^2 I b^o \phi_i}{RT}$$

We can now solve eqn 5.77 for r_D :

$$r_D = \left(\frac{\epsilon RT}{2\rho F^2 I b^o} \right)^{1/2} \quad (5.80)$$

To calculate the activity coefficient we need to find the electrical work of charging the central ion when it is surrounded by its atmosphere. To do so, we need to know the potential at the ion due to its atmosphere, ϕ_{atmos} . This potential is the difference between the total potential, given by eqn 5.75, and the potential due to the central ion itself:

$$\phi_{\text{atmos}} = \phi - \phi_{\text{central ion}} = Z_i \left(\frac{e^{-r/r_D}}{r} - \frac{1}{r} \right)$$

The potential at the central ion (at $r = 0$) is obtained by taking the limit of this expression as $r \rightarrow 0$ and is

$$\phi_{\text{atmos}}(0) = \frac{Z_i}{r_D}$$

This expression shows us that the potential of the ionic atmosphere is equivalent to the potential arising from a single charge of equal magnitude but opposite sign to that of the central ion and located at a distance r_D from the ion. If the charge of the central ion were q and not $z_i e$, then the potential due to its atmosphere would be

$$\phi_{\text{atmos}}(0) = -\frac{q}{4\pi\epsilon r_D}$$

The work of adding a charge dq to a region where the electrical potential is $\phi_{\text{atmos}}(0)$ is

$$dw_e = \phi_{\text{atmos}}(0) dq$$

Therefore, the total molar work of fully charging the ions is

$$\begin{aligned} w_e &= N_A \int_0^{z_i e} \phi_{\text{atmos}}(0) dq = -\frac{N_A}{4\pi\epsilon r_D} \int_0^{z_i e} q dq \\ &= -\frac{N_A z_i^2 e^2}{8\pi\epsilon r_D} = -\frac{z_i^2 F^2}{8\pi\epsilon N_A r_D} \end{aligned}$$

where in the last step we have used $F = N_A e$. It follows from eqn 5.73 that the mean activity coefficient of the ions is

$$\ln \gamma_{\pm} = \frac{pw_{e,+} + qw_{e,-}}{sRT} = -\frac{(pz_+^2 + qz_-^2)F^2}{8\pi\epsilon s N_A RT r_D}$$

However, for neutrality $pz_+ + qz_- = 0$; therefore

Comment 5.7

For this step, multiply $pz_+ + qz_- = 0$ by p and also, separately, by q ; add the two expressions and rearrange the result by using $p + q = s$ and $z_+ z_- = -|z_+ z_-|$.

$$\ln \gamma_{\pm} = -\frac{|z_+ z_-| F^2}{8\pi\epsilon N_A RT r_D}$$

Replacing r_D with the expression in eqn 5.79 gives

$$\begin{aligned} \ln \gamma_{\pm} &= -\frac{|z_+ z_-| F^2}{8\pi\epsilon N_A RT} \left(\frac{2\rho F^2 I b^{\oplus}}{\epsilon RT} \right)^{1/2} \\ &= -|z_+ z_-| \left\{ \frac{F^3}{4\pi N_A} \left(\frac{\rho b^{\oplus}}{2\epsilon^3 R^3 T^3} \right)^{1/2} \right\} I^{1/2} \end{aligned}$$

where we have grouped terms in such a way as to show that this expression is beginning to take the form of eqn 5.69. Indeed, conversion to common logarithms (by using $\ln x = \ln 10 \times \log x$) gives

$$\log \gamma_{\pm} = -|z_+ z_-| \left\{ \frac{F^3}{4\pi N_A \ln 10} \left(\frac{\rho b^{\oplus}}{2\epsilon^3 R^3 T^3} \right)^{1/2} \right\} I^{1/2}$$

which is eqn 5.69 ($\log \gamma_{\pm} = -|z_+ z_-| AI^{1/2}$) with

$$A = \frac{F^3}{4\pi N_A \ln 10} \left(\frac{\rho b^{\oplus}}{2\epsilon^3 R^3 T^3} \right)^{1/2} \quad (5.81)$$

Discussion questions

- 5.1 State and justify the thermodynamic criterion for solution–vapour equilibrium.
- 5.2 How is Raoult's law modified so as to describe the vapour pressure of real solutions?
- 5.3 Explain how colligative properties are used to determine molar mass.

- 5.4 Explain the origin of colligative properties.
- 5.5 Explain what is meant by a regular solution.
- 5.6 Describe the general features of the Debye–Hückel theory of electrolyte solutions.

Exercises

5.1(a) The partial molar volumes of acetone (propanone) and chloroform (trichloromethane) in a mixture in which the mole fraction of CHCl_3 is 0.4693 are $74.166 \text{ cm}^3 \text{ mol}^{-1}$ and $80.235 \text{ cm}^3 \text{ mol}^{-1}$, respectively. What is the volume of a solution of mass 1.000 kg?

5.1(b) The partial molar volumes of two liquids A and B in a mixture in which the mole fraction of A is 0.3713 are $188.2 \text{ cm}^3 \text{ mol}^{-1}$ and $176.14 \text{ cm}^3 \text{ mol}^{-1}$, respectively. The molar masses of A and B are 241.1 g mol^{-1} and 198.2 g mol^{-1} . What is the volume of a solution of mass 1.000 kg?

5.2(a) At 25°C , the density of a 50 per cent by mass ethanol–water solution is 0.914 g cm^{-3} . Given that the partial molar volume of water in the solution is $17.4 \text{ cm}^3 \text{ mol}^{-1}$, calculate the partial molar volume of the ethanol.

5.2(b) At 20°C , the density of a 20 per cent by mass ethanol–water solution is 968.7 kg m^{-3} . Given that the partial molar volume of ethanol in the solution is $52.2 \text{ cm}^3 \text{ mol}^{-1}$, calculate the partial molar volume of the water.

5.3(a) At 300 K, the partial vapour pressures of HCl (that is, the partial pressure of the HCl vapour) in liquid GeCl_4 are as follows:

x_{HCl}	0.005	0.012	0.019
$p_{\text{HCl}}/\text{kPa}$	32.0	76.9	121.8

Show that the solution obeys Henry's law in this range of mole fractions, and calculate Henry's law constant at 300 K.

5.3(b) At 310 K, the partial vapour pressures of a substance B dissolved in a liquid A are as follows:

x_B	0.010	0.015	0.020
p_B/kPa	82.0	122.0	166.1

Show that the solution obeys Henry's law in this range of mole fractions, and calculate Henry's law constant at 310 K.

5.4(a) Predict the partial vapour pressure of HCl above its solution in liquid germanium tetrachloride of molality 0.10 mol kg⁻¹. For data, see Exercise 5.3a.

5.4(b) Predict the partial vapour pressure of the component B above its solution in A in Exercise 5.3b when the molality of B is 0.25 mol kg⁻¹. The molar mass of A is 74.1 g mol⁻¹.

5.5(a) The vapour pressure of benzene is 53.3 kPa at 60.6°C, but it fell to 51.5 kPa when 19.0 g of an involatile organic compound was dissolved in 500 g of benzene. Calculate the molar mass of the compound.

5.5(b) The vapour pressure of 2-propanol is 50.00 kPa at 338.8°C, but it fell to 49.62 kPa when 8.69 g of an involatile organic compound was dissolved in 250 g of 2-propanol. Calculate the molar mass of the compound.

5.6(a) The addition of 100 g of a compound to 750 g of CCl₄ lowered the freezing point of the solvent by 10.5 K. Calculate the molar mass of the compound.

5.6(b) The addition of 5.00 g of a compound to 250 g of naphthalene lowered the freezing point of the solvent by 0.780 K. Calculate the molar mass of the compound.

5.7(a) The osmotic pressure of an aqueous solution at 300 K is 120 kPa. Calculate the freezing point of the solution.

5.7(b) The osmotic pressure of an aqueous solution at 288 K is 99.0 kPa. Calculate the freezing point of the solution.

5.8(a) Consider a container of volume 5.0 dm³ that is divided into two compartments of equal size. In the left compartment there is nitrogen at 1.0 atm and 25°C; in the right compartment there is hydrogen at the same temperature and pressure. Calculate the entropy and Gibbs energy of mixing when the partition is removed. Assume that the gases are perfect.

5.8(b) Consider a container of volume 250 cm³ that is divided into two compartments of equal size. In the left compartment there is argon at 100 kPa and 0°C; in the right compartment there is neon at the same temperature and pressure. Calculate the entropy and Gibbs energy of mixing when the partition is removed. Assume that the gases are perfect.

5.9(a) Air is a mixture with a composition given in *Self-test 1.4*. Calculate the entropy of mixing when it is prepared from the pure (and perfect) gases.

5.9(b) Calculate the Gibbs energy, entropy, and enthalpy of mixing when 1.00 mol C₆H₁₄ (hexane) is mixed with 1.00 mol C₇H₁₆ (heptane) at 298 K; treat the solution as ideal.

5.10(a) What proportions of hexane and heptane should be mixed (a) by mole fraction, (b) by mass in order to achieve the greatest entropy of mixing?

5.10(b) What proportions of benzene and ethylbenzene should be mixed (a) by mole fraction, (b) by mass in order to achieve the greatest entropy of mixing?

5.11(a) Use Henry's law and the data in Table 5.1 to calculate the solubility (as a molality) of CO₂ in water at 25°C when its partial pressure is (a) 0.10 atm, (b) 1.00 atm.

5.11(b) The mole fractions of N₂ and O₂ in air at sea level are approximately 0.78 and 0.21. Calculate the molalities of the solution formed in an open flask of water at 25°C.

5.12(a) A water carbonating plant is available for use in the home and operates by providing carbon dioxide at 5.0 atm. Estimate the molar concentration of the soda water it produces.

5.12(b) After some weeks of use, the pressure in the water carbonating plant mentioned in the previous exercise has fallen to 2.0 atm. Estimate the molar concentration of the soda water it produces at this stage.

5.13(a) The enthalpy of fusion of anthracene is 28.8 kJ mol⁻¹ and its melting point is 217°C. Calculate its ideal solubility in benzene at 25°C.

5.13(b) Predict the ideal solubility of lead in bismuth at 280°C given that its melting point is 327°C and its enthalpy of fusion is 5.2 kJ mol⁻¹.

5.14(a) The osmotic pressure of solutions of polystyrene in toluene were measured at 25°C and the pressure was expressed in terms of the height of the solvent of density 1.004 g cm⁻³:

$c/(\text{g dm}^{-3})$	2.042	6.613	9.521	12.602
h/cm	0.592	1.910	2.750	3.600

Calculate the molar mass of the polymer.

5.14(b) The molar mass of an enzyme was determined by dissolving it in water, measuring the osmotic pressure at 20°C, and extrapolating the data to zero concentration. The following data were obtained:

$c/(\text{mg cm}^{-3})$	3.221	4.618	5.112	6.722
h/cm	5.746	8.238	9.119	11.990

Calculate the molar mass of the enzyme.

5.15(a) Substances A and B are both volatile liquids with $p_A^* = 300$ Torr, $p_B^* = 250$ Torr, and $K_B = 200$ Torr (concentration expressed in mole fraction). When $x_A = 0.9$, $b_B = 2.22$ mol kg⁻¹, $p_A = 250$ Torr, and $p_B = 25$ Torr. Calculate the activities and activity coefficients of A and B. Use the mole fraction, Raoult's law basis system for A and the Henry's law basis system (both mole fractions and molalities) for B.

5.15(b) Given that $p^*(\text{H}_2\text{O}) = 0.02308$ atm and $p(\text{H}_2\text{O}) = 0.02239$ atm in a solution in which 0.122 kg of a non-volatile solute ($M = 241$ g mol⁻¹) is dissolved in 0.920 kg water at 293 K, calculate the activity and activity coefficient of water in the solution.

5.16(a) A dilute solution of bromine in carbon tetrachloride behaves as an ideal-dilute solution. The vapour pressure of pure CCl₄ is 33.85 Torr at 298 K. The Henry's law constant when the concentration of Br₂ is expressed as a mole fraction is 122.36 Torr. Calculate the vapour pressure of each component, the total pressure, and the composition of the vapour phase when the mole fraction of Br₂ is 0.050, on the assumption that the conditions of the ideal-dilute solution are satisfied at this concentration.

5.16(b) Benzene and toluene form nearly ideal solutions. The boiling point of pure benzene is 80.1°C. Calculate the chemical potential of benzene relative to that of pure benzene when $x_{\text{benzene}} = 0.30$ at its boiling point. If the activity coefficient of benzene in this solution were actually 0.93 rather than 1.00, what would be its vapour pressure?

5.17(a) By measuring the equilibrium between liquid and vapour phases of an acetone (A)–methanol (M) solution at 57.2°C at 1.00 atm, it was found that $x_A = 0.400$ when $y_A = 0.516$. Calculate the activities and activity coefficients of both components in this solution on the Raoult's law basis. The vapour pressures of the pure components at this temperature are: $p_A^* = 105$ kPa and $p_M^* = 73.5$ kPa. (x_A is the mole fraction in the liquid and y_A the mole fraction in the vapour.)

5.17(b) By measuring the equilibrium between liquid and vapour phases of a solution at 30°C at 1.00 atm, it was found that $x_A = 0.220$ when $y_A = 0.314$. Calculate the activities and activity coefficients of both components in this solution on the Raoult's law basis. The vapour pressures of the pure components at this temperature are: $p_A^* = 73.0$ kPa and $p_B^* = 92.1$ kPa. (x_A is the mole fraction in the liquid and y_A the mole fraction in the vapour.)

5.18(a) Calculate the ionic strength of a solution that is 0.10 mol kg⁻¹ in KCl(aq) and 0.20 mol kg⁻¹ in CuSO₄(aq).

5.18(b) Calculate the ionic strength of a solution that is 0.040 mol kg⁻¹ in K₃[Fe(CN)₆](aq), 0.030 mol kg⁻¹ in KCl(aq), and 0.050 mol kg⁻¹ in NaBr(aq).

5.19(a) Calculate the masses of (a) $\text{Ca}(\text{NO}_3)_2$ and, separately, (b) NaCl to add to a $0.150 \text{ mol kg}^{-1}$ solution of $\text{KNO}_3(\text{aq})$ containing 500 g of solvent to raise its ionic strength to 0.250.

5.19(b) Calculate the masses of (a) KNO_3 and, separately, (b) $\text{Ba}(\text{NO}_3)_2$ to add to a $0.110 \text{ mol kg}^{-1}$ solution of $\text{KNO}_3(\text{aq})$ containing 500 g of solvent to raise its ionic strength to 1.00.

5.20(a) Estimate the mean ionic activity coefficient and activity of a solution that is $0.010 \text{ mol kg}^{-1} \text{ CaCl}_2(\text{aq})$ and $0.030 \text{ mol kg}^{-1} \text{ NaF}(\text{aq})$.

5.20(b) Estimate the mean ionic activity coefficient and activity of a solution that is $0.020 \text{ mol kg}^{-1} \text{ NaCl}(\text{aq})$ and $0.035 \text{ mol kg}^{-1} \text{ Ca}(\text{NO}_3)_2(\text{aq})$.

5.21(a) The mean activity coefficients of HBr in three dilute aqueous solutions at 25°C are 0.930 (at 5.0 mmol kg^{-1}), 0.907 (at $10.0 \text{ mmol kg}^{-1}$), and 0.879 (at $20.0 \text{ mmol kg}^{-1}$). Estimate the value of B in the extended Debye–Hückel law.

5.21(b) The mean activity coefficients of KCl in three dilute aqueous solutions at 25°C are 0.927 (at 5.0 mmol kg^{-1}), 0.902 (at $10.0 \text{ mmol kg}^{-1}$), and 0.816 (at $50.0 \text{ mmol kg}^{-1}$). Estimate the value of B in the extended Debye–Hückel law.

Problems*

Numerical problems

5.1 The following table gives the mole fraction of methylbenzene (A) in liquid and gaseous mixtures with butanone at equilibrium at 303.15 K and the total pressure p . Take the vapour to be perfect and calculate the partial pressures of the two components. Plot them against their respective mole fractions in the liquid mixture and find the Henry's law constants for the two components.

x_A	0	0.0898	0.2476	0.3577	0.5194	0.6036
y_A	0	0.0410	0.1154	0.1762	0.2772	0.3393
p/kPa	36.066	34.121	30.900	28.626	25.239	23.402
x_A	0.7188	0.8019	0.9105	1		
y_A	0.4450	0.5435	0.7284	1		
p/kPa	20.6984	18.592	15.496	12.295		

5.2 The volume of an aqueous solution of NaCl at 25°C was measured at a series of molalities b , and it was found that the volume fitted the expression $v = 1003 + 16.62x + 1.77x^{3/2} + 0.12x^2$ where $v = V/\text{cm}^3$, V is the volume of a solution formed from 1.000 kg of water, and $x = b/b^\circ$. Calculate the partial molar volume of the components in a solution of molality $0.100 \text{ mol kg}^{-1}$.

5.3 At 18°C the total volume V of a solution formed from MgSO_4 and 1.000 kg of water fits the expression $v = 1001.21 + 34.69(x - 0.070)^2$, where $v = V/\text{cm}^3$ and $x = b/b^\circ$. Calculate the partial molar volumes of the salt and the solvent when in a solution of molality $0.050 \text{ mol kg}^{-1}$.

5.4 The densities of aqueous solutions of copper(II) sulfate at 20°C were measured as set out below. Determine and plot the partial molar volume of CuSO_4 in the range of the measurements.

$m(\text{CuSO}_4)/\text{g}$	5	10	15	20
$\rho/(\text{g cm}^{-3})$	1.051	1.107	1.167	1.230

where $m(\text{CuSO}_4)$ is the mass of CuSO_4 dissolved in 100 g of solution.

5.5 What proportions of ethanol and water should be mixed in order to produce 100 cm^3 of a mixture containing 50 per cent by mass of ethanol? What change in volume is brought about by adding 1.00 cm^3 of ethanol to the mixture? (Use data from Fig. 5.1.)

5.6 Potassium fluoride is very soluble in glacial acetic acid and the solutions have a number of unusual properties. In an attempt to understand them, freezing point depression data were obtained by taking a solution of known molality and then diluting it several times (J. Emsley, *J. Chem. Soc. A*, 2702 (1971)). The following data were obtained:

$b/(\text{mol kg}^{-1})$	0.015	0.037	0.077	0.295	0.602
$\Delta T/\text{K}$	0.115	0.295	0.470	1.381	2.67

Calculate the apparent molar mass of the solute and suggest an interpretation. Use $\Delta_{\text{fus}}H = 11.4 \text{ kJ mol}^{-1}$ and $T_f^* = 290 \text{ K}$.

5.7 In a study of the properties of an aqueous solution of $\text{Th}(\text{NO}_3)_4$ (by A. Apelblat, D. Azoulay, and A. Sahar, *J. Chem. Soc. Faraday Trans. I*, 1618, (1973)), a freezing point depression of 0.0703 K was observed for an aqueous solution of molality 9.6 mmol kg^{-1} . What is the apparent number of ions per formula unit?

5.8 The table below lists the vapour pressures of mixtures of iodoethane (I) and ethyl acetate (A) at 50°C . Find the activity coefficients of both components on (a) the Raoult's law basis, (b) the Henry's law basis with iodoethane as solute.

x_I	0	0.0579	0.1095	0.1918	0.2353	0.3718
p_I/kPa	0	3.73	7.03	11.7	14.05	20.72
p_A/kPa	37.38	35.48	33.64	30.85	29.44	25.05
x_I	0.5478	0.6349	0.8253	0.9093	1.0000	
p_I/kPa	28.44	31.88	39.58	43.00	47.12	
p_A/kPa	19.23	16.39	8.88	5.09	0	

5.9 Plot the vapour pressure data for a mixture of benzene (B) and acetic acid (A) given below and plot the vapour pressure/composition curve for the mixture at 50°C . Then confirm that Raoult's and Henry's laws are obeyed in the appropriate regions. Deduce the activities and activity coefficients of the components on the Raoult's law basis and then, taking B as the solute, its activity and activity coefficient on a Henry's law basis. Finally, evaluate the excess Gibbs energy of the mixture over the composition range spanned by the data.

x_A	0.0160	0.0439	0.0835	0.1138	0.1714	
p_A/kPa	0.484	0.967	1.535	1.89	2.45	
p_B/kPa	35.05	34.29	33.28	32.64	30.90	
x_A	0.2973	0.3696	0.5834	0.6604	0.8437	0.9931
p_A/kPa	3.31	3.83	4.84	5.36	6.76	7.29
p_B/kPa	28.16	26.08	20.42	18.01	10.0	0.47

5.10† Aminabhavi *et al.* examined mixtures of cyclohexane with various long-chain alkanes (T.M. Aminabhavi, V.B. Patil, M.I. Aralaguppi, J.D. Ortego, and K.C. Hansen, *J. Chem. Eng. Data* **41**, 526 (1996)). Among their data are the following measurements of the density of a mixture of cyclohexane and pentadecane as a function of mole fraction of cyclohexane (x_c) at 298.15 K :

x_c	0.6965	0.7988	0.9004
$\rho/(\text{g cm}^{-3})$	0.7661	0.7674	0.7697

* Problems denoted with the symbol † were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

Compute the partial molar volume for each component in a mixture that has a mole fraction cyclohexane of 0.7988.

5.11‡ Comelli and Francesconi examined mixtures of propionic acid with various other organic liquids at 313.15 K (F. Comelli and R. Francesconi, *J. Chem. Eng. Data* **41**, 101 (1996)). They report the excess volume of mixing propionic acid with oxane as $V^E = x_1 x_2 \{a_0 + a_1(x_1 - x_2)\}$, where x_1 is the mole fraction of propionic acid, x_2 that of oxane, $a_0 = -2.4697 \text{ cm}^3 \text{ mol}^{-1}$ and $a_1 = 0.0608 \text{ cm}^3 \text{ mol}^{-1}$. The density of propionic acid at this temperature is $0.97174 \text{ g cm}^{-3}$; that of oxane is $0.86398 \text{ g cm}^{-3}$. (a) Derive an expression for the partial molar volume of each component at this temperature. (b) Compute the partial molar volume for each component in an equimolar mixture.

5.12‡ Francesconi *et al.* studied the liquid–vapour equilibria of trichloromethane and 1,2-epoxybutane at several temperatures (R. Francesconi, B. Lunelli, and F. Comelli, *J. Chem. Eng. Data* **41**, 310 (1996)). Among their data are the following measurements of the mole fractions of trichloromethane in the liquid phase (x_T) and the vapour phase (y_T) at 298.15 K as a function of pressure.

p/kPa	23.40	21.75	20.25	18.75	18.15	20.25	22.50	26.30
x	0	0.129	0.228	0.353	0.511	0.700	0.810	1
y	0	0.065	0.145	0.285	0.535	0.805	0.915	1

Compute the activity coefficients of both components on the basis of Raoult's law.

5.13‡ Chen and Lee studied the liquid–vapour equilibria of cyclohexanol with several gases at elevated pressures (J.-T. Chen and M.-J. Lee, *J. Chem. Eng. Data* **41**, 339 (1996)). Among their data are the following measurements of the mole fractions of cyclohexanol in the vapour phase (y) and the liquid phase (x) at 393.15 K as a function of pressure.

p/bar	10.0	20.0	30.0	40.0	60.0	80.0
y_{cyc}	0.0267	0.0149	0.0112	0.00947	0.00835	0.00921
x_{cyc}	0.9741	0.9464	0.9204	0.892	0.836	0.773

Determine the Henry's law constant of CO_2 in cyclohexanol, and compute the activity coefficient of CO_2 .

5.14‡ Equation 5.39 indicates that solubility is an exponential function of temperature. The data in the table below gives the solubility, S , of calcium acetate in water as a function of temperature.

$\theta/^\circ\text{C}$	0	20	40	60	80
$S/(\text{mol dm}^{-3})$	36.4	34.9	33.7	32.7	31.7

Determine the extent to which the data fit the exponential $S = S_0 e^{\tau/T}$ and obtain values for S_0 and τ . Express these constants in terms of properties of the solute.

5.15 The excess Gibbs energy of solutions of methylcyclohexane (MCH) and tetrahydrofuran (THF) at 303.15 K was found to fit the expression

$$G^E = RTx(1-x)\{0.4857 - 0.1077(2x-1) + 0.0191(2x-1)^2\}$$

where x is the mole fraction of the methylcyclohexane. Calculate the Gibbs energy of mixing when a mixture of 1.00 mol of MCH and 3.00 mol of THF is prepared.

5.16 The mean activity coefficients for aqueous solutions of NaCl at 25°C are given below. Confirm that they support the Debye–Hückel limiting law and that an improved fit is obtained with the extended law.

$b/(\text{mmol kg}^{-1})$	1.0	2.0	5.0	10.0	20.0
$\gamma_{\pm}$	0.9649	0.9519	0.9275	0.9024	0.8712

Theoretical problems

5.17 The excess Gibbs energy of a certain binary mixture is equal to $gRTx(1-x)$ where g is a constant and x is the mole fraction of a solute A.

Find an expression for the chemical potential of A in the mixture and sketch its dependence on the composition.

5.18 Use the Gibbs–Duhem equation to derive the Gibbs–Duhem–Margules equation

$$\left(\frac{\partial \ln f_A}{\partial \ln x_A}\right)_{p,T} = \left(\frac{\partial \ln f_B}{\partial \ln x_B}\right)_{p,T}$$

where f is the fugacity. Use the relation to show that, when the fugacities are replaced by pressures, if Raoult's law applies to one component in a mixture it must also apply to the other.

5.19 Use the Gibbs–Duhem equation to show that the partial molar volume (or any partial molar property) of a component B can be obtained if the partial molar volume (or other property) of A is known for all compositions up to the one of interest. Do this by proving that

$$V_B = V_B^* - \int_{V_A^*}^{V_A} \frac{x_A}{1-x_A} dV_A$$

Use the following data (which are for 298 K) to evaluate the integral graphically to find the partial molar volume of acetone at $x = 0.500$.

$x(\text{CHCl}_3)$	0	0.194	0.385	0.559	0.788	0.889	1.000
$V_m/(\text{cm}^3 \text{ mol}^{-1})$	73.99	75.29	76.50	77.55	79.08	79.82	80.67

5.20 Use the Gibbs–Helmholtz equation to find an expression for $d \ln x_A$ in terms of dT . Integrate $d \ln x_A$ from $x_A = 0$ to the value of interest, and integrate the right-hand side from the transition temperature for the pure liquid A to the value in the solution. Show that, if the enthalpy of transition is constant, then eqns 5.33 and 5.36 are obtained.

5.21 The 'osmotic coefficient', ϕ , is defined as $\phi = -(x_A/x_B) \ln a_A$. By writing $r = x_B/x_A$, and using the Gibbs–Duhem equation, show that we can calculate the activity of B from the activities of A over a composition range by using the formula

$$\ln \left(\frac{a_B}{r}\right) = \phi - \phi(0) + \int_0^r \left(\frac{\phi-1}{r}\right) dr$$

5.22 Show that the osmotic pressure of a real solution is given by $\Pi V = -RT \ln a_A$. Go on to show that, provided the concentration of the solution is low, this expression takes the form $\Pi V = \phi RT[B]$ and hence that the osmotic coefficient, ϕ , (which is defined in Problem 5.21) may be determined from osmometry.

5.23 Show that the freezing-point depression of a real solution in which the solvent of molar mass M has activity a_A obeys

$$\frac{d \ln a_A}{d(\Delta T)} = -\frac{M}{K_f}$$

and use the Gibbs–Duhem equation to show that

$$\frac{d \ln a_B}{d(\Delta T)} = -\frac{1}{b_B K_f}$$

where a_B is the solute activity and b_B is its molality. Use the Debye–Hückel limiting law to show that the osmotic coefficient (ϕ , Problem 5.21) is given by $\phi = 1 - \frac{1}{3} A' I$ with $A' = 2.303A$ and $I = b/b^\circ$.

Applications: to biology and polymer science

5.24 Haemoglobin, the red blood protein responsible for oxygen transport, binds about 1.34 cm^3 of oxygen per gram. Normal blood has a haemoglobin concentration of 150 g dm^{-3} . Haemoglobin in the lungs is about 97 per cent saturated with oxygen, but in the capillary is only about 75 per cent saturated.

What volume of oxygen is given up by 100 cm³ of blood flowing from the lungs in the capillary?

5.25 For the calculation of the solubility c of a gas in a solvent, it is often convenient to use the expression $c = Kp$, where K is the Henry's law constant. Breathing air at high pressures, such as in scuba diving, results in an increased concentration of dissolved nitrogen. The Henry's law constant for the solubility of nitrogen is 0.18 μg/(g H₂O atm). What mass of nitrogen is dissolved in 100 g of water saturated with air at 4.0 atm and 20°C? Compare your answer to that for 100 g of water saturated with air at 1.0 atm. (Air is 78.08 mole per cent N₂.) If nitrogen is four times as soluble in fatty tissues as in water, what is the increase in nitrogen concentration in fatty tissue in going from 1 atm to 4 atm?

5.26 Ethidium bromide binds to DNA by a process called *intercalation*, in which the aromatic ethidium cation fits between two adjacent DNA base pairs. An equilibrium dialysis experiment was used to study the binding of ethidium bromide (EB) to a short piece of DNA. A 1.00 μmol dm⁻³ aqueous solution of the DNA sample was dialysed against an excess of EB. The following data were obtained for the total concentration of EB:

[EB]/(μmol dm⁻³)

Side without DNA	0.042	0.092	0.204	0.526	1.150
Side with DNA	0.292	0.590	1.204	2.531	4.150

From these data, make a Scatchard plot and evaluate the intrinsic equilibrium constant, K , and total number of sites per DNA molecule. Is the identical and independent sites model for binding applicable?

5.27 The form of the Scatchard equation given in *Impact 15.2* applies only when the macromolecule has identical and independent binding sites. For non-identical independent binding sites, the Scatchard equation is

$$\frac{v}{[A]_{\text{out}}} = \sum_i \frac{N_i K_i}{1 + K_i [A]_{\text{out}}}$$

Plot $v/[A]$ for the following cases. (a) There are four independent sites on an enzyme molecule and the intrinsic binding constant is $K = 1.0 \times 10^7$. (b) There are a total of six sites per polymer. Four of the sites are identical and have an intrinsic binding constant of 1×10^5 . The binding constants for the other two sites are 2×10^6 .

5.28 The addition of a small amount of a salt, such as (NH₄)₂SO₄, to a solution containing a charged protein increases the solubility of the protein in water. This observation is called the *salting-in effect*. However, the addition of large amounts of salt can decrease the solubility of the protein to such an extent that the protein precipitates from solution. This observation is called

the *salting-out effect* and is used widely by biochemists to isolate and purify proteins. Consider the equilibrium $PX_{\nu}(s) \rightleftharpoons P^{\nu+}(aq) + \nu X^-(aq)$, where $P^{\nu+}$ is a polycationic protein of charge $+\nu$ and X^- is its counter ion. Use Le Chatelier's principle and the physical principles behind the Debye-Hückel theory to provide a molecular interpretation for the salting-in and salting-out effects.

5.29† Polymer scientists often report their data in rather strange units. For example, in the determination of molar masses of polymers in solution by osmometry, osmotic pressures are often reported in grams per square centimetre (g cm⁻²) and concentrations in grams per cubic centimetre (g cm⁻³). (a) With these choices of units, what would be the units of R in the van't Hoff equation? (b) The data in the table below on the concentration dependence of the osmotic pressure of polyisobutene in chlorobenzene at 25°C have been adapted from J. Leonard and H. Daoust (*J. Polymer Sci.* 57, 53 (1962)). From these data, determine the molar mass of polyisobutene by plotting Π/c against c . (c) Theta solvents are solvents for which the second osmotic coefficient is zero; for 'poor' solvents the plot is linear and for good solvents the plot is nonlinear. From your plot, how would you classify chlorobenzene as a solvent for polyisobutene? Rationalize the result in terms of the molecular structure of the polymer and solvent. (d) Determine the second and third osmotic virial coefficients by fitting the curve to the virial form of the osmotic pressure equation. (e) Experimentally, it is often found that the virial expansion can be represented as

$$\Pi/c = RT/M (1 + B'c + gB'^2c^2 + \dots)$$

and in good solvents, the parameter g is often about 0.25. With terms beyond the second power ignored, obtain an equation for $(\Pi/c)^{1/2}$ and plot this quantity against c . Determine the second and third virial coefficients from the plot and compare to the values from the first plot. Does this plot confirm the assumed value of g ?

$10^{-2}(\Pi/c)/(\text{g cm}^{-2}/\text{g cm}^{-3})$	2.6	2.9	3.6	4.3	6.0	12.0
$c/(\text{g cm}^{-3})$	0.0050	0.010	0.020	0.033	0.057	0.10
$10^{-2}(\Pi/c)/(\text{g cm}^{-2}/\text{g cm}^{-3})$	19.0	31.0	38.0	52	63	
$c/(\text{g cm}^{-3})$	0.145	0.195	0.245	0.27	0.29	

5.30† K. Sato, F.R. Eirich, and J.E. Mark (*J. Polymer Sci., Polym. Phys.* 14, 619 (1976)) have reported the data in the table below for the osmotic pressures of polychloroprene ($\rho = 1.25 \text{ g cm}^{-3}$) in toluene ($\rho = 0.858 \text{ g cm}^{-3}$) at 30°C. Determine the molar mass of polychloroprene and its second osmotic virial coefficient.

Problems

Phase diagrams for pure substances were introduced in Chapter 4. Now we develop their use systematically and show how they are rich summaries of empirical information about a wide range of systems. To set the stage, we introduce the famous phase rule of Gibbs, which shows the extent to which various parameters can be varied yet the equilibrium between phases preserved. With the rule established, we see how it can be used to discuss the phase diagrams that we met in the two preceding chapters. The chapter then introduces systems of gradually increasing complexity. In each case we shall see how the phase diagram for the system summarizes empirical observations on the conditions under which the various phases of the system are stable.

In this chapter we describe a systematic way of discussing the physical changes mixtures undergo when they are heated or cooled and when their compositions are changed. In particular, we see how to use phase diagrams to judge whether two substances are mutually miscible, whether an equilibrium can exist over a range of conditions, or whether the system must be brought to a definite pressure, temperature, and composition before equilibrium is established. Phase diagrams are of considerable commercial and industrial significance, particularly for semiconductors, ceramics, steels, and alloys. They are also the basis of separation procedures in the petroleum industry and of the formulation of foods and cosmetic preparations.

Phases, components, and degrees of freedom

All phase diagrams can be discussed in terms of a relationship, the phase rule, derived by J.W. Gibbs. We shall derive this rule first, and then apply it to a wide variety of systems. The phase rule requires a careful use of terms, so we begin by presenting a number of definitions.

6.1 Definitions

The term **phase** was introduced at the start of Chapter 4, where we saw that it signifies a state of matter that is uniform throughout, not only in chemical composition but also in physical state.¹ Thus we speak of the solid, liquid, and gas phases of a substance, and of its various solid phases (as for black phosphorus and white phosphorus). The number of phases in a system is denoted P . A gas, or a gaseous mixture, is a single phase, a crystal is a single phase, and two totally miscible liquids form a single phase.

¹ The words are Gibbs's.

A solution of sodium chloride in water is a single phase. Ice is a single phase ($P = 1$) even though it might be chipped into small fragments. A slurry of ice and water is a two-phase system ($P = 2$) even though it is difficult to map the boundaries between the phases. A system in which calcium carbonate undergoes thermal decomposition consists of two solid phases (one consisting of calcium carbonate and the other of calcium oxide) and one gaseous phase (consisting of carbon dioxide).

An alloy of two metals is a two-phase system ($P = 2$) if the metals are immiscible, but a single-phase system ($P = 1$) if they are miscible. This example shows that it is not always easy to decide whether a system consists of one phase or of two. A solution of solid B in solid A—a homogeneous mixture of the two substances—is uniform on a molecular scale. In a solution, atoms of A are surrounded by atoms of A and B, and any sample cut from the sample, however small, is representative of the composition of the whole.

A dispersion is uniform on a macroscopic scale but not on a microscopic scale, for it consists of grains or droplets of one substance in a matrix of the other. A small sample could come entirely from one of the minute grains of pure A and would not be representative of the whole (Fig. 6.1). Dispersions are important because, in many advanced materials (including steels), heat treatment cycles are used to achieve the precipitation of a fine dispersion of particles of one phase (such as a carbide phase) within a matrix formed by a saturated solid solution phase. The ability to control this microstructure resulting from phase equilibria makes it possible to tailor the mechanical properties of the materials to a particular application.

By a **constituent** of a system we mean a chemical species (an ion or a molecule) that is present. Thus, a mixture of ethanol and water has two constituents. A solution of sodium chloride has three constituents: water, Na^+ ions, and Cl^- ions. The term constituent should be carefully distinguished from ‘component’, which has a more technical meaning. A **component** is a *chemically independent* constituent of a system. The number of components, C , in a system is the minimum number of independent species necessary to define the composition of all the phases present in the system.

When no reaction takes place and there are no other constraints (such as charge balance), the number of components is equal to the number of constituents. Thus, pure water is a one-component system ($C = 1$), because we need only the species H_2O to specify its composition. Similarly, a mixture of ethanol and water is a two-component system ($C = 2$): we need the species H_2O and $\text{C}_2\text{H}_5\text{OH}$ to specify its composition. An aqueous solution of sodium chloride has two components because, by charge balance, the number of Na^+ ions must be the same as the number of Cl^- ions.

A system that consists of hydrogen, oxygen, and water at room temperature has three components ($C = 3$), despite it being possible to form H_2O from H_2 and O_2 : under the conditions prevailing in the system, hydrogen and oxygen do not react to form water, so they are independent constituents. When a reaction can occur under the conditions prevailing in the system, we need to decide the minimum number of species that, after allowing for reactions in which one species is synthesized from others, can be used to specify the composition of all the phases. Consider, for example, the equilibrium

Phase 1 Phase 2 Phase 3

in which there are three constituents and three phases. To specify the composition of the gas phase (Phase 3) we need the species CO_2 , and to specify the composition of Phase 2 we need the species CaO . However, we do not need an additional species to specify the composition of Phase 1 because its identity (CaCO_3) can be expressed in terms of the other two constituents by making use of the stoichiometry of the reaction. Hence, the system has only two components ($C = 2$).

Fig. 6.1 The difference between (a) a single-phase solution, in which the composition is uniform on a microscopic scale, and (b) a dispersion, in which regions of one component are embedded in a matrix of a second component.

Example 6.1 *Counting components*

How many components are present in a system in which ammonium chloride undergoes thermal decomposition?

Method Begin by writing down the chemical equation for the reaction and identifying the constituents of the system (all the species present) and the phases. Then decide whether, under the conditions prevailing in the system, any of the constituents can be prepared from any of the other constituents. The removal of these constituents leaves the number of independent constituents. Finally, identify the minimum number of these independent constituents that are needed to specify the composition of all the phases.

Answer The chemical reaction is

There are three constituents and two phases (one solid, one gas). However, NH_3 and HCl are formed in fixed stoichiometric proportions by the reaction. Therefore, the compositions of both phases can be expressed in terms of the single species NH_4Cl . It follows that there is only one component in the system ($C = 1$). If additional HCl (or NH_3) were supplied to the system, the decomposition of NH_4Cl would not give the correct composition of the gas phase and HCl (or NH_3) would have to be invoked as a second component.

Self-test 6.1 Give the number of components in the following systems: (a) water, allowing for its autoprotolysis, (b) aqueous acetic acid, (c) magnesium carbonate in equilibrium with its decomposition products. [(a) 1, (b) 2, (c) 2]

The **variance**, F , of a system is the number of intensive variables that can be changed independently without disturbing the number of phases in equilibrium. In a single-component, single-phase system ($C = 1$, $P = 1$), the pressure and temperature may be changed independently without changing the number of phases, so $F = 2$. We say that such a system is **bivariant**, or that it has two **degrees of freedom**. On the other hand, if two phases are in equilibrium (a liquid and its vapour, for instance) in a single-component system ($C = 1$, $P = 2$), the temperature (or the pressure) can be changed at will, but the change in temperature (or pressure) demands an accompanying change in pressure (or temperature) to preserve the number of phases in equilibrium. That is, the variance of the system has fallen to 1.

Comment 6.1

Josiah Willard Gibbs spent most of his working life at Yale, and may justly be regarded as the originator of chemical thermodynamics. He reflected for years before publishing his conclusions, and then did so in precisely expressed papers in an obscure journal (*The Transactions of the Connecticut Academy of Arts and Sciences*). He needed interpreters before the power of his work was recognized and before it could be applied to industrial processes. He is regarded by many as the first great American theoretical scientist.

6.2 The phase rule

In one of the most elegant calculations of the whole of chemical thermodynamics, J.W. Gibbs deduced the **phase rule**, which is a general relation between the variance, F , the number of components, C , and the number of phases at equilibrium, P , for a system of any composition:

$$F = C - P + 2 \quad (6.1)$$

Justification 6.1 *The phase rule*

Consider first the special case of a one-component system. For two phases in equilibrium, we can write $\mu_1(\alpha) = \mu_1(\beta)$. Each chemical potential is a function of the pressure and temperature, so

$$\mu_1(\alpha; p, T) = \mu_1(\beta; p, T)$$

This is an equation relating p and T , so only one of these variables is independent (just as the equation $x + y = 2$ is a relation for y in terms of x : $y = 2 - x$). That conclusion is consistent with $F = 1$. For three phases in mutual equilibrium,

$$\mu_j(\alpha; p, T) = \mu_j(\beta; p, T) = \mu_j(\gamma; p, T)$$

This relation is actually two equations for two unknowns ($\mu_j(\alpha; p, T) = \mu_j(\beta; p, T)$ and $\mu_j(\beta; p, T) = \mu_j(\gamma; p, T)$), and therefore has a solution only for a single value of p and T (just as the pair of equations $x + y = 2$ and $3x - y = 4$ has the single solution $x = \frac{3}{2}$ and $y = \frac{1}{2}$). That conclusion is consistent with $F = 0$. Four phases cannot be in mutual equilibrium in a one-component system because the three equalities

$$\mu_j(\alpha; p, T) = \mu_j(\beta; p, T) \quad \mu_j(\beta; p, T) = \mu_j(\gamma; p, T) \quad \mu_j(\gamma; p, T) = \mu_j(\delta; p, T)$$

are three equations for two unknowns (p and T) and are not consistent (just as $x + y = 2$, $3x - y = 4$, and $x + 4y = 6$ have no solution).

Now consider the general case. We begin by counting the total number of intensive variables. The pressure, p , and temperature, T , count as 2. We can specify the composition of a phase by giving the mole fractions of $C - 1$ components. We need specify only $C - 1$ and not all C mole fractions because $x_1 + x_2 + \dots + x_C = 1$, and all mole fractions are known if all except one are specified. Because there are P phases, the total number of composition variables is $P(C - 1)$. At this stage, the total number of intensive variables is $P(C - 1) + 2$.

At equilibrium, the chemical potential of a component J must be the same in every phase (Section 4.4):

$$\mu_j(\alpha) = \mu_j(\beta) = \dots \quad \text{for } P \text{ phases}$$

That is, there are $P - 1$ equations of this kind to be satisfied for each component J . As there are C components, the total number of equations is $C(P - 1)$. Each equation reduces our freedom to vary one of the $P(C - 1) + 2$ intensive variables. It follows that the total number of degrees of freedom is

$$F = P(C - 1) + 2 - C(P - 1) = C - P + 2$$

which is eqn 6.1.

(a) One-component systems

For a one-component system, such as pure water, $F = 3 - P$. When only one phase is present, $F = 2$ and both p and T can be varied independently without changing the number of phases. In other words, a single phase is represented by an *area* on a phase diagram. When two phases are in equilibrium $F = 1$, which implies that pressure is not freely variable if the temperature is set; indeed, at a given temperature, a liquid has a characteristic vapour pressure. It follows that the equilibrium of two phases is represented by a *line* in the phase diagram. Instead of selecting the temperature, we could select the pressure, but having done so the two phases would be in equilibrium at a single definite temperature. Therefore, freezing (or any other phase transition) occurs at a definite temperature at a given pressure.

When three phases are in equilibrium, $F = 0$ and the system is invariant. This special condition can be established only at a definite temperature and pressure that is characteristic of the substance and outside our control. The equilibrium of three phases is therefore represented by a *point*, the triple point, on a phase diagram. Four phases cannot be in equilibrium in a one-component system because F cannot be negative. These features are summarized in Fig. 6.2.

We can identify the features in Fig. 6.2 in the experimentally determined phase diagram for water (Fig. 6.3). This diagram summarizes the changes that take place as a sample, such as that at a , is cooled at constant pressure. The sample remains entirely

Fig. 6.2 The typical regions of a one-component phase diagram. The lines represent conditions under which the two adjoining phases are in equilibrium. A point represents the unique set of conditions under which three phases coexist in equilibrium. Four phases cannot mutually coexist in equilibrium.

Fig. 6.3 The phase diagram for water, a simplified version of Fig. 4.5. The label T_3 marks the temperature of the triple point, T_b the normal boiling point, and T_f the normal freezing point.

gaseous until the temperature reaches b , when liquid appears. Two phases are now in equilibrium and $F = 1$. Because we have decided to specify the pressure, which uses up the single degree of freedom, the temperature at which this equilibrium occurs is not under our control. Lowering the temperature takes the system to c in the one-phase, liquid region. The temperature can now be varied around the point c at will, and only when ice appears at d does the variance become 1 again.

(b) Experimental procedures

Detecting a phase change is not always as simple as seeing water boil in a kettle, so special techniques have been developed. Two techniques are **thermal analysis**, which takes advantage of the effect of the enthalpy change during a first-order transition (Section 4.7), and differential scanning calorimetry (see *Impact I2.1*). They are useful for solid–solid transitions, where simple visual inspection of the sample may be inadequate. In thermal analysis, a sample is allowed to cool and its temperature is monitored. At a first-order transition, heat is evolved and the cooling stops until the transition is complete. The cooling curve along the isobar cde in Fig. 6.3 therefore has the shape shown in Fig. 6.4. The transition temperature is obvious, and is used to mark point d on the phase diagram.

Modern work on phase transitions often deals with systems at very high pressures, and more sophisticated detection procedures must be adopted. Some of the highest pressures currently attainable are produced in a **diamond-anvil cell** like that illustrated in Fig. 6.5. The sample is placed in a minute cavity between two gem-quality diamonds, and then pressure is exerted simply by turning the screw. The advance in design this represents is quite remarkable for, with a turn of the screw, pressures of up to about 1 Mbar can be reached that a few years ago could not be reached with equipment weighing tons.

The pressure is monitored spectroscopically by observing the shift of spectral lines in small pieces of ruby added to the sample, and the properties of the sample itself are observed optically through the diamond anvils. One application of the technique is to study the transition of covalent solids to metallic solids. Iodine, I_2 , for instance, becomes metallic at around 200 kbar and makes a transition to a monatomic metallic

Fig. 6.4 The cooling curve for the isobar cde in Fig. 6.3. The halt marked d corresponds to the pause in the fall of temperature while the first-order exothermic transition (freezing) occurs. This pause enables T_f to be located even if the transition cannot be observed visually.

Fig. 6.5 Ultrahigh pressures (up to about 2 Mbar) can be achieved using a diamond anvil. The sample, together with a ruby for pressure measurement and a drop of liquid for pressure transmission, are placed between two gem-quality diamonds. The principle of its action is like that of a nutcracker: the pressure is exerted by turning the screw by hand.

solid at around 210 kbar. Studies such as these are relevant to the structure of material deep inside the Earth (at the centre of the Earth the pressure is around 5 Mbar) and in the interiors of the giant planets, where even hydrogen may be metallic.

Two-component systems

When two components are present in a system, $C = 2$ and $F = 4 - P$. If the temperature is constant, the remaining variance is $F' = 3 - P$, which has a maximum value of 2. (The prime on F indicates that one of the degrees of freedom has been discarded, in this case the temperature.) One of these two remaining degrees of freedom is the pressure and the other is the composition (as expressed by the mole fraction of one component). Hence, one form of the phase diagram is a map of pressures and compositions at which each phase is stable. Alternatively, the pressure could be held constant and the phase diagram depicted in terms of temperature and composition.

6.3 Vapour pressure diagrams

The partial vapour pressures of the components of an ideal solution of two volatile liquids are related to the composition of the liquid mixture by Raoult's law (Section 5.3a)

$$p_A = x_A p_A^* \quad p_B = x_B p_B^* \quad (6.2)^\circ$$

where p_A^* is the vapour pressure of pure A and p_B^* that of pure B. The total vapour pressure p of the mixture is therefore

$$p = p_A + p_B = x_A p_A^* + x_B p_B^* = p_B^* + (p_A^* - p_B^*)x_A \quad (6.3)^\circ$$

This expression shows that the total vapour pressure (at some fixed temperature) changes linearly with the composition from p_B^* to p_A^* as x_A changes from 0 to 1 (Fig. 6.6).

(a) The composition of the vapour

The compositions of the liquid and vapour that are in mutual equilibrium are not necessarily the same. Common sense suggests that the vapour should be richer in the more volatile component. This expectation can be confirmed as follows. The partial pressures of the components are given by eqn 6.2. It follows from Dalton's law that the mole fractions in the gas, y_A and y_B , are

$$y_A = \frac{p_A}{p} \quad y_B = \frac{p_B}{p} \quad (6.4)$$

Provided the mixture is ideal, the partial pressures and the total pressure may be expressed in terms of the mole fractions in the liquid by using eqn 6.2 for p_i and eqn 6.3 for the total vapour pressure p , which gives

$$y_A = \frac{x_A p_A^*}{p_B^* + (p_A^* - p_B^*)x_A} \quad y_B = 1 - y_A \quad (6.5)^\circ$$

Figure 6.7 shows the composition of the vapour plotted against the composition of the liquid for various values of $p_A^*/p_B^* > 1$. We see that in all cases $y_A > x_A$, that is, the vapour is richer than the liquid in the more volatile component. Note that if B is non-volatile, so that $p_B^* = 0$ at the temperature of interest, then it makes no contribution to the vapour ($y_B = 0$).

Equation 6.3 shows how the total vapour pressure of the mixture varies with the composition of the liquid. Because we can relate the composition of the liquid to the composition of the vapour through eqn 6.5, we can now also relate the total vapour pressure to the composition of the vapour:

Fig. 6.6 The variation of the total vapour pressure of a binary mixture with the mole fraction of A in the liquid when Raoult's law is obeyed.

Fig. 6.7 The mole fraction of A in the vapour of a binary ideal solution expressed in terms of its mole fraction in the liquid, calculated using eqn 6.5 for various values of p_A^*/p_B^* (the label on each curve) with A more volatile than B. In all cases the vapour is richer than the liquid in A.

Exploration To reproduce the results of Fig. 6.7, first rearrange eqn 6.5 so that y_A is expressed as a function of x_A and the ratio p_A^*/p_B^* . Then plot y_A against x_A for several values of $p_A/p_B > 1$.

Fig. 6.8 The dependence of the vapour pressure of the same system as in Fig. 6.7, but expressed in terms of the mole fraction of A in the vapour by using eqn 6.6. Individual curves are labelled with the value of p_A^*/p_B^* .

Exploration To reproduce the results of Fig. 6.8, first rearrange eqn 6.6 so that the ratio p_A/p_A^* is expressed as a function of y_A and the ratio p_A^*/p_B^* . Then plot p_A/p_A^* against y_A for several values of $p_A^*/p_B^* > 1$.

$$p = \frac{p_A^* p_B^*}{p_A^* + (p_B^* - p_A^*) y_A} \quad (6.6)^\circ$$

This expression is plotted in Fig. 6.8.

(b) The interpretation of the diagrams

If we are interested in distillation, both the vapour and the liquid compositions are of equal interest. It is therefore sensible to combine Figs. 6.7 and 6.8 into one (Fig. 6.9). The point *a* indicates the vapour pressure of a mixture of composition x_A , and the point *b* indicates the composition of the vapour that is in equilibrium with the liquid at that pressure. Note that, when two phases are in equilibrium, $P = 2$ so $F' = 1$ (as usual, the prime indicating that one degree of freedom, the temperature, has already been discarded). That is, if the composition is specified (so using up the only remaining degree of freedom), the pressure at which the two phases are in equilibrium is fixed.

A richer interpretation of the phase diagram is obtained if we interpret the horizontal axis as showing the *overall* composition, z_A , of the system. If the horizontal axis of the vapour pressure diagram is labelled with z_A , then all the points down to the solid diagonal line in the graph correspond to a system that is under such high pressure that it contains only a liquid phase (the applied pressure is higher than the vapour pressure), so $z_A = x_A$, the composition of the liquid. On the other hand, all points below the lower curve correspond to a system that is under such low pressure that it contains only a vapour phase (the applied pressure is lower than the vapour pressure), so $z_A = y_A$.

Points that lie between the two lines correspond to a system in which there are two phases present, one a liquid and the other a vapour. To see this interpretation, consider the effect of lowering the pressure on a liquid mixture of overall composition *a* in Fig. 6.10. The lowering of pressure can be achieved by drawing out a piston (Fig. 6.11). This degree of freedom is permitted by the phase rule because $F' = 2$ when $P = 1$, and even if the composition is selected one degree of freedom remains. The changes to the system do not affect the overall composition, so the state of the system moves down the vertical line that passes through *a*. This vertical line is called an

Fig. 6.9 The dependence of the total vapour pressure of an ideal solution on the mole fraction of A in the entire system. A point between the two lines corresponds to both liquid and vapour being present; outside that region there is only one phase present. The mole fraction of A is denoted z_A , as explained below.

Fig. 6.10 The points of the pressure–composition diagram discussed in the text. The vertical line through *a* is an *isopleth*, a line of constant composition of the entire system.

isopleth, from the Greek words for ‘equal abundance’. Until the point a_1 is reached (when the pressure has been reduced to p_1), the sample consists of a single liquid phase. At a_1 the liquid can exist in equilibrium with its vapour. As we have seen, the composition of the vapour phase is given by point a'_1 . A line joining two points representing phases in equilibrium is called a **tie line**. The composition of the liquid is the same as initially (a_1 lies on the isopleth through a), so we have to conclude that at this pressure there is virtually no vapour present; however, the tiny amount of vapour that is present has the composition a'_1 .

Now consider the effect of lowering the pressure to p_2 , so taking the system to a pressure and overall composition represented by the point a''_2 . This new pressure is below the vapour pressure of the original liquid, so it vaporizes until the vapour pressure of the remaining liquid falls to p_2 . Now we know that the composition of such a liquid must be a_2 . Moreover, the composition of the vapour in equilibrium with that liquid must be given by the point a'_2 at the other end of the tie line. Note that two phases are now in equilibrium, so $F' = 1$ for all points between the two lines; hence, for a given pressure (such as at p_2) the variance is zero, and the vapour and liquid phases have fixed compositions (Fig. 6.12). If the pressure is reduced to p_3 , a similar readjustment in composition takes place, and now the compositions of the liquid and vapour are represented by the points a_3 and a'_3 , respectively. The latter point corresponds to a system in which the composition of the vapour is the same as the overall composition, so we have to conclude that the amount of liquid present is now virtually zero, but the tiny amount of liquid present has the composition a_3 . A further decrease in pressure takes the system to the point a_4 ; at this stage, only vapour is present and its composition is the same as the initial overall composition of the system (the composition of the original liquid).

(c) The lever rule

A point in the two-phase region of a phase diagram indicates not only qualitatively that both liquid and vapour are present, but represents quantitatively the relative amounts of each. To find the relative amounts of two phases α and β that are in equilibrium, we measure the distances l_α and l_β along the horizontal tie line, and then use the **lever rule** (Fig. 6.13):

Fig. 6.12 The general scheme of interpretation of a pressure–composition diagram (a vapour pressure diagram).

Fig. 6.13 The lever rule. The distances l_α and l_β are used to find the proportions of the amounts of phases α (such as vapour) and β (for example, liquid) present at equilibrium. The lever rule is so called because a similar rule relates the masses at two ends of a lever to their distances from a pivot ($m_\alpha l_\alpha = m_\beta l_\beta$ for balance).

Fig. 6.11 (a) A liquid in a container exists in equilibrium with its vapour. The superimposed fragment of the phase diagram shows the compositions of the two phases and their abundances (by the lever rule). (b) When the pressure is changed by drawing out a piston, the compositions of the phases adjust as shown by the tie line in the phase diagram. (c) When the piston is pulled so far out that all the liquid has vaporized and only the vapour is present, the pressure falls as the piston is withdrawn and the point on the phase diagram moves into the one-phase region.

$$n_{\alpha}l_{\alpha} = n_{\beta}l_{\beta} \quad (6.7)$$

Here n_{α} is the amount of phase α and n_{β} the amount of phase β . In the case illustrated in Fig. 6.13, because $l_{\beta} \approx 2l_{\alpha}$, the amount of phase α is about twice the amount of phase β .

Justification 6.2 The lever rule

To prove the lever rule we write $n = n_{\alpha} + n_{\beta}$ and the overall amount of A as nz_A . The overall amount of A is also the sum of its amounts in the two phases:

$$nz_A = n_{\alpha}x_A + n_{\beta}y_A$$

Since also

$$nz_A = n_{\alpha}z_A + n_{\beta}z_A$$

by equating these two expressions it follows that

$$n_{\alpha}(x_A - z_A) = n_{\beta}(z_A - y_A)$$

which corresponds to eqn 6.7.

Fig. 6.14 The temperature–composition diagram corresponding to an ideal mixture with the component A more volatile than component B. Successive boilings and condensations of a liquid originally of composition a_1 lead to a condensate that is pure A. The separation technique is called fractional distillation.

Comment 6.2

The textbook's web site contains links to online databases of phase diagrams.

Illustration 6.1 Using the lever rule

At p_1 in Fig. 6.10, the ratio $l_{\text{vap}}/l_{\text{liq}}$ is almost infinite for this tie line, so $n_{\text{liq}}/n_{\text{vap}}$ is also almost infinite, and there is only a trace of vapour present. When the pressure is reduced to p_2 , the value of $l_{\text{vap}}/l_{\text{liq}}$ is about 0.3, so $n_{\text{liq}}/n_{\text{vap}} \approx 0.3$ and the amount of liquid is about 0.3 times the amount of vapour. When the pressure has been reduced to p_3 , the sample is almost completely gaseous and because $l_{\text{vap}}/l_{\text{liq}} \approx 0$ we conclude that there is only a trace of liquid present.

6.4 Temperature–composition diagrams

To discuss distillation we need a **temperature–composition diagram**, a phase diagram in which the boundaries show the composition of the phases that are in equilibrium at various temperatures (and a given pressure, typically 1 atm). An example is shown in Fig. 6.14. Note that the liquid phase now lies in the lower part of the diagram.

(a) The distillation of mixtures

The region between the lines in Fig. 6.14 is a two-phase region where $F' = 1$. As usual, the prime indicates that one degree of freedom has been discarded; in this case, the pressure is being kept fixed, and hence at a given temperature the compositions of the phases in equilibrium are fixed. The regions outside the phase lines correspond to a single phase, so $F' = 2$, and the temperature and composition are both independently variable.

Consider what happens when a liquid of composition a_1 is heated. It boils when the temperature reaches T_2 . Then the liquid has composition a_2 (the same as a_1) and the vapour (which is present only as a trace) has composition a_2' . The vapour is richer in the more volatile component A (the component with the lower boiling point). From the location of a_2 , we can state the vapour's composition at the boiling point, and from the location of the tie line joining a_2 and a_2' we can read off the boiling temperature (T_2) of the original liquid mixture.

In a **simple distillation**, the vapour is withdrawn and condensed. This technique is used to separate a volatile liquid from a non-volatile solute or solid. In **fractional distillation**, the boiling and condensation cycle is repeated successively. This technique is used to separate volatile liquids. We can follow the changes that occur by seeing what happens when the first condensate of composition a_3 is reheated. The phase diagram shows that this mixture boils at T_3 and yields a vapour of composition a'_3 , which is even richer in the more volatile component. That vapour is drawn off, and the first drop condenses to a liquid of composition a_4 . The cycle can then be repeated until in due course almost pure A is obtained.

The efficiency of a fractionating column is expressed in terms of the number of **theoretical plates**, the number of effective vaporization and condensation steps that are required to achieve a condensate of given composition from a given distillate. Thus, to achieve the degree of separation shown in Fig. 6.15a, the fractionating column must correspond to three theoretical plates. To achieve the same separation for the system shown in Fig. 6.15b, in which the components have more similar partial pressures, the fractionating column must be designed to correspond to five theoretical plates.

(b) Azeotropes

Although many liquids have temperature–composition phase diagrams resembling the ideal version in Fig. 6.14, in a number of important cases there are marked deviations. A maximum in the phase diagram (Fig. 6.16) may occur when the favourable interactions between A and B molecules reduce the vapour pressure of the mixture below the ideal value: in effect, the A–B interactions stabilize the liquid. In such cases the excess Gibbs energy, G^E (Section 5.4), is negative (more favourable to mixing than ideal). Examples of this behaviour include trichloromethane/propanone and nitric acid/water mixtures. Phase diagrams showing a minimum (Fig. 6.17) indicate that the mixture is destabilized relative to the ideal solution, the A–B interactions then being unfavourable. For such mixtures G^E is positive (less favourable to mixing than ideal), and there may be contributions from both enthalpy and entropy effects. Examples include dioxane/water and ethanol/water mixtures.

Fig. 6.15 The number of theoretical plates is the number of steps needed to bring about a specified degree of separation of two components in a mixture. The two systems shown correspond to (a) 3, (b) 5 theoretical plates.

Fig. 6.16 A high-boiling azeotrope. When the liquid of composition a is distilled, the composition of the remaining liquid changes towards b but no further.

Fig. 6.17 A low-boiling azeotrope. When the mixture at a is fractionally distilled, the vapour in equilibrium in the fractionating column moves towards b and then remains unchanged.

Deviations from ideality are not always so strong as to lead to a maximum or minimum in the phase diagram, but when they do there are important consequences for distillation. Consider a liquid of composition a on the right of the maximum in Fig. 6.16. The vapour (at a'_2) of the boiling mixture (at a_2) is richer in A. If that vapour is removed (and condensed elsewhere), then the remaining liquid will move to a composition that is richer in B, such as that represented by a_3 , and the vapour in equilibrium with this mixture will have composition a'_3 . As that vapour is removed, the composition of the boiling liquid shifts to a point such as a_4 , and the composition of the vapour shifts to a'_4 . Hence, as evaporation proceeds, the composition of the remaining liquid shifts towards B as A is drawn off. The boiling point of the liquid rises, and the vapour becomes richer in B. When so much A has been evaporated that the liquid has reached the composition b , the vapour has the same composition as the liquid. Evaporation then occurs without change of composition. The mixture is said to form an **azeotrope**.² When the azeotropic composition has been reached, distillation cannot separate the two liquids because the condensate has the same composition as the azeotropic liquid. One example of azeotrope formation is hydrochloric acid/water, which is azeotropic at 80 per cent by mass of water and boils unchanged at 108.6°C.

The system shown in Fig. 6.17 is also azeotropic, but shows its azeotropy in a different way. Suppose we start with a mixture of composition a_1 , and follow the changes in the composition of the vapour that rises through a fractionating column (essentially a vertical glass tube packed with glass rings to give a large surface area). The mixture boils at a_2 to give a vapour of composition a'_2 . This vapour condenses in the column to a liquid of the same composition (now marked a_3). That liquid reaches equilibrium with its vapour at a'_3 , which condenses higher up the tube to give a liquid of the same composition, which we now call a_4 . The fractionation therefore shifts the vapour towards the azeotropic composition at b , but not beyond, and the azeotropic vapour emerges from the top of the column. An example is ethanol/water, which boils unchanged when the water content is 4 per cent by mass and the temperature is 78°C.

(c) Immiscible liquids

Finally we consider the distillation of two immiscible liquids, such as octane and water. At equilibrium, there is a tiny amount of A dissolved in B, and similarly a tiny amount of B dissolved in A: both liquids are saturated with the other component (Fig. 6.18a). As a result, the total vapour pressure of the mixture is close to $p = p_A^* + p_B^*$. If the temperature is raised to the value at which this total vapour pressure is equal to the atmospheric pressure, boiling commences and the dissolved substances are purged from their solution. However, this boiling results in a vigorous agitation of the mixture, so each component is kept saturated in the other component, and the purging continues as the very dilute solutions are replenished. This intimate contact is essential: two immiscible liquids heated in a container like that shown in Fig. 6.18b would not boil at the same temperature. The presence of the saturated solutions means that the 'mixture' boils at a lower temperature than either component would alone because boiling begins when the total vapour pressure reaches 1 atm, not when either vapour pressure reaches 1 atm. This distinction is the basis of **steam distillation**, which enables some heat-sensitive, water-insoluble organic compounds to be distilled at a lower temperature than their normal boiling point. The only snag is that the composition of the condensate is in proportion to the vapour pressures of the components, so oils of low volatility distil in low abundance.

Fig. 6.18 The distillation of (a) two immiscible liquids can be regarded as (b) the joint distillation of the separated components, and boiling occurs when the sum of the partial pressures equals the external pressure.

² The name comes from the Greek words for 'boiling without changing'.

6.5 Liquid–liquid phase diagrams

Now we consider temperature–composition diagrams for systems that consist of pairs of **partially miscible** liquids, which are liquids that do not mix in all proportions at all temperatures. An example is hexane and nitrobenzene. The same principles of interpretation apply as to liquid–vapour diagrams. When $P = 2$, $F' = 1$ (the prime denoting the adoption of constant pressure), and the selection of a temperature implies that the compositions of the immiscible liquid phases are fixed. When $P = 1$ (corresponding to a system in which the two liquids are fully mixed), both the temperature and the composition may be adjusted.

(a) Phase separation

Suppose a small amount of a liquid B is added to a sample of another liquid A at a temperature T' . It dissolves completely, and the binary system remains a single phase. As more B is added, a stage comes at which no more dissolves. The sample now consists of two phases in equilibrium with each other ($P = 2$), the most abundant one consisting of A saturated with B, the minor one a trace of B saturated with A. In the temperature–composition diagram drawn in Fig. 6.19, the composition of the former is represented by the point a' and that of the latter by the point a'' . The relative abundances of the two phases are given by the lever rule.

When more B is added, A dissolves in it slightly. The compositions of the two phases in equilibrium remain a' and a'' because $P = 2$ implies that $F' = 0$, and hence that the compositions of the phases are invariant at a fixed temperature and pressure. However, the amount of one phase increases at the expense of the other. A stage is reached when so much B is present that it can dissolve all the A, and the system reverts to a single phase. The addition of more B now simply dilutes the solution, and from then on it remains a single phase.

The composition of the two phases at equilibrium varies with the temperature. For hexane and nitrobenzene, raising the temperature increases their miscibility. The two-phase system therefore becomes less extensive, because each phase in equilibrium is richer in its minor component: the A-rich phase is richer in B and the B-rich phase is richer in A. We can construct the entire phase diagram by repeating the observations at different temperatures and drawing the envelope of the two-phase region.

Fig. 6.19 The temperature–composition diagram for hexane and nitrobenzene at 1 atm. The region below the curve corresponds to the compositions and temperatures at which the liquids are partially miscible. The upper critical temperature, T_{uc} , is the temperature above which the two liquids are miscible in all proportions.

Example 6.2 Interpreting a liquid–liquid phase diagram

A mixture of 50 g of hexane (0.59 mol C_6H_{14}) and 50 g of nitrobenzene (0.41 mol $C_6H_5NO_2$) was prepared at 290 K. What are the compositions of the phases, and in what proportions do they occur? To what temperature must the sample be heated in order to obtain a single phase?

Method The compositions of phases in equilibrium are given by the points where the tie-line representing the temperature intersects the phase boundary. Their proportions are given by the lever rule (eqn 6.7). The temperature at which the components are completely miscible is found by following the isopleth upwards and noting the temperature at which it enters the one-phase region of the phase diagram.

Answer We denote hexane by H and nitrobenzene by N; refer to Fig. 6.20, which is a simplified version of Fig. 6.19. The point $x_N = 0.41$, $T = 290$ K occurs in the two-phase region of the phase diagram. The horizontal tie line cuts the phase

Fig. 6.20 The temperature–composition diagram for hexane and nitrobenzene at 1 atm again, with the points and lengths discussed in the text.

Fig. 6.21 The phase diagram for palladium and palladium hydride, which has an upper critical temperature at 300°C.

Comment 6.3

This expression is an example of a *transcendental equation*, an equation that does not have a solution that can be expressed in a closed form. The solutions can be found numerically by using mathematical software or by plotting the first term against the second and identifying the points of intersection as β is changed.

Comment 6.4

The upper critical solution temperature and the lower critical solution temperature are also called the ‘upper consolute temperature’ and ‘lower consolute temperature’, respectively.

boundary at $x_N = 0.35$ and $x_N = 0.83$, so those are the compositions of the two phases. According to the lever rule, the ratio of amounts of each phase is equal to the ratio of the distances l_α and l_β :

$$\frac{n_\alpha}{n_\beta} = \frac{l_\beta}{l_\alpha} = \frac{0.83 - 0.41}{0.41 - 0.35} = \frac{0.42}{0.06} = 7$$

That is, there is about 7 times more hexane-rich phase than nitrobenzene-rich phase. Heating the sample to 292 K takes it into the single-phase region.

Because the phase diagram has been constructed experimentally, these conclusions are not based on any assumptions about ideality. They would be modified if the system were subjected to a different pressure.

Self-test 6.2 Repeat the problem for 50 g of hexane and 100 g of nitrobenzene at 273 K.
[$x_N = 0.09$ and 0.95 in ratio 1:1.3; 294 K]

(b) Critical solution temperatures

The **upper critical solution temperature**, T_{uc} , is the highest temperature at which phase separation occurs. Above the upper critical temperature the two components are fully miscible. This temperature exists because the greater thermal motion overcomes any potential energy advantage in molecules of one type being close together. One example is the nitrobenzene/hexane system shown in Fig. 6.19. An example of a solid solution is the palladium/hydrogen system, which shows two phases, one a solid solution of hydrogen in palladium and the other a palladium hydride, up to 300°C but forms a single phase at higher temperatures (Fig. 6.21).

The thermodynamic interpretation of the upper critical solution temperature focuses on the Gibbs energy of mixing and its variation with temperature. We saw in Section 5.4 that a simple model of a real solution results in a Gibbs energy of mixing that behaves as shown in Fig. 5.20. Provided the parameter β that was introduced in eqn 5.30 is greater than 2, the Gibbs energy of mixing has a double minimum (Fig. 6.22). As a result, for $\beta > 2$ we can expect phase separation to occur. The same model shows that the compositions corresponding to the minima are obtained by looking for the conditions at which $\partial\Delta_{mix}G/\partial x = 0$, and a simple manipulation of eqn 5.31 shows that we have to solve

$$\ln \frac{x}{1-x} + \beta(1-2x) = 0$$

The solutions are plotted in Fig. 6.23. We see that, as β decreases, which can be interpreted as an increase in temperature provided the intermolecular forces remain constant, then the two minima move together and merge when $\beta = 2$.

Some systems show a **lower critical solution temperature**, T_{lc} , below which they mix in all proportions and above which they form two phases. An example is water and triethylamine (Fig. 6.24). In this case, at low temperatures the two components are more miscible because they form a weak complex; at higher temperatures the complexes break up and the two components are less miscible.

Some systems have both upper and lower critical solution temperatures. They occur because, after the weak complexes have been disrupted, leading to partial miscibility, the thermal motion at higher temperatures homogenizes the mixture again, just as in the case of ordinary partially miscible liquids. The most famous example is nicotine and water, which are partially miscible between 61°C and 210°C (Fig. 6.25).

Fig. 6.22 The temperature variation of the Gibbs energy of mixing of a system that is partially miscible at low temperatures. A system of composition in the region $P = 2$ forms two phases with compositions corresponding to the two local minima of the curve. This illustration is a duplicate of Fig. 5.20.

Exploration Working from eqn 5.31, write an expression for $T_{\min}$, the temperature at which $\Delta_{\text{mix}}G$ has a minimum, as a function of β and x_A . Then, plot $T_{\min}$ against x_A for several values of β . Provide a physical interpretation for any maxima or minima that you observe in these plots.

Fig. 6.23 The location of the phase boundary as computed on the basis of the β -parameter model introduced in Section 5.4.

Exploration Using mathematical software or an electronic spreadsheet, generate the plot of β against x_A by one of two methods: (a) solve the transcendental equation $\ln \{x/(1-x)\} + \beta(1-2x) = 0$ numerically, or (b) plot the first term of the transcendental equation against the second and identify the points of intersection as β is changed.

Fig. 6.24 The temperature–composition diagram for water and triethylamine. This system shows a lower critical temperature at 292 K. The labels indicate the interpretation of the boundaries.

(c) The distillation of partially miscible liquids

Consider a pair of liquids that are partially miscible and form a low-boiling azeotrope. This combination is quite common because both properties reflect the tendency of the two kinds of molecule to avoid each other. There are two possibilities: one in which the liquids become fully miscible before they boil; the other in which boiling occurs before mixing is complete.

Figure 6.26 shows the phase diagram for two components that become fully miscible before they boil. Distillation of a mixture of composition a_1 leads to a vapour of composition b_1 , which condenses to the completely miscible single-phase solution at b_2 . Phase separation occurs only when this distillate is cooled to a point in the two-phase liquid region, such as b_3 . This description applies only to the first drop of distillate. If distillation continues, the composition of the remaining liquid changes. In the end, when the whole sample has evaporated and condensed, the composition is back to a_1 .

Figure 6.27 shows the second possibility, in which there is no upper critical solution temperature. The distillate obtained from a liquid initially of composition a_1 has composition b_3 and is a two-phase mixture. One phase has composition b'_3 and the other has composition b''_3 .

The behaviour of a system of composition represented by the isopleth e in Fig. 6.27 is interesting. A system at e_1 forms two phases, which persist (but with changing proportions) up to the boiling point at e_2 . The vapour of this mixture has the same

Fig. 6.25 The temperature–composition diagram for water and nicotine, which has both upper and lower critical temperatures. Note the high temperatures for the liquid (especially the water): the diagram corresponds to a sample under pressure.

Fig. 6.26 The temperature–composition diagram for a binary system in which the upper critical temperature is less than the boiling point at all compositions. The mixture forms a low-boiling azeotrope.

Fig. 6.27 The temperature–composition diagram for a binary system in which boiling occurs before the two liquids are fully miscible.

composition as the liquid (the liquid is an azeotrope). Similarly, condensing a vapour of composition e_3 gives a two-phase liquid of the same overall composition. At a fixed temperature, the mixture vaporizes and condenses like a single substance.

Example 6.3 Interpreting a phase diagram

State the changes that occur when a mixture of composition $x_B = 0.95$ (a_1) in Fig. 6.28 is boiled and the vapour condensed.

Method The area in which the point lies gives the number of phases; the compositions of the phases are given by the points at the intersections of the horizontal tie line with the phase boundaries; the relative abundances are given by the lever rule (eqn 6.7).

Answer The initial point is in the one-phase region. When heated it boils at 350 K (a_2) giving a vapour of composition $x_B = 0.66$ (b_1). The liquid gets richer in B, and the last drop (of pure B) evaporates at 390 K. The boiling range of the liquid is therefore 350 to 390 K. If the initial vapour is drawn off, it has a composition $x_B = 0.66$. This composition would be maintained if the sample were very large, but for a finite sample it shifts to higher values and ultimately to $x_B = 0.95$. Cooling the distillate corresponds to moving down the $x_B = 0.66$ isopleth. At 330 K, for instance, the liquid phase has composition $x_B = 0.87$, the vapour $x_B = 0.49$; their relative proportions are 1:3. At 320 K the sample consists of three phases: the vapour and two liquids. One liquid phase has composition $x_B = 0.30$; the other has composition $x_B = 0.80$ in the ratio 0.62:1. Further cooling moves the system into the two-phase region, and at 298 K the compositions are 0.20 and 0.90 in the ratio 0.82:1. As further distillate boils over, the overall composition of the distillate becomes richer in B. When the last drop has been condensed the phase composition is the same as at the beginning.

Fig. 6.28 The points of the phase diagram in Fig. 6.27 that are discussed in Example 6.3.

Self-test 6.3 Repeat the discussion, beginning at the point $x_B = 0.4$, $T = 298$ K.

6.6 Liquid–solid phase diagrams

Knowledge of the temperature–composition diagrams for solid mixtures guides the design of important industrial processes, such as the manufacture of liquid crystal displays and semiconductors. In this section, we shall consider systems where solid and liquid phases may both be present at temperatures below the boiling point.

Consider the two-component liquid of composition a_1 in Fig. 6.29. The changes that occur may be expressed as follows.

1. $a_1 \rightarrow a_2$. The system enters the two-phase region labelled ‘Liquid + B’. Pure solid B begins to come out of solution and the remaining liquid becomes richer in A.
2. $a_2 \rightarrow a_3$. More of the solid forms, and the relative amounts of the solid and liquid (which are in equilibrium) are given by the lever rule. At this stage there are roughly equal amounts of each. The liquid phase is richer in A than before (its composition is given by b_3) because some B has been deposited.
3. $a_3 \rightarrow a_4$. At the end of this step, there is less liquid than at a_3 , and its composition is given by e . This liquid now freezes to give a two-phase system of pure B and pure A.

(a) Eutectics

The isopleth at e in Fig. 6.29 corresponds to the **eutectic** composition, the mixture with the lowest melting point.³ A liquid with the eutectic composition freezes at a single temperature, without previously depositing solid A or B. A solid with the eutectic composition melts, without change of composition, at the lowest temperature of any mixture. Solutions of composition to the right of e deposit B as they cool, and solutions to the left deposit A: only the eutectic mixture (apart from pure A or pure B) solidifies at a single definite temperature ($F' = 0$ when $C = 2$ and $P = 3$) without gradually unloading one or other of the components from the liquid.

One technologically important eutectic is solder, which has mass composition of about 67 per cent tin and 33 per cent lead and melts at 183°C. The eutectic formed by 23 per cent NaCl and 77 per cent H₂O by mass melts at –21.1°C. When salt is added to ice under isothermal conditions (for example, when spread on an icy road) the mixture melts if the temperature is above –21.1°C (and the eutectic composition has been achieved). When salt is added to ice under adiabatic conditions (for example, when added to ice in a vacuum flask) the ice melts, but in doing so it absorbs heat from the rest of the mixture. The temperature of the system falls and, if enough salt is added, cooling continues down to the eutectic temperature. Eutectic formation occurs in the great majority of binary alloy systems, and is of great importance for the microstructure of solid materials. Although a eutectic solid is a two-phase system, it crystallizes out in a nearly homogeneous mixture of microcrystals. The two microcrystalline phases can be distinguished by microscopy and structural techniques such as X-ray diffraction (Chapter 20).

Thermal analysis is a very useful practical way of detecting eutectics. We can see how it is used by considering the rate of cooling down the isopleth through a_1 in Fig. 6.29. The liquid cools steadily until it reaches a_2 , when B begins to be deposited (Fig. 6.30). Cooling is now slower because the solidification of B is exothermic and retards the cooling. When the remaining liquid reaches the eutectic composition, the temperature remains constant ($F' = 0$) until the whole sample has solidified: this region of constant temperature is the eutectic halt. If the liquid has the eutectic composition e initially, the liquid cools steadily down to the freezing temperature of the eutectic,

Fig. 6.29 The temperature–composition phase diagram for two almost immiscible solids and their completely miscible liquids. Note the similarity to Fig. 6.27. The isopleth through e corresponds to the eutectic composition, the mixture with lowest melting point.

Fig. 6.30 The cooling curves for the system shown in Fig. 6.29. For isopleth a , the rate of cooling slows at a_2 because solid B deposits from solution. There is a complete halt at a_4 while the eutectic solidifies. This halt is longest for the eutectic isopleth, e . The eutectic halt shortens again for compositions beyond e (richer in A). Cooling curves are used to construct the phase diagram.

³ The name comes from the Greek words for ‘easily melted’.

Fig. 6.31 The phase diagram for a system in which A and B react to form a compound $C = AB$. This resembles two versions of Fig. 6.29 in each half of the diagram. The constituent C is a true compound, not just an equimolar mixture.

when there is a long **eutectic halt** as the entire sample solidifies (like the freezing of a pure liquid).

Monitoring the cooling curves at different overall compositions gives a clear indication of the structure of the phase diagram. The solid–liquid boundary is given by the points at which the rate of cooling changes. The longest eutectic halt gives the location of the eutectic composition and its melting temperature.

(b) Reacting systems

Many binary mixtures react to produce compounds, and technologically important examples of this behaviour include the III/V semiconductors, such as the gallium arsenide system, which forms the compound GaAs. Although three constituents are present, there are only two components because GaAs is formed from the reaction $\text{Ga} + \text{As} \rightleftharpoons \text{GaAs}$. We shall illustrate some of the principles involved with a system that forms a compound C that also forms eutectic mixtures with the species A and B (Fig. 6.31).

A system prepared by mixing an excess of B with A consists of C and unreacted B. This is a binary B, C system, which we suppose forms a eutectic. The principal change from the eutectic phase diagram in Fig. 6.29 is that the whole of the phase diagram is squeezed into the range of compositions lying between equal amounts of A and B ($x_B = 0.5$, marked C in Fig. 6.31) and pure B. The interpretation of the information in the diagram is obtained in the same way as for Fig. 6.32. The solid deposited on cooling along the isopleth a is the compound C. At temperatures below a_4 there are two solid phases, one consisting of C and the other of B. The pure compound C melts **congruently**, that is, the composition of the liquid it forms is the same as that of the solid compound.

(c) Incongruent melting

In some cases the compound C is not stable as a liquid. An example is the alloy Na_2K , which survives only as a solid (Fig. 6.32). Consider what happens as a liquid at a_1 is cooled:

1. $a_1 \rightarrow a_2$. Some solid Na is deposited, and the remaining liquid is richer in K.
2. $a_2 \rightarrow$ just below a_3 . The sample is now entirely solid, and consists of solid Na and solid Na_2K .

Fig. 6.32 The phase diagram for an actual system (sodium and potassium) like that shown in Fig. 6.35, but with two differences. One is that the compound is Na_2K , corresponding to A_2B and not AB as in that illustration. The second is that the compound exists only as the solid, not as the liquid. The transformation of the compound at its melting point is an example of incongruent melting.

Now consider the isopleth through b_1 :

1. $b_1 \rightarrow b_2$. No obvious change occurs until the phase boundary is reached at b_2 when solid Na begins to deposit.

2. $b_2 \rightarrow b_3$. Solid Na deposits, but at b_3 a reaction occurs to form Na_2K : this compound is formed by the K atoms diffusing into the solid Na.

3. b_3 . At b_3 , three phases are in mutual equilibrium: the liquid, the compound Na_2K , and solid Na. The horizontal line representing this three-phase equilibrium is called a **peritectic line**.

At this stage the liquid Na/K mixture is in equilibrium with a little solid Na_2K , but there is still no liquid compound.

4. $b_3 \rightarrow b_4$. As cooling continues, the amount of solid compound increases until at b_4 the liquid reaches its eutectic composition. It then solidifies to give a two-phase solid consisting of solid K and solid Na_2K .

If the solid is reheated, the sequence of events is reversed. No liquid Na_2K forms at any stage because it is too unstable to exist as a liquid. This behaviour is an example of **incongruent melting**, in which a compound melts into its components and does not itself form a liquid phase.

1

IMPACT ON MATERIALS SCIENCE

16.1 Liquid crystals

A *mesophase* is a phase intermediate between solid and liquid. Mesophases are of great importance in biology, for they occur as lipid bilayers and in vesicular systems. A mesophase may arise when molecules have highly non-spherical shapes, such as being long and thin (1), or disk-like (2). When the solid melts, some aspects of the long-range order characteristic of the solid may be retained, and the new phase may be a *liquid crystal*, a substance having liquid-like imperfect long-range order in at least one direction in space but positional or orientational order in at least one other direction. *Calamitic liquid crystals* (from the Greek word for reed) are made from long and thin molecules, whereas *discotic liquid crystals* are made from disk-like molecules. A

2

Fig. 6.33 The arrangement of molecules in (a) the nematic phase, (b) the smectic phase, and (c) the cholesteric phase of liquid crystals. In the cholesteric phase, the stacking of layers continues to give a helical arrangement of molecules.

thermotropic liquid crystal displays a transition to the liquid crystalline phase as the temperature is changed. A *lyotropic* liquid crystal is a solution that undergoes a transition to the liquid crystalline phase as the composition is changed.

One type of retained long-range order gives rise to a *smectic phase* (from the Greek word for soapy), in which the molecules align themselves in layers (see Fig. 6.33). Other materials, and some smectic liquid crystals at higher temperatures, lack the layered structure but retain a parallel alignment; this mesophase is called a *nematic phase* (from the Greek for thread, which refers to the observed defect structure of the phase). In the *cholesteric phase* (from the Greek for bile solid) the molecules lie in sheets at angles that change slightly between each sheet. That is, they form helical structures with a pitch that depends on the temperature. As a result, cholesteric liquid crystals diffract light and have colours that depend on the temperature. Disk-like molecules such as (2) can form nematic and *columnar* mesophases. In the latter, the aromatic rings stack one on top of the other and are separated by very small distances (less than 0.5 nm).

The optical properties of nematic liquid crystals are anisotropic, meaning that they depend on the relative orientation of the molecular assemblies with respect to the polarization of the incident beam of light. Nematic liquid crystals also respond in special ways to electric fields. Together, these unique optical and electrical properties form the basis of operation of liquid crystal displays (LCDs). In a ‘twisted nematic’ LCD, the liquid crystal is held between two flat plates about 10 μm apart. The inner surface of each plate is coated with a transparent conducting material, such as indium–tin oxide. The plates also have a surface that causes the liquid crystal to adopt a particular orientation at its interface and are typically set at 90° to each other but 270° in a ‘supertwist’ arrangement. The entire assembly is set between two polarizers, optical filters that allow light of one specific plane of polarization to pass. The incident light passes through the outer polarizer, then its plane of polarization is rotated as it passes through the twisted nematic and, depending on the setting of the second polarizer, will pass through (if that is how the second polarizer is arranged). When a potential difference is applied across the cell, the helical arrangement is lost and the plane of the light is no longer rotated and will be blocked by the second polarizer.

Although there are many liquid crystalline materials, some difficulty is often experienced in achieving a technologically useful temperature range for the existence of the mesophase. To overcome this difficulty, mixtures can be used. An example of the type of phase diagram that is then obtained is shown in Fig. 6.34. As can be seen, the mesophase exists over a wider range of temperatures than either liquid crystalline material alone.

IMPACT ON MATERIALS SCIENCE

I6.2 Ultrapurity and controlled impurity

Advances in technology have called for materials of extreme purity. For example, semiconductor devices consist of almost perfectly pure silicon or germanium doped to a precisely controlled extent. For these materials to operate successfully, the impurity level must be kept down to less than 1 ppb (1 part in 10^9 , which corresponds to 1 mg of impurity in 1 t of material, about a small grain of salt in 5 t of sugar).⁴

In the technique of *zone refining* the sample is in the form of a narrow cylinder. This cylinder is heated in a thin disk-like zone which is swept from one end of the sample to the other. The advancing liquid zone accumulates the impurities as it passes. In practice, a train of hot and cold zones are swept repeatedly from one end to the other

⁴ 1 t = 10^3 kg.

Fig. 6.34 The phase diagram at 1 atm for a binary system of two liquid crystalline materials, 4,4'-dimethoxyazobenzene (A) and 4,4'-diethoxyazobenzene (B).

Fig. 6.35 The procedure for zone refining. (a) Initially, impurities are distributed uniformly along the sample. (b) After a molten zone is passed along the rod, the impurities are more concentrated at the right. In practice, a series of molten zones are passed along the rod from left to right.

Fig. 6.36 A binary temperature–composition diagram can be used to discuss zone refining, as explained in the text.

as shown in Fig. 6.35. The zone at the end of the sample is the impurity dump: when the heater has gone by, it cools to a dirty solid which can be discarded.

The technique makes use of the non-equilibrium properties of the system. It relies on the impurities being more soluble in the molten sample than in the solid, and sweeps them up by passing a molten zone repeatedly from one end to the other along a sample. The phase diagram in Fig. 6.36 gives some insight into the process. Consider a liquid (this represents the molten zone) on the isopleth through a_1 , and let it cool without the entire sample coming to overall equilibrium. If the temperature falls to a_2 a solid of composition b_2 is deposited and the remaining liquid (the zone where the heater has moved on) is at a_2' . Cooling that liquid down an isopleth passing through a_2' deposits solid of composition b_3 and leaves liquid at a_3' . The process continues until the last drop of liquid to solidify is heavily contaminated with B. There is plenty of everyday evidence that impure liquids freeze in this way. For example, an ice cube is clear near the surface but misty in the core: the water used to make ice normally contains dissolved air; freezing proceeds from the outside, and air is accumulated in the retreating liquid phase. It cannot escape from the interior of the cube, and so when that freezes it occludes the air in a mist of tiny bubbles.

A modification of zone refining is *zone levelling*. It is used to introduce controlled amounts of impurity (for example, of indium into germanium). A sample rich in the required dopant is put at the head of the main sample, and made molten. The zone is then dragged repeatedly in alternate directions through the sample, where it deposits a uniform distribution of the impurity.

Checklist of key ideas

☐ 1. A phase is a state of matter that is uniform throughout, not only in chemical composition but also in physical state.	☐ 3. The variance F , or degree of freedom, is the number of intensive variables that can be changed independently without disturbing the number of phases in equilibrium.
☐ 2. A constituent is a chemical species (an ion or a molecule). A component is a chemically independent constituent of a system.	☐ 4. The phase rule states that $F = C - P + 2$.

- ☐ 5. Thermal analysis is a technique for detecting phase transitions that takes advantage of the effect of the enthalpy change during a first-order transition.
- ☐ 6. The vapour pressure of an ideal solution is given by $p = p_B^* + (p_A^* - p_B^*)x_A$. The composition of the vapour, $y_A = x_A p_A^* / \{p_B^* + (p_A^* - p_B^*)x_A\}$, $y_B = 1 - y_A$.
- ☐ 7. The total vapour pressure of a mixture is given by $p = p_A^* p_B^* / \{p_A^* + (p_B^* - p_A^*)y_A\}$.
- ☐ 8. An isopleth is a line of constant composition in a phase diagram. A tie line is a line joining two points representing phases in equilibrium.
- ☐ 9. The lever rule allows for the calculation of the relative amounts of two phases in equilibrium: $n_\alpha l_\alpha = n_\beta l_\beta$.
- ☐ 10. A temperature–composition diagram is a phase diagram in which the boundaries show the composition of the phases that are in equilibrium at various temperatures.
- ☐ 11. An azeotrope is a mixture that boils without change of composition.
- ☐ 12. Partially miscible liquids are liquids that do not mix in all proportions at all temperatures.
- ☐ 13. The upper critical solution temperature is the highest temperature at which phase separation occurs in a binary liquid mixture. The lower critical solution temperature is the temperature below which the components of a binary mixture mix in all proportions and above which they form two phases.
- ☐ 14. A eutectic is the mixture with the lowest melting point; a liquid with the eutectic composition freezes at a single temperature. A eutectic halt is a delay in cooling while the eutectic freezes.
- ☐ 15. Incongruent melting occurs when a compound melts into its components and does not itself form a liquid phase.

Discussion questions

- 6.1** Define the following terms: phase, constituent, component, and degree of freedom.
- 6.2** What factors determine the number of theoretical plates required to achieve a desired degree of separation in fractional distillation?
- 6.3** Draw phase diagrams for the following types of systems. Label the regions and intersections of the diagrams, stating what materials (possibly compounds or azeotropes) are present and whether they are solid liquid or gas. (a) One-component, pressure–temperature diagram, liquid density greater than that of solid. (b) Two-component, temperature–composition, solid–liquid diagram, one compound AB formed that melts congruently, negligible solid–solid solubility.
- 6.4** Draw phase diagrams for the following types of systems. Label the regions and intersections of the diagrams, stating what materials (possibly compounds or azeotropes) are present and whether they are solid liquid or gas. (a) Two-component, temperature–composition, solid–liquid diagram, one compound of formula AB_2 that melts incongruently, negligible solid–solid solubility; (b) two-component, constant temperature–composition, liquid–vapour diagram, formation of an azeotrope at $x_B = 0.333$, complete miscibility.
- 6.5** Label the regions of the phase diagram in Fig. 6.37. State what substances (if compounds give their formulas) exist in each region. Label each substance in each region as solid, liquid, or gas.
- 6.6** Label the regions of the phase diagram in Fig. 6.38. State what substances (if compounds give their formulas) exist in each region. Label each substance in each region as solid, liquid, or gas.

Fig. 6.38

Exercises

6.1(a) At 90°C, the vapour pressure of methylbenzene is 53.3 kPa and that of 1,2-dimethylbenzene is 20.0 kPa. What is the composition of a liquid mixture that boils at 90°C when the pressure is 0.50 atm? What is the composition of the vapour produced?

6.1(b) At 90°C, the vapour pressure of 1,2-dimethylbenzene is 20 kPa and that of 1,3-dimethylbenzene is 18 kPa. What is the composition of a liquid mixture that boils at 90°C when the pressure is 19 kPa? What is the composition of the vapour produced?

6.2(a) The vapour pressure of pure liquid A at 300 K is 76.7 kPa and that of pure liquid B is 52.0 kPa. These two compounds form ideal liquid and gaseous mixtures. Consider the equilibrium composition of a mixture in which the mole fraction of A in the vapour is 0.350. Calculate the total pressure of the vapour and the composition of the liquid mixture.

6.2(b) The vapour pressure of pure liquid A at 293 K is 68.8 kPa and that of pure liquid B is 82.1 kPa. These two compounds form ideal liquid and gaseous mixtures. Consider the equilibrium composition of a mixture in which the mole fraction of A in the vapour is 0.612. Calculate the total pressure of the vapour and the composition of the liquid mixture.

6.3(a) It is found that the boiling point of a binary solution of A and B with $x_A = 0.6589$ is 88°C. At this temperature the vapour pressures of pure A and B are 127.6 kPa and 50.60 kPa, respectively. (a) Is this solution ideal? (b) What is the initial composition of the vapour above the solution?

6.3(b) It is found that the boiling point of a binary solution of A and B with $x_A = 0.4217$ is 96°C. At this temperature the vapour pressures of pure A and B are 110.1 kPa and 76.5 kPa, respectively. (a) Is this solution ideal? (b) What is the initial composition of the vapour above the solution?

6.4(a) Dibromoethene (DE, $p_{DE}^* = 22.9$ kPa at 358 K) and dibromopropene (DP, $p_{DP}^* = 17.1$ kPa at 358 K) form a nearly ideal solution. If $z_{DE} = 0.60$, what is (a) p_{total} when the system is all liquid, (b) the composition of the vapour when the system is still almost all liquid?

6.4(b) Benzene and toluene form nearly ideal solutions. Consider an equimolar solution of benzene and toluene. At 20°C the vapour pressures of pure benzene and toluene are 9.9 kPa and 2.9 kPa, respectively. The solution is boiled by reducing the external pressure below the vapour pressure. Calculate (a) the pressure when boiling begins, (b) the composition of each component in the vapour, and (c) the vapour pressure when only a few drops of liquid remain. Assume that the rate of vaporization is low enough for the temperature to remain constant at 20°C.

6.5(a) The following temperature/composition data were obtained for a mixture of octane (O) and methylbenzene (M) at 1.00 atm, where x is the

mole fraction in the liquid and y the mole fraction in the vapour at equilibrium.

$\theta/^\circ\text{C}$	110.9	112.0	114.0	115.8	117.3	119.0	121.1	123.0
x_M	0.908	0.795	0.615	0.527	0.408	0.300	0.203	0.097
y_M	0.923	0.836	0.698	0.624	0.527	0.410	0.297	0.164

The boiling points are 110.6°C and 125.6°C for M and O, respectively. Plot the temperature/composition diagram for the mixture. What is the composition of the vapour in equilibrium with the liquid of composition (a) $x_M = 0.250$ and (b) $x_O = 0.250$?

6.5(b) The following temperature/composition data were obtained for a mixture of two liquids A and B at 1.00 atm, where x is the mole fraction in the liquid and y the mole fraction in the vapour at equilibrium.

$\theta/^\circ\text{C}$	125	130	135	140	145	150
x_A	0.91	0.65	0.45	0.30	0.18	0.098
y_A	0.99	0.91	0.77	0.61	0.45	0.25

The boiling points are 124°C for A and 155°C for B. Plot the temperature–composition diagram for the mixture. What is the composition of the vapour in equilibrium with the liquid of composition (a) $x_A = 0.50$ and (b) $x_B = 0.33$?

6.6(a) State the number of components in the following systems.

(a) NaH_2PO_4 in water at equilibrium with water vapour but disregarding the fact that the salt is ionized. (b) The same, but taking into account the ionization of the salt.

6.6(b) State the number of components for a system in which AlCl_3 is dissolved in water, noting that hydrolysis and precipitation of $\text{Al}(\text{OH})_3$ occur.

6.7(a) Blue $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ crystals release their water of hydration when heated. How many phases and components are present in an otherwise empty heated container?

6.7(b) Ammonium chloride, NH_4Cl , decomposes when it is heated.

(a) How many components and phases are present when the salt is heated in an otherwise empty container? (b) Now suppose that additional ammonia is also present. How many components and phases are present?

6.8(a) A saturated solution of Na_2SO_4 , with excess of the solid, is present at equilibrium with its vapour in a closed vessel. (a) How many phases and components are present. (b) What is the variance (the number of degrees of freedom) of the system? Identify the independent variables.

6.8(b) Suppose that the solution referred to in Exercise 6.8a is not saturated. (a) How many phases and components are present. (b) What is the variance (the number of degrees of freedom) of the system? Identify the independent variables.

6.9(a) Methylethyl ether (A) and diborane, B_2H_6 (B), form a compound that melts congruently at 133 K. The system exhibits two eutectics, one at 25 mol per cent B and 123 K and a second at 90 mol per cent B and 104 K. The melting points of pure A and B are 131 K and 110 K, respectively. Sketch the phase diagram for this system. Assume negligible solid–solid solubility.

6.9(b) Sketch the phase diagram of the system NH_3/N_2H_4 given that the two substances do not form a compound with each other, that NH_3 freezes at $-78^\circ C$ and N_2H_4 freezes at $+2^\circ C$, and that a eutectic is formed when the mole fraction of N_2H_4 is 0.07 and that the eutectic melts at $-80^\circ C$.

6.10(a) Figure 6.39 shows the phase diagram for two partially miscible liquids, which can be taken to be that for water (A) and 2-methyl-1-propanol (B). Describe what will be observed when a mixture of composition $x_B = 0.8$ is heated, at each stage giving the number, composition, and relative amounts of the phases present.

Fig. 6.39

6.10(b) Figure 6.40 is the phase diagram for silver and tin. Label the regions, and describe what will be observed when liquids of compositions *a* and *b* are cooled to 200 K.

Fig. 6.40

6.11(a) Indicate on the phase diagram in Fig. 6.41 the feature that denotes incongruent melting. What is the composition of the eutectic mixture and at what temperature does it melt?

6.11(b) Indicate on the phase diagram in Fig. 6.42 the feature that denotes incongruent melting. What is the composition of the eutectic mixture and at what temperature does it melt?

6.12(a) Sketch the cooling curves for the isopleths *a* and *b* in Fig. 6.41.

6.12(b) Sketch the cooling curves for the isopleths *a* and *b* in Fig. 6.42.

Fig. 6.41

Fig. 6.42

6.13(a) Use the phase diagram in Fig. 6.40 to state (a) the solubility of Ag in Sn at $800^\circ C$ and (b) the solubility of Ag_3Sn in Ag at $460^\circ C$, (c) the solubility of Ag_3Sn in Ag at $300^\circ C$.

6.13(b) Use the phase diagram in Fig. 6.41 to state (a) the solubility of B in A at $500^\circ C$ and (b) the solubility of AB_2 in A at $390^\circ C$, (c) the solubility of AB_2 in B at $300^\circ C$.

6.14(a) Figure 6.43 shows the experimentally determined phase diagrams for the nearly ideal solution of hexane and heptane. (a) Label the regions of the diagrams as to which phases are present. (b) For a solution containing 1 mol each of hexane and heptane, estimate the vapour pressure at $70^\circ C$ when vaporization on reduction of the external pressure just begins. (c) What is the vapour pressure of the solution at $70^\circ C$ when just one drop of liquid remains. (d) Estimate from the figures the mole fraction of hexane in the liquid and vapour phases for the conditions of part b. (e) What are the mole fractions for the conditions of part c? (f) At $85^\circ C$ and 760 Torr, what are the amounts of substance in the liquid and vapour phases when $z_{heptane} = 0.40$?

6.14(b) Uranium tetrafluoride and zirconium tetrafluoride melt at $1035^\circ C$ and $912^\circ C$, respectively. They form a continuous series of solid solutions with a minimum melting temperature of $765^\circ C$ and composition $x(ZrF_4) = 0.77$. At $900^\circ C$, the liquid solution of composition $x(ZrF_4) = 0.28$ is in equilibrium with a solid solution of composition $x(ZrF_4) = 0.14$. At $850^\circ C$ the two compositions are 0.87 and 0.90, respectively. Sketch the phase diagram for this system and state what is observed when a liquid of composition $x(ZrF_4) = 0.40$ is cooled slowly from $900^\circ C$ to $500^\circ C$.

6.15(a) Methane (melting point 91 K) and tetrafluoromethane (melting point 89 K) do not form solid solutions with each other, and as liquids they are only partially miscible. The upper critical temperature of the liquid mixture is 94 K at $x(CF_4) = 0.43$ and the eutectic temperature is 84 K at $x(CF_4) = 0.88$. At 86 K, the phase in equilibrium with the tetrafluoromethane-rich

Problems*

Numerical problems

6.1‡ 1-Butanol and chlorobenzene form a minimum-boiling azeotropic system. The mole fraction of 1-butanol in the liquid (x) and vapour (y) phases at 1.000 atm is given below for a variety of boiling temperatures (H. Artigas, C. Lafuente, P. Cea, F.M. Royo, and J.S. Urieta, *J. Chem. Eng. Data* **42**, 132 (1997)).

T/K	396.57	393.94	391.60	390.15	389.03	388.66	388.57
x	0.1065	0.1700	0.2646	0.3687	0.5017	0.6091	0.7171
y	0.2859	0.3691	0.4505	0.5138	0.5840	0.6409	0.7070

Pure chlorobenzene boils at 404.86 K. (a) Construct the chlorobenzene-rich portion of the phase diagram from the data. (b) Estimate the temperature at which a solution whose mole fraction of 1-butanol is 0.300 begins to boil. (c) State the compositions and relative proportions of the two phases present after a solution initially 0.300 1-butanol is heated to 393.94 K.

6.2‡ An *et al.* investigated the liquid–liquid coexistence curve of *N,N*-dimethylacetamide and heptane (X. An, H. Zhao, F. Fuguo, and W. Shen, *J. Chem. Thermodynamics* **28**, 1221 (1996)). Mole fractions of *N,N*-dimethylacetamide in the upper (x_1) and lower (x_2) phases of a two-phase region are given below as a function of temperature:

T/K	309.820	309.422	309.031	308.006	306.686
x_1	0.473	0.400	0.371	0.326	0.293
x_2	0.529	0.601	0.625	0.657	0.690
T/K	304.553	301.803	299.097	296.000	294.534
x_1	0.255	0.218	0.193	0.168	0.157
x_2	0.724	0.758	0.783	0.804	0.814

solution changes from solid methane to a methane-rich liquid. At that temperature, the two liquid solutions that are in mutual equilibrium have the compositions $x(\text{CF}_4) = 0.10$ and $x(\text{CF}_4) = 0.80$. Sketch the phase diagram.

6.15(b) Describe the phase changes that take place when a liquid mixture of 4.0 mol B_2H_6 (melting point 131 K) and 1.0 mol CH_3OCH_3 (melting point 135 K) is cooled from 140 K to 90 K. These substances form a compound $(\text{CH}_3)_2\text{OB}_2\text{H}_6$ that melts congruently at 133 K. The system exhibits one eutectic at $x(\text{B}_2\text{H}_6) = 0.25$ and 123 K and another at $x(\text{B}_2\text{H}_6) = 0.90$ and 104 K.

6.16(a) Refer to the information in Exercise 6.15(b) and sketch the cooling curves for liquid mixtures in which $x(\text{B}_2\text{H}_6)$ is (a) 0.10, (b) 0.30, (c) 0.50, (d) 0.80, and (e) 0.95.

6.16(b) Refer to the information in Exercise 6.15(a) and sketch the cooling curves for liquid mixtures in which $x(\text{CF}_4)$ is (a) 0.10, (b) 0.30, (c) 0.50, (d) 0.80, and (e) 0.95.

6.17(a) Hexane and perfluorohexane show partial miscibility below 22.70°C. The critical concentration at the upper critical temperature is $x = 0.355$, where x is the mole fraction of C_6F_{14} . At 22.0°C the two solutions in equilibrium have $x = 0.24$ and $x = 0.48$, respectively, and at 21.5°C the mole fractions are 0.22 and 0.51. Sketch the phase diagram. Describe the phase changes that occur when perfluorohexane is added to a fixed amount of hexane at (a) 23°C, (b) 22°C.

6.17(b) Two liquids, A and B, show partial miscibility below 52.4°C. The critical concentration at the upper critical temperature is $x = 0.459$, where x is the mole fraction of A. At 40.0°C the two solutions in equilibrium have $x = 0.22$ and $x = 0.60$, respectively, and at 42.5°C the mole fractions are 0.24 and 0.48. Sketch the phase diagram. Describe the phase changes that occur when B is added to a fixed amount of A at (a) 48°C, (b) 52.4°C.

(a) Plot the phase diagram. (b) State the proportions and compositions of the two phases that form from mixing 0.750 mol of *N,N*-dimethylacetamide with 0.250 mol of heptane at 296.0 K. To what temperature must the mixture be heated to form a single-phase mixture?

6.3‡ The following data have been obtained for the liquid–vapour equilibrium compositions of mixtures of nitrogen and oxygen at 100 kPa.

T/K	77.3	78	80	82	84	86	88	90.2
$x(\text{O}_2)$	0	10	34	54	70	82	92	100
$y(\text{O}_2)$	0	2	11	22	35	52	73	100
$p^*(\text{O}_2)/\text{Torr}$	154	171	225	294	377	479	601	760

Plot the data on a temperature–composition diagram and determine the extent to which it fits the predictions for an ideal solution by calculating the activity coefficients of O_2 at each composition.

6.4 Phosphorus and sulfur form a series of binary compounds. The best characterized are P_4S_3 , P_4S_7 , and P_4S_{10} , all of which melt congruently. Assuming that only these three binary compounds of the two elements exist, (a) draw schematically only the P/S phase diagram. Label each region of the diagram with the substance that exists in that region and indicate its phase. Label the horizontal axis as x_s and give the numerical values of x_s that correspond to the compounds. The melting point of pure phosphorus is 44°C and that of pure sulfur is 119°C. (b) Draw, schematically, the cooling curve for a mixture of composition $x_s = 0.28$. Assume that a eutectic occurs at $x_s = 0.2$ and negligible solid–solid solubility.

6.5 The table below gives the break and halt temperatures found in the cooling curves of two metals A and B. Construct a phase diagram consistent

* Problems denoted with the symbol ‡ were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

with the data of these curves. Label the regions of the diagram, stating what phases and substances are present. Give the probable formulas of any compounds that form.

$100x_B$	$\theta_{\text{break}}/^{\circ}\text{C}$	$\theta_{\text{halt},1}/^{\circ}\text{C}$	$\theta_{\text{halt},2}/^{\circ}\text{C}$
0		1100

70.0	550	400	
80.0		400	
90.0	450	400	
100.0		500	

6.6 Consider the phase diagram in Fig. 6.44, which represents a solid–liquid equilibrium. Label all regions of the diagram according to the chemical species that exist in that region and their phases. Indicate the number of species and phases present at the points labelled *b*, *d*, *e*, *f*, *g*, and *k*. Sketch cooling curves for compositions $x_B = 0.16$, 0.23 , 0.57 , 0.67 , and 0.84 .

Fig. 6.44

6.7 Sketch the phase diagram for the Mg/Cu system using the following information: $\theta_f(\text{Mg}) = 648^{\circ}\text{C}$, $\theta_f(\text{Cu}) = 1085^{\circ}\text{C}$; two intermetallic compounds are formed with $\theta_f(\text{MgCu}_2) = 800^{\circ}\text{C}$ and $\theta_f(\text{Mg}_2\text{Cu}) = 580^{\circ}\text{C}$; eutectics of mass percentage Mg composition and melting points 10 per cent (690°C), 33 per cent (560°C), and 65 per cent (380°C). A sample of Mg/Cu alloy containing 25 per cent Mg by mass was prepared in a crucible heated to 800°C in an inert atmosphere. Describe what will be observed if the melt is cooled slowly to room temperature. Specify the composition and relative abundances of the phases and sketch the cooling curve.

6.8† Figure 6.45 shows $\Delta_{\text{mix}}G(x_{\text{pb}}, T)$ for a mixture of copper and lead. (a) What does the graph reveal about the miscibility of copper and lead and the spontaneity of solution formation? What is the variance (*F*) at (i) 1500 K, (ii) 1100 K? (b) Suppose that at 1500 K a mixture of composition (i) $x_{\text{pb}} = 0.1$, (ii) $x_{\text{pb}} = 0.7$, is slowly cooled to 1100 K. What is the equilibrium composition of the final mixture? Include an estimate of the relative amounts of each phase. (c) What is the solubility of (i) lead in copper, (ii) copper in lead at 1100 K?

6.9† The temperature–composition diagram for the Ca/Si binary system is shown in Fig. 6.46. (a) Identify eutectics, congruent melting compounds, and incongruent melting compounds. (b) If a 20 per cent by atom composition melt of silicon at 1500°C is cooled to 1000°C , what phases (and phase composition) would be at equilibrium? Estimate the relative amounts of each phase. (c) Describe the equilibrium phases observed when an 80 per cent by

Fig. 6.45

Fig. 6.46

atom composition Si melt is cooled to 1030°C . What phases, and relative amounts, would be at equilibrium at a temperature (i) slightly higher than 1030°C , (ii) slightly lower than 1030°C ? Draw a graph of the mole percentages of both Si(s) and $\text{CaSi}_2(\text{s})$ as a function of mole percentage of melt that is freezing at 1030°C .

6.10 Iron(II) chloride (melting point 677°C) and potassium chloride (melting point 776°C) form the compounds KFeCl_3 and K_2FeCl_4 at elevated temperatures. KFeCl_3 melts congruently at 380°C and K_2FeCl_4 melts incongruently at 399°C . Eutectics are formed with compositions $x = 0.38$ (melting point 351°C) and $x = 0.54$ (melting point 393°C), where x is the mole fraction of FeCl_2 . The KCl solubility curve intersects the K_2FeCl_4 curve at $x = 0.34$. Sketch the phase diagram. State the phases that are in equilibrium when a mixture of composition $x = 0.36$ is cooled from 400°C to 300°C .

Theoretical problems

6.11 Show that two phases are in thermal equilibrium only if their temperatures are the same.

6.12 Show that two phases are in mechanical equilibrium only if their pressures are equal.

Applications: to biology, materials science, and chemical engineering

6.13 The unfolding, or *denaturation*, of a biological macromolecule may be brought about by treatment with substances, called *denaturants*, that disrupt the intermolecular interactions responsible for the native three-dimensional conformation of the polymer. For example, urea, $\text{CO}(\text{NH}_2)_2$, competes for NH and CO groups and interferes with hydrogen bonding in a polypeptide.

Fig. 6.47

In a theoretical study of a protein, the temperature–composition diagram shown in Fig. 6.47 was obtained. It shows three structural regions: the native form, the unfolded form, and a ‘molten globule’ form, a partially unfolded but still compact form of the protein. (i) Is the molten globule form ever stable when the denaturant concentration is below 0.1? (ii) Describe what happens to the polymer as the native form is heated in the presence of denaturant at concentration 0.15.

6.14 The basic structural element of a membrane is a phospholipid, such as phosphatidyl choline, which contains long hydrocarbon chains (typically in the range C_{14} – C_{24}) and a variety of polar groups, such as $-\text{CH}_2\text{CH}_2\text{N}(\text{CH}_3)_3^+$. The hydrophobic chains stack together to form an extensive bilayer about 5 nm across, leaving the polar groups exposed to the aqueous environment on either side of the membrane (see Chapter 19 for details). All lipid bilayers undergo a transition from a state of low chain mobility (the *gel* form) to high chain mobility (the *liquid crystal* form) at a temperature that depends on the structure of the lipid. Biological cell membranes exist as liquid crystals at physiological temperatures. In an experimental study of membrane-like assemblies, a phase diagram like that shown in Fig. 6.48 was obtained. The two components are dielaidoylphosphatidylcholine (DEL) and dipalmitoylphosphatidylcholine (DPL). Explain what happens as a liquid mixture of composition $x_{\text{DEL}} = 0.5$ is cooled from 45°C.

Fig. 6.48

6.15 The compound *p*-azoxyanisole forms a liquid crystal. 5.0 g of the solid was placed in a tube, which was then evacuated and sealed. Use the phase rule to prove that the solid will melt at a definite temperature and that the liquid

crystal phase will make a transition to a normal liquid phase at a definite temperature.

6.16 Some polymers can form liquid crystal mesophases with unusual physical properties. For example, liquid crystalline Kevlar (3) is strong enough to be the material of choice for bulletproof vests and is stable at temperatures up to 600 K. What molecular interactions contribute to the formation, thermal stability, and mechanical strength of liquid crystal mesophases in Kevlar?

3

6.17 Use a phase diagram like that shown in Fig. 6.36 to indicate how zone levelling may be described.

6.18 The technique of *float zoning*, which is similar to zone refining (Impact I6.2), has produced very pure samples of silicon for use in the semiconductor industry. Consult a textbook of materials science or metallurgy and prepare a discussion of the principles, advantages, and disadvantages of float zoning.

6.19 Magnesium oxide and nickel oxide withstand high temperatures. However, they do melt when the temperature is high enough and the behaviour of mixtures of the two is of considerable interest to the ceramics industry. Draw the temperature–composition diagram for the system using the data below, where x is the mole fraction of MgO in the solid and y its mole fraction in the liquid.

$\theta/^\circ\text{C}$	1960	2200	2400	2600	2800
x	0	0.35	0.60	0.83	1.00
y	0	0.18	0.38	0.65	1.00

State (a) the melting point of a mixture with $x = 0.30$, (b) the composition and proportion of the phases present when a solid of composition $x = 0.30$ is heated to 2200°C, (c) the temperature at which a liquid of composition $y = 0.70$ will begin to solidify.

6.20 The bismuth–cadmium phase diagram is of interest in metallurgy, and its general form can be estimated from expressions for the depression of freezing point. Construct the diagram using the following data: $T_f(\text{Bi}) = 544.5 \text{ K}$, $T_f(\text{Cd}) = 594 \text{ K}$, $\Delta_{\text{fus}}H(\text{Bi}) = 10.88 \text{ kJ mol}^{-1}$, $\Delta_{\text{fus}}H(\text{Cd}) = 6.07 \text{ kJ mol}^{-1}$. The metals are mutually insoluble as solids. Use the phase diagram to state what would be observed when a liquid of composition $x(\text{Bi}) = 0.70$ is cooled slowly from 550 K. What are the relative abundances of the liquid and solid at (a) 460 K and (b) 350 K? Sketch the cooling curve for the mixture.

6.21† Carbon dioxide at high pressure is used to separate various compounds in citrus oil. The mole fraction of CO_2 in the liquid (x) and vapour (y) at 323.2 K is given below for a variety of pressures (Y. Iwai, T. Morotomi, K. Sakamoto, Y. Koga, and Y. Arai, *J. Chem. Eng. Data* **41**, 951 (1996)).

p/MPa	3.94	6.02	7.97	8.94	9.27
x	0.2873	0.4541	0.6650	0.7744	0.8338
y	0.9982	0.9980	0.9973	0.9958	0.9922

(a) Plot the portion of the phase diagram represented by these data. (b) State the compositions and relative proportions of the two phases present after an equimolar gas mixture is compressed to 6.02 MPa at 323.2 K.

Problems

This chapter develops the concept of chemical potential and shows how it is used to account for the equilibrium composition of chemical reactions. The equilibrium composition corresponds to a minimum in the Gibbs energy plotted against the extent of reaction, and by locating this minimum we establish the relation between the equilibrium constant and the standard Gibbs energy of reaction. The thermodynamic formulation of equilibrium enables us to establish the quantitative effects of changes in the conditions. The principles of thermodynamics established in the preceding chapters can be applied to the description of the thermodynamic properties of reactions that take place in electrochemical cells, in which, as the reaction proceeds, it drives electrons through an external circuit. Thermodynamic arguments can be used to derive an expression for the electric potential of such cells and the potential can be related to their composition. There are two major topics developed in this connection. One is the definition and tabulation of standard potentials; the second is the use of these standard potentials to predict the equilibrium constants and other thermodynamic properties of chemical reactions.

Chemical reactions tend to move towards a dynamic equilibrium in which both reactants and products are present but have no further tendency to undergo net change. In some cases, the concentration of products in the equilibrium mixture is so much greater than that of the unchanged reactants that for all practical purposes the reaction is 'complete'. However, in many important cases the equilibrium mixture has significant concentrations of both reactants and products. In this chapter we see how to use thermodynamics to predict the equilibrium composition under any reaction conditions. Because many reactions of ions involve the transfer of electrons, they can be studied (and utilized) by allowing them to take place in an electrochemical cell. Measurements like those described in this chapter provide data that are very useful for discussing the characteristics of electrolyte solutions and of ionic equilibria in solution.

Spontaneous chemical reactions

We have seen that the direction of spontaneous change at constant temperature and pressure is towards lower values of the Gibbs energy, G . The idea is entirely general, and in this chapter we apply it to the discussion of chemical reactions.

7.1 The Gibbs energy minimum

We locate the equilibrium composition of a reaction mixture by calculating the Gibbs energy of the reaction mixture and identifying the composition that corresponds to minimum G .

(a) The reaction Gibbs energy

Consider the equilibrium $A \rightleftharpoons B$. Even though this reaction looks trivial, there are many examples of it, such as the isomerization of pentane to 2-methylbutane and the conversion of L-alanine to D-alanine. Suppose an infinitesimal amount $d\xi$ of A turns into B, then the change in the amount of A present is $dn_A = -d\xi$ and the change in the amount of B present is $dn_B = +d\xi$. The quantity ξ (xi) is called the **extent of reaction**; it has the dimensions of amount of substance and is reported in moles. When the extent of reaction changes by a finite amount $\Delta\xi$, the amount of A present changes from $n_{A,0}$ to $n_{A,0} - \Delta\xi$ and the amount of B changes from $n_{B,0}$ to $n_{B,0} + \Delta\xi$. So, if initially 2.0 mol A is present and we wait until $\Delta\xi = +1.5$ mol, then the amount of A remaining will be 0.5 mol.

The **reaction Gibbs energy**, $\Delta_r G$, is defined as the slope of the graph of the Gibbs energy plotted against the extent of reaction:

$$\Delta_r G = \left(\frac{\partial G}{\partial \xi} \right)_{p,T} \quad [7.1]$$

Although Δ normally signifies a *difference* in values, here Δ_r signifies a *derivative*, the slope of G with respect to ξ . However, to see that there is a close relationship with the normal usage, suppose the reaction advances by $d\xi$. The corresponding change in Gibbs energy is

$$dG = \mu_A dn_A + \mu_B dn_B = -\mu_A d\xi + \mu_B d\xi = (\mu_B - \mu_A) d\xi$$

This equation can be reorganized into

$$\left(\frac{\partial G}{\partial \xi} \right)_{p,T} = \mu_B - \mu_A$$

That is,

$$\Delta_r G = \mu_B - \mu_A \quad (7.2)$$

We see that $\Delta_r G$ can also be interpreted as the difference between the chemical potentials (the partial molar Gibbs energies) of the reactants and products *at the composition of the reaction mixture*.

Because chemical potential varies with composition, the slope of the plot of Gibbs energy against extent of reaction changes as the reaction proceeds. Moreover, because the reaction runs in the direction of decreasing G (that is, down the slope of G plotted against ξ), we see from eqn 7.2 that the reaction $A \rightarrow B$ is spontaneous when $\mu_A > \mu_B$, whereas the reverse reaction is spontaneous when $\mu_B > \mu_A$. The slope is zero, and the reaction is spontaneous in neither direction, when

$$\Delta_r G = 0 \quad (7.3)$$

This condition occurs when $\mu_B = \mu_A$ (Fig. 7.1). It follows that, if we can find the composition of the reaction mixture that ensures $\mu_B = \mu_A$, then we can identify the composition of the reaction mixture at equilibrium.

(b) Exergonic and endergonic reactions

We can express the spontaneity of a reaction at constant temperature and pressure in terms of the reaction Gibbs energy:

If $\Delta_r G < 0$, the forward reaction is spontaneous.

If $\Delta_r G > 0$, the reverse reaction is spontaneous.

If $\Delta_r G = 0$, the reaction is at equilibrium.

Fig. 7.1 As the reaction advances (represented by motion from left to right along the horizontal axis) the slope of the Gibbs energy changes. Equilibrium corresponds to zero slope, at the foot of the valley.

Fig. 7.2 If two weights are coupled as shown here, then the heavier weight will move the lighter weight in its non-spontaneous direction: overall, the process is still spontaneous. The weights are the analogues of two chemical reactions: a reaction with a large negative ΔG can force another reaction with a less ΔG to run in its non-spontaneous direction.

Comment 7.1

Note that in the definition of $\Delta_r G^\circ$, the Δ_r has its normal meaning as a difference whereas in the definition of $\Delta_r G$ the Δ_r signifies a derivative.

A reaction for which $\Delta_r G < 0$ is called **exergonic** (from the Greek words for work producing). The name signifies that, because the process is spontaneous, it can be used to drive another process, such as another reaction, or used to do non-expansion work. A simple mechanical analogy is a pair of weights joined by a string (Fig. 7.2): the lighter of the pair of weights will be pulled up as the heavier weight falls down. Although the lighter weight has a natural tendency to move downward, its coupling to the heavier weight results in it being raised. In biological cells, the oxidation of carbohydrates act as the heavy weight that drives other reactions forward and results in the formation of proteins from amino acids, muscle contraction, and brain activity. A reaction for which $\Delta_r G > 0$ is called **endergonic** (signifying work consuming). The reaction can be made to occur only by doing work on it, such as electrolysis of water to reverse its spontaneous formation reaction. Reactions at equilibrium are spontaneous in neither direction: they are neither exergonic nor endergonic.

7.2 The description of equilibrium

With the background established, we are now ready to see how to apply thermodynamics to the description of chemical equilibrium.

(a) Perfect gas equilibria

When A and B are perfect gases we can use eqn 5.14 ($\mu = \mu^\circ + RT \ln p$, with p interpreted as p/p°) to write

$$\begin{aligned}\Delta_r G &= \mu_B - \mu_A = (\mu_B^\circ + RT \ln p_B) - (\mu_A^\circ + RT \ln p_A) \\ &= \Delta_r G^\circ + RT \ln \frac{p_B}{p_A}\end{aligned}\quad (7.4)^\circ$$

If we denote the ratio of partial pressures by Q , we obtain

$$\Delta_r G = \Delta_r G^\circ + RT \ln Q \quad Q = \frac{p_B}{p_A} \quad (7.5)^\circ$$

The ratio Q is an example of a **reaction quotient**. It ranges from 0 when $p_B = 0$ (corresponding to pure A) to infinity when $p_A = 0$ (corresponding to pure B). The **standard reaction Gibbs energy**, $\Delta_r G^\circ$, is defined (like the standard reaction enthalpy) as the difference in the standard molar Gibbs energies of the reactants and products. For our reaction

$$\Delta_r G^\circ = G_{B,m}^\circ - G_{A,m}^\circ = \mu_B^\circ - \mu_A^\circ \quad (7.6)$$

In Section 3.6 we saw that the difference in standard molar Gibbs energies of the products and reactants is equal to the difference in their standard Gibbs energies of formation, so in practice we calculate $\Delta_r G^\circ$ from

$$\Delta_r G^\circ = \Delta_f G^\circ(B) - \Delta_f G^\circ(A) \quad (7.7)$$

At equilibrium $\Delta_r G = 0$. The ratio of partial pressures at equilibrium is denoted K , and eqn 7.5 becomes

$$0 = \Delta_r G^\circ + RT \ln K$$

This expression rearranges to

$$RT \ln K = -\Delta_r G^\circ \quad K = \left(\frac{p_B}{p_A} \right)_{\text{equilibrium}} \quad (7.8)^\circ$$

This relation is a special case of one of the most important equations in chemical thermodynamics: it is the link between tables of thermodynamic data, such as those in the *Data section* at the end of this volume, and the chemically important **equilibrium constant**, K .

Molecular interpretation 7.1 The approach to equilibrium

In molecular terms, the minimum in the Gibbs energy, which corresponds to $\Delta_r G = 0$, stems from the Gibbs energy of mixing of the two gases. Hence, an important contribution to the position of chemical equilibrium is the mixing of the products with the reactants as the products are formed.

Consider a hypothetical reaction in which A molecules change into B molecules without mingling together. The Gibbs energy of the system changes from $G^\circ(A)$ to $G^\circ(B)$ in proportion to the amount of B that had been formed, and the slope of the plot of G against the extent of reaction is a constant and equal to $\Delta_r G^\circ$ at all stages of the reaction (Fig. 7.3). There is no intermediate minimum in the graph. However, in fact, the newly produced B molecules do mix with the surviving A molecules. We have seen that the contribution of a mixing process to the change in Gibbs energy is given by eqn 5.27 ($\Delta_{\text{mix}} G = nRT(x_A \ln x_A + x_B \ln x_B)$). This expression makes a U-shaped contribution to the total change in Gibbs energy. As can be seen from Fig. 7.3, there is now an intermediate minimum in the Gibbs energy, and its position corresponds to the equilibrium composition of the reaction mixture.

We see from eqn 7.8 that, when $\Delta_r G^\circ > 0$, the equilibrium constant $K < 1$. Therefore, at equilibrium the partial pressure of A exceeds that of B , which means that the reactant A is favoured in the equilibrium. When $\Delta_r G^\circ < 0$, the equilibrium constant $K > 1$, so at equilibrium the partial pressure of B exceeds that of A . Now the product B is favoured in the equilibrium.

(b) The general case of a reaction

We can easily extend the argument that led to eqn 7.8 to a general reaction. First, we need to generalize the concept of extent of reaction.

Consider the reaction $2A + B \rightarrow 3C + D$. A more sophisticated way of expressing the chemical equation is to write it in the symbolic form

$$0 = 3C + D - 2A - B$$

by subtracting the reactants from both sides (and replacing the arrow by an equals sign). This equation has the form

$$0 = \sum_J \nu_J J \quad (7.9)$$

where J denotes the substances and the ν_J are the corresponding **stoichiometric numbers** in the chemical equation. In our example, these numbers have the values $\nu_A = -2$, $\nu_B = -1$, $\nu_C = +3$, and $\nu_D = +1$. A stoichiometric number is positive for products and negative for reactants. Then we define ξ so that, if it changes by $\Delta\xi$, then the change in the amount of any species J is $\nu_J \Delta\xi$.

Fig. 7.3 If the mixing of reactants and products is ignored, then the Gibbs energy changes linearly from its initial value (pure reactants) to its final value (pure products) and the slope of the line is $\Delta_r G^\circ$. However, as products are produced, there is a further contribution to the Gibbs energy arising from their mixing (lowest curve). The sum of the two contributions has a minimum. That minimum corresponds to the equilibrium composition of the system.

Illustration 7.1 Identifying stoichiometric numbers

To express the equation

in the notation of eqn 7.9, we rearrange it to

and then identify the stoichiometric numbers as $\nu_{\text{N}_2} = -1$, $\nu_{\text{H}_2} = -3$, and $\nu_{\text{NH}_3} = +2$. Therefore, if initially there is 10 mol N_2 present, then when the extent of reaction changes from $\xi = 0$ to $\xi = 1$ mol, implying that $\Delta\xi = +1$ mol, the amount of N_2 changes from 10 mol to 9 mol. All the N_2 has been consumed when $\xi = 10$ mol. When $\Delta\xi = +1$ mol, the amount of H_2 changes by $-3 \times (1 \text{ mol}) = -3$ mol and the amount of NH_3 changes by $+2 \times (1 \text{ mol}) = +2$ mol.

A note on good practice Stoichiometric *numbers* may be positive or negative; stoichiometric *coefficients* are always positive. Few, however, make the distinction between the two types of quantity.

The reaction Gibbs energy, $\Delta_r G$, is defined in the same way as before, eqn 7.1. In the *Justification* below, we show that the Gibbs energy of reaction can always be written

$$\Delta_r G = \Delta_r G^\ominus + RT \ln Q \quad (7.11)$$

with the standard reaction Gibbs energy calculated from

$$\Delta_r G^\ominus = \sum_{\text{Products}} \nu \Delta_f G^\ominus - \sum_{\text{Reactants}} \nu \Delta_f G^\ominus \quad (7.12a)$$

or, more formally,

$$\Delta_r G^\ominus = \sum_j \nu_j \Delta_f G^\ominus(\text{J}) \quad (7.12b)$$

The reaction quotient, Q , has the form

$$Q = \frac{\text{activities of products}}{\text{activities of reactants}} \quad (7.13a)$$

with each species raised to the power given by its stoichiometric coefficient. More formally, to write the general expression for Q we introduce the symbol Π to denote the product of what follows it (just as Σ denotes the sum), and define Q as

$$Q = \prod_j a_j^{\nu_j} \quad [7.13b]$$

Because reactants have negative stoichiometric numbers, they automatically appear as the denominator when the product is written out explicitly. Recall from Table 5.3 that, for pure solids and liquids, the activity is 1, so such substances make no contribution to Q even though they may appear in the chemical equation.

Illustration 7.2 Writing a reaction quotient

Consider the reaction $2 \text{A} + 3 \text{B} \rightarrow \text{C} + 2 \text{D}$, in which case $\nu_{\text{A}} = -2$, $\nu_{\text{B}} = -3$, $\nu_{\text{C}} = +1$, and $\nu_{\text{D}} = +2$. The reaction quotient is then

$$Q = a_{\text{A}}^{-2} a_{\text{B}}^{-3} a_{\text{C}} a_{\text{D}}^2 = \frac{a_{\text{C}} a_{\text{D}}^2}{a_{\text{A}}^2 a_{\text{B}}^3}$$

Justification 7.1 *The dependence of the reaction Gibbs energy on the reaction quotient*

Consider the reaction with stoichiometric numbers ν_j . When the reaction advances by $d\xi$, the amounts of reactants and products change by $dn_j = \nu_j d\xi$. The resulting infinitesimal change in the Gibbs energy at constant temperature and pressure is

$$dG = \sum_j \mu_j dn_j = \sum_j \mu_j \nu_j d\xi = \left(\sum_j \nu_j \mu_j \right) d\xi \quad (7.14)$$

It follows that

$$\Delta_r G = \left(\frac{\partial G}{\partial \xi} \right)_{p,T} = \sum_j \nu_j \mu_j \quad (7.15)$$

To make further progress, we note that the chemical potential of a species J is related to its activity by eqn 5.25 ($\mu_j = \mu_j^\circ + RT \ln a_j$). When this expression is substituted into eqn 7.15 we obtain

$$\begin{aligned} \Delta_r G &= \overbrace{\sum_j \nu_j \mu_j^\circ}^{\Delta_r G^\circ} + RT \sum_j \nu_j \ln a_j \\ &= \Delta_r G^\circ + RT \sum_j \ln a_j^{\nu_j} = \Delta_r G^\circ + RT \ln \overbrace{\prod_j a_j^{\nu_j}}^Q \\ &= \Delta_r G^\circ + RT \ln Q \end{aligned}$$

with Q given by eqn 7.13b.

Comment 7.2

Recall that $a \ln x = \ln x^a$ and $\ln x + \ln y$

$$+ \cdots = \ln xy \cdots, \text{ so } \sum_i \ln x_i = \ln \left(\prod_i x_i \right).$$

Now we conclude the argument based on eqn 7.11. At equilibrium, the slope of G is zero: $\Delta_r G = 0$. The activities then have their equilibrium values and we can write

$$K = \left(\prod_j a_j^{\nu_j} \right)_{\text{equilibrium}} \quad [7.16]$$

This expression has the same form as Q , eqn 7.13, but is evaluated using equilibrium activities. From now on, we shall not write the ‘equilibrium’ subscript explicitly, and will rely on the context to make it clear that for K we use equilibrium values and for Q we use the values at the specified stage of the reaction.

An equilibrium constant K expressed in terms of activities (or fugacities) is called a **thermodynamic equilibrium constant**. Note that, because activities are dimensionless numbers, the thermodynamic equilibrium constant is also dimensionless. In elementary applications, the activities that occur in eqn 7.16 are often replaced by the numerical values of molalities (that is, by replacing a_j by b_j/b° , where $b^\circ = 1 \text{ mol kg}^{-1}$), molar concentrations (that is, as $[J]/c^\circ$, where $c^\circ = 1 \text{ mol dm}^{-3}$), or the numerical values of partial pressures (that is, by p_j/p° , where $p^\circ = 1 \text{ bar}$). In such cases, the resulting expressions are only approximations. The approximation is particularly severe for electrolyte solutions, for in them activity coefficients differ from 1 even in very dilute solutions (Section 5.9).

Illustration 7.3 Writing an equilibrium constant.

The equilibrium constant for the heterogeneous equilibrium $\text{CaCO}_3(\text{s}) \rightleftharpoons \text{CaO}(\text{s}) + \text{CO}_2(\text{g})$ is

$$K = a_{\text{CaCO}_3(\text{s})}^{-1} a_{\text{CaO}(\text{s})} a_{\text{CO}_2(\text{g})} = \frac{\overbrace{a_{\text{CaO}(\text{s})} a_{\text{CO}_2(\text{g})}}^1}{\underbrace{a_{\text{CaCO}_3(\text{s})}}_1} = a_{\text{CO}_2}$$

(Table 5.3). Provided the carbon dioxide can be treated as a perfect gas, we can go on to write

$$K \approx p_{\text{CO}_2}/p^\ominus$$

and conclude that in this case the equilibrium constant is the numerical value of the decomposition vapour pressure of calcium carbonate.

Comment 7.3

In Chapter 17 we shall see that the right-hand side of eqn 7.17 may be expressed in terms of spectroscopic data for gas-phase species; so this expression also provides a link between spectroscopy and equilibrium composition.

At this point we set $\Delta_r G = 0$ in eqn 7.11 and replace Q by K . We immediately obtain

$$RT \ln K = -\Delta_r G^\ominus \quad (7.17)$$

This is an exact and highly important thermodynamic relation, for it enables us to predict the equilibrium constant of any reaction from tables of thermodynamic data, and hence to predict the equilibrium composition of the reaction mixture.

Example 7.1 Calculating an equilibrium constant

Calculate the equilibrium constant for the ammonia synthesis reaction, eqn 7.10, at 298 K and show how K is related to the partial pressures of the species at equilibrium when the overall pressure is low enough for the gases to be treated as perfect.

Method Calculate the standard reaction Gibbs energy from eqn 7.12 and convert it to the value of the equilibrium constant by using eqn 7.17. The expression for the equilibrium constant is obtained from eqn 7.16, and because the gases are taken to be perfect, we replace each activity by the ratio $p/p^\ominus$, where p is a partial pressure.

Answer The standard Gibbs energy of the reaction is

$$\begin{aligned} \Delta_r G^\ominus &= 2\Delta_f G^\ominus(\text{NH}_3, \text{g}) - \{\Delta_f G^\ominus(\text{N}_2, \text{g}) + 3\Delta_f G^\ominus(\text{H}_2, \text{g})\} \\ &= 2\Delta_f G^\ominus(\text{NH}_3, \text{g}) = 2 \times (-16.5 \text{ kJ mol}^{-1}) \end{aligned}$$

Then,

$$\ln K = -\frac{2 \times (-16.5 \times 10^3 \text{ J mol}^{-1})}{(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})} = \frac{2 \times 16.5 \times 10^3}{8.3145 \times 298}$$

Hence, $K = 6.1 \times 10^5$. This result is thermodynamically exact. The thermodynamic equilibrium constant for the reaction is

$$K = \frac{a_{\text{NH}_3}^2}{a_{\text{N}_2} a_{\text{H}_2}^3}$$

and this ratio has exactly the value we have just calculated. At low overall pressures, the activities can be replaced by the ratios $p/p^\ominus$, where p is a partial pressure, and an approximate form of the equilibrium constant is

$$K = \frac{(p_{\text{NH}_3}/p^\ominus)^2}{(p_{\text{N}_2}/p^\ominus)(p_{\text{H}_2}/p^\ominus)^3} = \frac{p_{\text{NH}_3}^2 p^{\ominus 2}}{p_{\text{N}_2} p_{\text{H}_2}^3}$$

Self-test 7.1 Evaluate the equilibrium constant for $\text{N}_2\text{O}_4(\text{g}) \rightleftharpoons 2 \text{NO}_2(\text{g})$ at 298 K. [$K = 0.15$]

Example 7.2 Estimating the degree of dissociation at equilibrium

The degree of dissociation, α , is defined as the fraction of reactant that has decomposed; if the initial amount of reactant is n and the amount at equilibrium is n_{eq} , then $\alpha = (n - n_{\text{eq}})/n$. The standard Gibbs energy of reaction for the decomposition $\text{H}_2\text{O}(\text{g}) \rightarrow \text{H}_2(\text{g}) + \frac{1}{2} \text{O}_2(\text{g})$ is $+118.08 \text{ kJ mol}^{-1}$ at 2300 K. What is the degree of dissociation of H_2O at 2300 K and 1.00 bar?

Method The equilibrium constant is obtained from the standard Gibbs energy of reaction by using eqn 7.17, so the task is to relate the degree of dissociation, α , to K and then to find its numerical value. Proceed by expressing the equilibrium compositions in terms of α , and solve for α in terms of K . Because the standard Gibbs energy of reaction is large and positive, we can anticipate that K will be small, and hence that $\alpha \ll 1$, which opens the way to making approximations to obtain its numerical value.

Answer The equilibrium constant is obtained from eqn 7.17 in the form

$$\begin{aligned} \ln K &= -\frac{\Delta_r G^\ominus}{RT} = -\frac{(+118.08 \times 10^3 \text{ J mol}^{-1})}{(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (2300 \text{ K})} \\ &= -\frac{118.08 \times 10^3}{8.3145 \times 2300} \end{aligned}$$

It follows that $K = 2.08 \times 10^{-3}$. The equilibrium composition can be expressed in terms of α by drawing up the following table:

	H_2O	H_2	O_2	
Initial amount	n	0	0	
Change to reach equilibrium	$-\alpha n$	$+\alpha n$	$+\frac{1}{2}\alpha n$	
Amount at equilibrium	$(1 - \alpha)n$	αn	$\frac{1}{2}\alpha n$	Total: $(1 + \frac{1}{2}\alpha)n$
Mole fraction, x_j	$\frac{1 - \alpha}{1 + \frac{1}{2}\alpha}$	$\frac{\alpha}{1 + \frac{1}{2}\alpha}$	$\frac{\frac{1}{2}\alpha}{1 + \frac{1}{2}\alpha}$	
Partial pressure, p_j	$\frac{(1 - \alpha)p}{1 + \frac{1}{2}\alpha}$	$\frac{\alpha p}{1 + \frac{1}{2}\alpha}$	$\frac{\frac{1}{2}\alpha p}{1 + \frac{1}{2}\alpha}$	

where, for the entries in the last row, we have used $p_j = x_j p$ (eqn 1.13). The equilibrium constant is therefore

$$K = \frac{p_{\text{H}_2} p_{\text{O}_2}^{1/2}}{p_{\text{H}_2\text{O}}} = \frac{\alpha^{3/2} p^{1/2}}{(1 - \alpha)(2 + \alpha)^{1/2}}$$

Comment 7.4

The textbook's web site contains links to online tools for the estimation of equilibrium constants of gas-phase reactions.

Fig. 7.4 The Boltzmann distribution of populations over the energy levels of two species A and B with similar densities of energy levels; the reaction $A \rightarrow B$ is endothermic in this example. The bulk of the population is associated with the species A, so that species is dominant at equilibrium.

In this expression, we have written p in place of p/p° , to keep the notation simple. Now make the approximation that $\alpha \ll 1$, and hence obtain

$$K \approx \frac{\alpha^{3/2} p^{1/2}}{2^{1/2}}$$

Under the stated condition, $p = 1.00$ bar (that is, $p/p^\circ = 1.00$), so $\alpha \approx (2^{1/2}K)^{2/3} = 0.0205$. That is, about 2 per cent of the water has decomposed.

A note on good practice Always check that the approximation is consistent with the final answer. In this case $\alpha \ll 1$ in accord with the original assumption.

Self-test 7.2 Given that the standard Gibbs energy of reaction at 2000 K is $+135.2 \text{ kJ mol}^{-1}$ for the same reaction, suppose that steam at 200 kPa is passed through a furnace tube at that temperature. Calculate the mole fraction of O_2 present in the output gas stream. [0.00221]

(c) The relation between equilibrium constants

The only remaining problem is to express the thermodynamic equilibrium constant in terms of the mole fractions, x_j , or molalities, b_j , of the species. To do so, we need to know the activity coefficients, and then to use $a_j = \gamma_j x_j$ or $a_j = \gamma_j b_j/b^\circ$ (recalling that the activity coefficients depend on the choice). For example, in the latter case, for an equilibrium of the form $A + B \rightleftharpoons C + D$, where all four species are solutes, we write

$$K = \frac{a_C a_D}{a_A a_B} = \frac{\gamma_C \gamma_D}{\gamma_A \gamma_B} \times \frac{b_C b_D}{b_A b_B} = K_\gamma K_b \quad (7.18)$$

The activity coefficients must be evaluated at the equilibrium composition of the mixture (for instance, by using one of the Debye–Hückel expressions, Section 5.9), which may involve a complicated calculation, because the activity coefficients are known only if the equilibrium composition is already known. In elementary applications, and to begin the iterative calculation of the concentrations in a real example, the assumption is often made that the activity coefficients are all so close to unity that $K_\gamma = 1$. Then we obtain the result widely used in elementary chemistry that $K \approx K_b$, and equilibria are discussed in terms of molalities (or molar concentrations) themselves.

Molecular interpretation 7.2 *The molecular origin of the equilibrium constant*

We can obtain a deeper insight into the origin and significance of the equilibrium constant by considering the Boltzmann distribution of molecules over the available states of a system composed of reactants and products (recall *Molecular interpretation 3.1*). When atoms can exchange partners, as in a reaction, the available states of the system include arrangements in which the atoms are present in the form of reactants and in the form of products: these arrangements have their characteristic sets of energy levels, but the Boltzmann distribution does not distinguish between their identities, only their energies. The atoms distribute themselves over both sets of energy levels in accord with the Boltzmann distribution (Fig. 7.4). At a given temperature, there will be a specific distribution of populations, and hence a specific composition of the reaction mixture.

It can be appreciated from the illustration that, if the reactants and products both have similar arrays of molecular energy levels, then the dominant species in a reaction mixture at equilibrium will be the species with the lower set of energy

levels. However, the fact that the Gibbs energy occurs in the expression is a signal that entropy plays a role as well as energy. Its role can be appreciated by referring to Fig. 7.5. We see that, although the B energy levels lie higher than the A energy levels, in this instance they are much more closely spaced. As a result, their total population may be considerable and B could even dominate in the reaction mixture at equilibrium. Closely spaced energy levels correlate with a high entropy (see *Molecular interpretation 3.1*), so in this case we see that entropy effects dominate adverse energy effects. This competition is mirrored in eqn 7.17, as can be seen most clearly by using $\Delta_r G^\ominus = \Delta_r H^\ominus - T\Delta_r S^\ominus$ and writing it in the form

$$K = e^{-\Delta_r H^\ominus/RT} e^{\Delta_r S^\ominus/R} \quad (7.19)$$

Note that a positive reaction enthalpy results in a lowering of the equilibrium constant (that is, an endothermic reaction can be expected to have an equilibrium composition that favours the reactants). However, if there is positive reaction entropy, then the equilibrium composition may favour products, despite the endothermic character of the reaction.

Fig. 7.5 Even though the reaction $A \rightarrow B$ is endothermic, the density of energy levels in B is so much greater than that in A that the population associated with B is greater than that associated with A, so B is dominant at equilibrium.

(d) Equilibria in biological systems

We saw in Section 5.7 that for biological systems it is appropriate to adopt the biological standard state, in which $a_{\text{H}^+} = 10^{-7}$ and $\text{pH} = -\log a_{\text{H}^+} = 7$. It follows from eqn 5.56 that the relation between the thermodynamic and biological standard Gibbs energies of reaction for a reaction of the form

is

$$\Delta_r G^\ominus = \Delta_r G^\ominus + 7\nu RT \ln 10 \quad (7.20\text{b})$$

Note that there is no difference between the two standard values if hydrogen ions are not involved in the reaction ($\nu = 0$).

Illustration 7.4 Using the biological standard state

Consider the reaction

at 37°C , for which $\Delta_r G^\ominus = -21.8 \text{ kJ mol}^{-1}$. NADH is the reduced form of nicotinamide adenine dinucleotide and NAD^+ is its oxidized form; the molecules play an important role in the later stages of the respiratory process. It follows that, because $\nu = 1$ and $7 \ln 10 = 16.1$,

$$\begin{aligned} \Delta_r G^\ominus &= -21.8 \text{ kJ mol}^{-1} + 16.1 \times (8.3145 \times 10^{-3} \text{ kJ K}^{-1} \text{ mol}^{-1}) \times (310 \text{ K}) \\ &= +19.7 \text{ kJ mol}^{-1} \end{aligned}$$

Note that the biological standard value is opposite in sign (in this example) to the thermodynamic standard value: the much lower concentration of hydronium ions (by seven orders of magnitude) at $\text{pH} = 7$ in place of $\text{pH} = 0$, has resulted in the reverse reaction becoming spontaneous.

Self-test 7.3 For a particular reaction of the form $A \rightarrow B + 2 \text{H}^+$ in aqueous solution, it was found that $\Delta_r G^\ominus = +20 \text{ kJ mol}^{-1}$ at 28°C . Estimate the value of $\Delta_r G^\ominus$. [-61 kJ mol^{-1}]

The response of equilibria to the conditions

Equilibria respond to changes in pressure, temperature, and concentrations of reactants and products. The equilibrium constant for a reaction is not affected by the presence of a catalyst or an enzyme (a biological catalyst). As we shall see in detail in Sections 22.* and 24.*, catalysts increase the rate at which equilibrium is attained but do not affect its position. However, it is important to note that in industry reactions rarely reach equilibrium, partly on account of the rates at which reactants mix.

7.3 How equilibria respond to pressure

The equilibrium constant depends on the value of $\Delta_r G^\circ$, which is defined at a single, standard pressure. The value of $\Delta_r G^\circ$, and hence of K , is therefore independent of the pressure at which the equilibrium is actually established. Formally we may express this independence as

$$\left(\frac{\partial K}{\partial p}\right)_T = 0 \quad (7.21)$$

The conclusion that K is independent of pressure does not necessarily mean that the equilibrium composition is independent of the pressure, and its effect depends on how the pressure is applied. The pressure within a reaction vessel can be increased by injecting an inert gas into it. However, so long as the gases are perfect, this addition of gas leaves all the partial pressures of the reacting gases unchanged: the partial pressures of a perfect gas is the pressure it would exert if it were alone in the container, so the presence of another gas has no effect. It follows that pressurization by the addition of an inert gas has no effect on the equilibrium composition of the system (provided the gases are perfect). Alternatively, the pressure of the system may be increased by confining the gases to a smaller volume (that is, by compression). Now the individual partial pressures are changed but their ratio (as it appears in the equilibrium constant) remains the same. Consider, for instance, the perfect gas equilibrium $A \rightleftharpoons 2 B$, for which the equilibrium constant is

$$K = \frac{p_B^2}{p_A p^\circ}$$

The right-hand side of this expression remains constant only if an increase in p_A cancels an increase in the *square* of p_B . This relatively steep increase of p_A compared to p_B will occur if the equilibrium composition shifts in favour of A at the expense of B. Then the number of A molecules will increase as the volume of the container is decreased and its partial pressure will rise more rapidly than can be ascribed to a simple change in volume alone (Fig. 7.6).

The increase in the number of A molecules and the corresponding decrease in the number of B molecules in the equilibrium $A \rightleftharpoons 2 B$ is a special case of a principle proposed by the French chemist Henri Le Chatelier.¹ **Le Chatelier's principle** states that:

A system at equilibrium, when subjected to a disturbance, responds in a way that tends to minimize the effect of the disturbance

The principle implies that, if a system at equilibrium is compressed, then the reaction will adjust so as to minimize the increase in pressure. This it can do by reducing the number of particles in the gas phase, which implies a shift $A \leftarrow 2 B$.

¹ Le Chatelier also invented oxyacetylene welding.

Fig. 7.6 When a reaction at equilibrium is compressed (from *a* to *b*), the reaction responds by reducing the number of molecules in the gas phase (in this case by producing the dimers represented by the linked spheres).

To treat the effect of compression quantitatively, we suppose that there is an amount n of A present initially (and no B). At equilibrium the amount of A is $(1 - \alpha)n$ and the amount of B is $2\alpha n$, where α is the extent of dissociation of A into 2B. It follows that the mole fractions present at equilibrium are

$$x_A = \frac{(1 - \alpha)n}{(1 - \alpha)n + 2\alpha n} = \frac{1 - \alpha}{1 + \alpha} \quad x_B = \frac{2\alpha}{1 + \alpha}$$

The equilibrium constant for the reaction is

$$K = \frac{p_B^2}{p_A p^\ominus} = \frac{x_B^2 p^2}{x_A p p^\ominus} = \frac{4\alpha^2 (p/p^\ominus)}{1 - \alpha^2}$$

which rearranges to

$$\alpha = \left(\frac{1}{1 + 4p/Kp^\ominus} \right)^{1/2} \quad (7.22)$$

This formula shows that, even though K is independent of pressure, the amounts of A and B do depend on pressure (Fig. 7.7). It also shows that as p is increased, α decreases, in accord with Le Chatelier's principle.

Fig. 7.7 The pressure dependence of the degree of dissociation, α , at equilibrium for an $A(g) \rightleftharpoons 2B(g)$ reaction for different values of the equilibrium constant K . The value $\alpha = 0$ corresponds to pure A; $\alpha = 1$ corresponds to pure B.

Exploration Plot x_A and x_B against the pressure p for several values of the equilibrium constant K .

Illustration 7.5 Predicting the effect of compression

To predict the effect of an increase in pressure on the composition of the ammonia synthesis at equilibrium, eqn 7.10, we note that the number of gas molecules decreases (from 4 to 2). So, Le Chatelier's principle predicts that an increase in pressure will favour the product. The equilibrium constant is

$$K = \frac{p_{\text{NH}_3}^2 p^{\ominus 2}}{p_{\text{N}_2} p_{\text{H}_2}^3} = \frac{x_{\text{NH}_3}^2 p^2 p^{\ominus 2}}{x_{\text{N}_2} x_{\text{H}_2}^3 p^4} = \frac{K_x p^{\ominus 2}}{p^2}$$

where K_x is the part of the equilibrium constant expression that contains the equilibrium mole fractions of reactants and products (note that, unlike K itself, K_x is not an equilibrium constant). Therefore, doubling the pressure must increase K_x by a factor of 4 to preserve the value of K .

Self-test 7.4 Predict the effect of a tenfold pressure increase on the equilibrium composition of the reaction $3\text{N}_2(g) + \text{H}_2(g) \rightarrow 2\text{N}_3\text{H}(g)$.

[100-fold increase in K_x]

7.4 The response of equilibria to temperature

Le Chatelier's principle predicts that a system at equilibrium will tend to shift in the endothermic direction if the temperature is raised, for then energy is absorbed as heat and the rise in temperature is opposed. Conversely, an equilibrium can be expected to shift in the exothermic direction if the temperature is lowered, for then energy is released and the reduction in temperature is opposed. These conclusions can be summarized as follows:

Exothermic reactions: increased temperature favours the reactants.

Endothermic reactions: increased temperature favours the products.

We shall now justify these remarks and see how to express the changes quantitatively.

(a) The van 't Hoff equation

The **van 't Hoff equation**, which is derived in the *Justification* below, is an expression for the slope of a plot of the equilibrium constant (specifically, $\ln K$) as a function of temperature. It may be expressed in either of two ways:

$$(a) \quad \frac{d \ln K}{dT} = \frac{\Delta_r H^\ominus}{RT^2} \quad (b) \quad \frac{d \ln K}{d(1/T)} = -\frac{\Delta_r H^\ominus}{R} \quad (7.23)$$

Justification 7.2 *The van 't Hoff equation*

From eqn 7.17, we know that

$$\ln K = -\frac{\Delta_r G^\ominus}{RT}$$

Differentiation of $\ln K$ with respect to temperature then gives

$$\frac{d \ln K}{dT} = -\frac{1}{R} \frac{d(\Delta_r G^\ominus/T)}{dT}$$

The differentials are complete because K and $\Delta_r G^\ominus$ depend only on temperature, not on pressure. To develop this equation we use the Gibbs–Helmholtz equation (eqn 3.53) in the form

$$\frac{d(\Delta_r G^\ominus/T)}{dT} = -\frac{\Delta_r H^\ominus}{T^2}$$

where $\Delta_r H^\ominus$ is the standard reaction enthalpy at the temperature T . Combining the two equations gives the van 't Hoff equation, eqn 7.23a. The second form of the equation is obtained by noting that

$$\frac{d(1/T)}{dT} = -\frac{1}{T^2}, \quad \text{so} \quad dT = -T^2 d(1/T)$$

It follows that eqn 7.23a can be rewritten as

$$-\frac{d \ln K}{T^2 d(1/T)} = \frac{\Delta_r H^\ominus}{RT^2}$$

which simplifies into eqn 7.23b.

Equation 7.23a shows that $d \ln K/dT < 0$ (and therefore that $dK/dT < 0$) for a reaction that is exothermic under standard conditions ($\Delta_r H^\ominus < 0$). A negative slope means that $\ln K$, and therefore K itself, decreases as the temperature rises. Therefore, as asserted above, in the case of an exothermic reaction the equilibrium shifts away from products. The opposite occurs in the case of endothermic reactions.

Some insight into the thermodynamic basis of this behaviour comes from the expression $\Delta_r G^\ominus = \Delta_r H^\ominus - T\Delta_r S^\ominus$ written in the form $-\Delta_r G^\ominus/T = -\Delta_r H^\ominus/T + \Delta_r S^\ominus$. When the reaction is exothermic, $-\Delta_r H^\ominus/T$ corresponds to a positive change of entropy of the surroundings and favours the formation of products. When the temperature is raised, $-\Delta_r H^\ominus/T$ decreases, and the increasing entropy of the surroundings has a less important role. As a result, the equilibrium lies less to the right. When the reaction is endothermic, the principal factor is the increasing entropy of the reaction system. The importance of the unfavourable change of entropy of the surroundings is reduced if the temperature is raised (because then $\Delta_r H^\ominus/T$ is smaller), and the reaction is able to shift towards products.

Fig. 7.8 The effect of temperature on a chemical equilibrium can be interpreted in terms of the change in the Boltzmann distribution with temperature and the effect of that change in the population of the species. (a) In an endothermic reaction, the population of B increases at the expense of A as the temperature is raised. (b) In an exothermic reaction, the opposite happens.

Molecular interpretation 7.3 *The temperature dependence of the equilibrium constant*

The typical arrangement of energy levels for an endothermic reaction is shown in Fig. 7.8a. When the temperature is increased, the Boltzmann distribution adjusts and the populations change as shown. The change corresponds to an increased population of the higher energy states at the expense of the population of the lower energy states. We see that the states that arise from the B molecules become more populated at the expense of the A molecules. Therefore, the total population of B states increases, and B becomes more abundant in the equilibrium mixture. Conversely, if the reaction is exothermic (Fig. 7.8b), then an increase in temperature increases the population of the A states (which start at higher energy) at the expense of the B states, so the reactants become more abundant.

Example 7.3 *Measuring a reaction enthalpy*

The data below show the temperature variation of the equilibrium constant of the reaction $\text{Ag}_2\text{CO}_3(\text{s}) \rightleftharpoons \text{Ag}_2\text{O}(\text{s}) + \text{CO}_2(\text{g})$. Calculate the standard reaction enthalpy of the decomposition.

T/K	350	400	450	500
K	3.98×10^{-4}	1.41×10^{-2}	1.86×10^{-1}	1.48

Method It follows from eqn 7.23b that, provided the reaction enthalpy can be assumed to be independent of temperature, a plot of $-\ln K$ against $1/T$ should be a straight line of slope $\Delta_r H^\ominus/R$.

Answer We draw up the following table:

T/K	350	400	450	500
$(10^3 \text{ K})/T$	2.86	2.50	2.22	2.00
$-\ln K$	7.83	4.26	1.68	-0.39

These points are plotted in Fig. 7.9. The slope of the graph is $+9.6 \times 10^3$, so

$$\Delta_r H^\ominus = (+9.6 \times 10^3 \text{ K}) \times R = +80 \text{ kJ mol}^{-1}$$

Fig. 7.9 When $-\ln K$ is plotted against $1/T$, a straight line is expected with slope equal to $\Delta_r H^\ominus/R$ if the standard reaction enthalpy does not vary appreciably with temperature. This is a non-calorimetric method for the measurement of reaction enthalpies.

Exploration The equilibrium constant of a reaction is found to fit the expression $\ln K = a + b/(T/\text{K}) + c/(T/\text{K})^3$ over a range of temperatures. (a) Write expressions for $\Delta_r H^\ominus$ and $\Delta_r S^\ominus$. (b) Plot $\ln K$ against $1/T$ between 400 K and 600 K for $a = -2.0$, $b = -1.0 \times 10^3$, and $c = 2.0 \times 10^7$.

Self-test 7.5 The equilibrium constant of the reaction $2 \text{SO}_2(\text{g}) + \text{O}_2(\text{g}) \rightleftharpoons 2 \text{SO}_3(\text{g})$ is 4.0×10^{24} at 300 K, 2.5×10^{10} at 500 K, and 3.0×10^4 at 700 K. Estimate the reaction enthalpy at 500 K. [−200 kJ mol^{−1}]

The temperature dependence of the equilibrium constant provides a non-calorimetric method of determining $\Delta_r H^\ominus$. A drawback is that the reaction enthalpy is actually temperature-dependent, so the plot is not expected to be perfectly linear. However, the temperature dependence is weak in many cases, so the plot is reasonably straight. In practice, the method is not very accurate, but it is often the only method available.

(b) The value of K at different temperatures

To find the value of the equilibrium constant at a temperature T_2 in terms of its value K_1 at another temperature T_1 , we integrate eqn 7.23b between these two temperatures:

$$\ln K_2 - \ln K_1 = -\frac{1}{R} \int_{1/T_1}^{1/T_2} \Delta_r H^\ominus d(1/T) \quad (7.24)$$

If we suppose that $\Delta_r H^\ominus$ varies only slightly with temperature over the temperature range of interest, then we may take it outside the integral. It follows that

$$\ln K_2 - \ln K_1 = -\frac{\Delta_r H^\ominus}{R} \left(\frac{1}{T_2} - \frac{1}{T_1} \right) \quad (7.25)$$

Illustration 7.6 Estimating an equilibrium constant at a different temperature

To estimate the equilibrium constant for the synthesis of ammonia at 500 K from its value at 298 K (6.1×10^5 for the reaction as written in eqn 7.10) we use the standard reaction enthalpy, which can be obtained from Table 2.7 in the *Data section* by using $\Delta_r H^\ominus = 2\Delta_f H^\ominus(\text{NH}_3, \text{g})$, and assume that its value is constant over the range of temperatures. Then, with $\Delta_r H^\ominus = -92.2 \text{ kJ mol}^{-1}$, from eqn 7.25 we find

$$\begin{aligned} \ln K_2 &= \ln(6.1 \times 10^5) - \frac{(-92.2 \times 10^3 \text{ J mol}^{-1})}{8.3145 \text{ J K}^{-1} \text{ mol}^{-1}} \left(\frac{1}{500 \text{ K}} - \frac{1}{298 \text{ K}} \right) \\ &= -1.71 \end{aligned}$$

It follows that $K_2 = 0.18$, a lower value than at 298 K, as expected for this exothermic reaction.

Self-test 7.6 The equilibrium constant for $\text{N}_2\text{O}_4(\text{g}) \rightleftharpoons 2 \text{NO}_2(\text{g})$ was calculated in Self-test 7.1. Estimate its value at 100°C. [15]

Knowledge of the temperature dependence of the equilibrium constant for a reaction can be useful in the design of laboratory and industrial processes. For example, synthetic chemists can improve the yield of a reaction by changing the temperature of the reaction mixture. Also, reduction of a metal oxide with carbon or carbon monoxide results in the extraction of the metal when the process is carried out at a temperature for which the equilibrium constant for the reaction is much greater than one.

IMPACT ON ENGINEERING

17.1 The extraction of metals from their oxides

Metals can be obtained from their oxides by reduction with carbon or carbon monoxide if any of the equilibria

lie to the right (that is, have $K > 1$). As we shall see, these equilibria can be discussed in terms of the thermodynamic functions for the reactions

The temperature dependences of the standard Gibbs energies of reactions (i)–(iv) depend on the reaction entropy through $d\Delta_r G^\circ/dT = -\Delta_r S^\circ$. Because in reaction (iii) there is a net increase in the amount of gas, the standard reaction entropy is large and positive; therefore, its $\Delta_r G^\circ$ decreases sharply with increasing temperature. In reaction (iv), there is a similar net decrease in the amount of gas, so $\Delta_r G^\circ$ increases sharply with increasing temperature. In reaction (ii), the amount of gas is constant, so the entropy change is small and $\Delta_r G^\circ$ changes only slightly with temperature. These remarks are summarized in Fig. 7.10, which is called an *Ellingham diagram*. Note that $\Delta_r G^\circ$ decreases upwards!

At room temperature, $\Delta_r G^\circ$ is dominated by the contribution of the reaction enthalpy ($T\Delta_r S^\circ$ being relatively small), so the order of increasing $\Delta_r G^\circ$ is the same as the order of increasing $\Delta_r H^\circ$ (Al_2O_3 is most exothermic; Ag_2O is least). The standard reaction entropy is similar for all metals because in each case gaseous oxygen is eliminated and a compact, solid oxide is formed. As a result, the temperature dependence of the standard Gibbs energy of oxidation should be similar for all metals, as is shown by the similar slopes of the lines in the diagram. The kinks at high temperatures correspond to the evaporation of the metals; less pronounced kinks occur at the melting temperatures of the metals and the oxides.

Successful reduction of the oxide depends on the outcome of the competition of the carbon for the oxygen bound to the metal. The standard Gibbs energies for the reductions can be expressed in terms of the standard Gibbs energies for the reactions above:

The equilibrium lies to the right if $\Delta_r G^\circ < 0$. This is the case when the line for reaction (i) lies below (is more positive than) the line for one of the reactions (ii) to (iv).

The spontaneity of a reduction at any temperature can be predicted simply by looking at the diagram: a metal oxide is reduced by any carbon reaction lying above it, because the overall reaction then has $\Delta_r G^\circ < 0$. For example, CuO can be reduced to Cu at any temperature above room temperature. Even in the absence of carbon, Ag_2O decomposes when heated above 200°C because then the standard Gibbs energy for reaction (i) becomes positive (and the reverse reaction is then spontaneous). On the other hand, Al_2O_3 is not reduced by carbon until the temperature has been raised to above 2000°C .

Fig. 7.10 An Ellingham diagram for the discussion of the reduction of metal ores.

Equilibrium electrochemistry

We shall now see how the foregoing ideas, with certain changes of technical detail, can be used to describe the equilibrium properties of reactions taking place in electrochemical cells. The ability to make very precise measurements of currents and potential differences ('voltages') means that electrochemical methods can be used to determine thermodynamic properties of reactions that may be inaccessible by other methods.

An **electrochemical cell** consists of two **electrodes**, or metallic conductors, in contact with an **electrolyte**, an ionic conductor (which may be a solution, a liquid, or a solid). An electrode and its electrolyte comprise an **electrode compartment**. The two electrodes may share the same compartment. The various kinds of electrode are summarized in Table 7.1. Any 'inert metal' shown as part of the specification is present to act as a source or sink of electrons, but takes no other part in the reaction other than acting as a catalyst for it. If the electrolytes are different, the two compartments may be joined by a **salt bridge**, which is a tube containing a concentrated electrolyte solution (almost always potassium chloride in agar jelly) that completes the electrical circuit and enables the cell to function. A **galvanic cell** is an electrochemical cell that produces electricity as a result of the spontaneous reaction occurring inside it. An **electrolytic cell** is an electrochemical cell in which a non-spontaneous reaction is driven by an external source of current.

7.5 Half-reactions and electrodes

It will be familiar from introductory chemistry courses that **oxidation** is the removal of electrons from a species, a **reduction** is the addition of electrons to a species, and a **redox reaction** is a reaction in which there is a transfer of electrons from one species to another. The electron transfer may be accompanied by other events, such as atom or ion transfer, but the net effect is electron transfer and hence a change in oxidation number of an element. The **reducing agent** (or 'reductant') is the electron donor; the **oxidizing agent** (or 'oxidant') is the electron acceptor. It should also be familiar that any redox reaction may be expressed as the difference of two reduction **half-reactions**, which are conceptual reactions showing the gain of electrons. Even reactions that are not redox reactions may often be expressed as the difference of two reduction half-reactions. The reduced and oxidized species in a half-reaction form a **redox couple**. In general we write a couple as Ox/Red and the corresponding reduction half-reaction as

Table 7.1 Varieties of electrode

Electrode type	Designation	Redox couple	Half-reaction
Metal/metal ion	$\text{M(s)} \text{M}^+(\text{aq})$	M^+/M	$\text{M}^+(\text{aq}) + e^- \rightarrow \text{M(s)}$
Gas	$\text{Pt(s)} \text{X}_2(\text{g}) \text{X}^+(\text{aq})$	X^+/X_2	$\text{X}^+(\text{aq}) + e^- \rightarrow \frac{1}{2} \text{X}_2(\text{g})$
	$\text{Pt(s)} \text{X}_2(\text{g}) \text{X}^-(\text{aq})$	X_2/X^-	$\frac{1}{2} \text{X}_2(\text{g}) + e^- \rightarrow \text{X}^-(\text{aq})$
Metal/insoluble salt	$\text{M(s)} \text{MX(s)} \text{X}^-(\text{aq})$	$\text{MX}/\text{M}, \text{X}^-$	$\text{MX(s)} + e^- \rightarrow \text{M(s)} + \text{X}^-(\text{aq})$
Redox	$\text{Pt(s)} \text{M}^+(\text{aq}), \text{M}^{2+}(\text{aq})$	M^{2+}/M^+	$\text{M}^{2+}(\text{aq}) + e^- \rightarrow \text{M}^+(\text{aq})$

Illustration 7.7 Expressing a reaction in terms of half-reactions

The dissolution of silver chloride in water $\text{AgCl(s)} \rightarrow \text{Ag}^+(\text{aq}) + \text{Cl}^-(\text{aq})$, which is not a redox reaction, can be expressed as the difference of the following two reduction half-reactions:

The redox couples are AgCl/Ag,Cl^- and Ag^+/Ag , respectively.

Self-test 7.7 Express the formation of H_2O from H_2 and O_2 in acidic solution (a redox reaction) as the difference of two reduction half-reactions.

We shall often find it useful to express the composition of an electrode compartment in terms of the reaction quotient, Q , for the half-reaction. This quotient is defined like the reaction quotient for the overall reaction, but the electrons are ignored.

Illustration 7.8 Writing the reaction quotient of a half-reaction

The reaction quotient for the reduction of O_2 to H_2O in acid solution, $\text{O}_2(\text{g}) + 4 \text{H}^+(\text{aq}) + 4 \text{e}^- \rightarrow 2 \text{H}_2\text{O(l)}$, is

$$Q = \frac{a_{\text{H}_2\text{O}}^2}{a_{\text{H}^+}^4 a_{\text{O}_2}} \approx \frac{p^\circ}{a_{\text{H}^+}^4 p_{\text{O}_2}}$$

The approximations used in the second step are that the activity of water is 1 (because the solution is dilute) and the oxygen behaves as a perfect gas, so $a_{\text{O}_2} \approx p_{\text{O}_2}/p^\circ$.

Self-test 7.8 Write the half-reaction and the reaction quotient for a chlorine gas electrode.
 $[\text{Cl}_2(\text{g}) + 2 \text{e}^- \rightarrow 2 \text{Cl}^-(\text{aq}), Q = a_{\text{Cl}^-}^2 p^\circ / p_{\text{Cl}_2}]$

The reduction and oxidation processes responsible for the overall reaction in a cell are separated in space: oxidation takes place at one electrode and reduction takes place at the other. As the reaction proceeds, the electrons released in the oxidation $\text{Red}_1 \rightarrow \text{Ox}_1 + \nu \text{e}^-$ at one electrode travel through the external circuit and re-enter the cell through the other electrode. There they bring about reduction $\text{Ox}_2 + \nu \text{e}^- \rightarrow \text{Red}_2$. The electrode at which oxidation occurs is called the **anode**; the electrode at which reduction occurs is called the **cathode**. In a galvanic cell, the cathode has a higher potential than the anode: the species undergoing reduction, Ox_2 , withdraws electrons from its electrode (the cathode, Fig. 7.11), so leaving a relative positive charge on it (corresponding to a high potential). At the anode, oxidation results in the transfer of electrons to the electrode, so giving it a relative negative charge (corresponding to a low potential).

7.6 Varieties of cells

The simplest type of cell has a single electrolyte common to both electrodes (as in Fig. 7.11). In some cases it is necessary to immerse the electrodes in different electrolytes,

Fig. 7.11 When a spontaneous reaction takes place in a galvanic cell, electrons are deposited in one electrode (the site of oxidation, the anode) and collected from another (the site of reduction, the cathode), and so there is a net flow of current which can be used to do work. Note that the + sign of the cathode can be interpreted as indicating the electrode at which electrons enter the cell, and the - sign of the anode is where the electrons leave the cell.

Fig. 7.12 One version of the Daniell cell. The copper electrode is the cathode and the zinc electrode is the anode. Electrons leave the cell from the zinc electrode and enter it again through the copper electrode.

as in the 'Daniell cell' in which the redox couple at one electrode is Cu^{2+}/Cu and at the other is Zn^{2+}/Zn (Fig. 7.12). In an **electrolyte concentration cell**, the electrode compartments are identical except for the concentrations of the electrolytes. In an **electrode concentration cell** the electrodes themselves have different concentrations, either because they are gas electrodes operating at different pressures or because they are amalgams (solutions in mercury) with different concentrations.

(a) Liquid junction potentials

In a cell with two different electrolyte solutions in contact, as in the Daniell cell, there is an additional source of potential difference across the interface of the two electrolytes. This potential is called the **liquid junction potential**, E_{lj} . Another example of a junction potential is that between different concentrations of hydrochloric acid. At the junction, the mobile H^+ ions diffuse into the more dilute solution. The bulkier Cl^- ions follow, but initially do so more slowly, which results in a potential difference at the junction. The potential then settles down to a value such that, after that brief initial period, the ions diffuse at the same rates. Electrolyte concentration cells always have a liquid junction; electrode concentration cells do not.

The contribution of the liquid junction to the potential can be reduced (to about 1 to 2 mV) by joining the electrolyte compartments through a salt bridge (Fig. 7.13). The reason for the success of the salt bridge is that the liquid junction potentials at either end are largely independent of the concentrations of the two dilute solutions, and so nearly cancel.

(b) Notation

In the notation for cells, phase boundaries are denoted by a vertical bar. For example, the cell in Fig. 7.11 is denoted

A liquid junction is denoted by $:$, so the cell in Fig. 7.12, is denoted

A double vertical line, $\parallel$, denotes an interface for which it is assumed that the junction potential has been eliminated. Thus the cell in Fig. 7.13 is denoted

An example of an electrolyte concentration cell in which the liquid junction potential is assumed to be eliminated is

7.7 The electromotive force

The current produced by a galvanic cell arises from the spontaneous chemical reaction taking place inside it. The **cell reaction** is the reaction in the cell written on the assumption that the right-hand electrode is the cathode, and hence that the spontaneous reaction is one in which reduction is taking place in the right-hand compartment. Later we see how to predict if the right-hand electrode is in fact the cathode; if it is, then the cell reaction is spontaneous as written. If the left-hand electrode turns out to be the cathode, then the reverse of the corresponding cell reaction is spontaneous.

To write the cell reaction corresponding to a cell diagram, we first write the right-hand half-reaction as a reduction (because we have assumed that to be spontaneous). Then we subtract from it the left-hand reduction half-reaction (for, by implication, that

Fig. 7.13 The salt bridge, essentially an inverted U-tube full of concentrated salt solution in a jelly, has two opposing liquid junction potentials that almost cancel.

electrode is the site of oxidation). Thus, in the cell $\text{Zn(s)}|\text{ZnSO}_4(\text{aq})||\text{CuSO}_4(\text{aq})|\text{Cu(s)}$ the two electrodes and their reduction half-reactions are

Hence, the overall cell reaction is the difference:

(a) The Nernst equation

A cell in which the overall cell reaction has not reached chemical equilibrium can do electrical work as the reaction drives electrons through an external circuit. The work that a given transfer of electrons can accomplish depends on the potential difference between the two electrodes. This potential difference is called the **cell potential** and is measured in volts, V ($1\text{ V} = 1\text{ J C}^{-1}\text{ s}$). When the cell potential is large, a given number of electrons travelling between the electrodes can do a large amount of electrical work. When the cell potential is small, the same number of electrons can do only a small amount of work. A cell in which the overall reaction is at equilibrium can do no work, and then the cell potential is zero.

According to the discussion in Section 3.5e, we know that the maximum non-expansion work, which in the current context is electrical work, that a system (the cell) can do is given by eqn 3.38 ($w_{\text{e,max}} = \Delta G$), with ΔG identified (as we shall show) with the Gibbs energy of the cell reaction, $\Delta_{\text{r}}G$. It follows that, to draw thermodynamic conclusions from measurements of the work a cell can do, we must ensure that the cell is operating reversibly, for only then is it producing maximum work. Moreover, we saw in Section 7.1a that the reaction Gibbs energy is actually a property relating to a specified composition of the reaction mixture. Therefore, to make use of $\Delta_{\text{r}}G$ we must ensure that the cell is operating reversibly at a specific, constant composition. Both these conditions are achieved by measuring the cell potential when it is balanced by an exactly opposing source of potential so that the cell reaction occurs reversibly, the composition is constant, and no current flows: in effect, the cell reaction is poised for change, but not actually changing. The resulting potential difference is called the **electromotive force** (emf), E , of the cell.

As we show in the *Justification* below, the relation between the reaction Gibbs energy and the emf of the cell is

$$-vFE = \Delta_{\text{r}}G \quad (7.27)$$

where F is Faraday's constant, $F = eN_{\text{A}}$, and v is the stoichiometric coefficient of the electrons in the half-reactions into which the cell reaction can be divided. This equation is the key connection between electrical measurements on the one hand and thermodynamic properties on the other. It will be the basis of all that follows.

Justification 7.3 *The relation between the electromotive force and the reaction Gibbs energy*

We consider the change in G when the cell reaction advances by an infinitesimal amount $d\xi$ at some composition. From eqn 7.15 we can write (at constant temperature and pressure)

$$dG = \Delta_{\text{r}}G d\xi$$

The maximum non-expansion (electrical) work that the reaction can do as it advances by $d\xi$ at constant temperature and pressure is therefore

$$dw_{\text{e}} = \Delta_{\text{r}}G d\xi$$

Fig. 7.14 A spontaneous reaction occurs in the direction of decreasing Gibbs energy. When expressed in terms of a cell potential, the spontaneous direction of change can be expressed in terms of the cell emf, E . The reaction is spontaneous as written (from left to right on the illustration) when $E > 0$. The reverse reaction is spontaneous when $E < 0$. When the cell reaction is at equilibrium, the cell potential is zero.

This work is infinitesimal, and the composition of the system is virtually constant when it occurs.

Suppose that the reaction advances by $d\xi$, then $vd\xi$ electrons must travel from the anode to the cathode. The total charge transported between the electrodes when this change occurs is $-veN_A d\xi$ (because $vd\xi$ is the amount of electrons and the charge per mole of electrons is $-eN_A$). Hence, the total charge transported is $-vFd\xi$ because $eN_A = F$. The work done when an infinitesimal charge $-vFd\xi$ travels from the anode to the cathode is equal to the product of the charge and the potential difference E (see Table 2.1 and Appendix 3):

$$dw_e = -vFed\xi$$

When we equate this relation to the one above ($dw_e = \Delta_r G d\xi$), the advancement $d\xi$ cancels, and we obtain eqn 7.27.

It follows from eqn 7.27 that, by knowing the reaction Gibbs energy at a specified composition, we can state the cell emf at that composition. Note that a negative reaction Gibbs energy, corresponding to a spontaneous cell reaction, corresponds to a positive cell emf. Another way of looking at the content of eqn 7.27 is that it shows that the driving power of a cell (that is, its emf) is proportional to the slope of the Gibbs energy with respect to the extent of reaction. It is plausible that a reaction that is far from equilibrium (when the slope is steep) has a strong tendency to drive electrons through an external circuit (Fig. 7.14). When the slope is close to zero (when the cell reaction is close to equilibrium), the emf is small.

Illustration 7.9 Converting between the cell emf and the reaction Gibbs energy

Equation 7.27 provides an electrical method for measuring a reaction Gibbs energy at any composition of the reaction mixture: we simply measure the cell's emf and convert it to $\Delta_r G$. Conversely, if we know the value of $\Delta_r G$ at a particular composition, then we can predict the emf. For example, if $\Delta_r G = -1 \times 10^2 \text{ kJ mol}^{-1}$ and $v = 1$, then

$$E = -\frac{\Delta_r G}{vF} = -\frac{(-1 \times 10^5 \text{ J mol}^{-1})}{1 \times (9.6485 \times 10^4 \text{ C mol}^{-1})} = 1 \text{ V}$$

where we have used $1 \text{ J} = 1 \text{ C V}$.

We can go on to relate the emf to the activities of the participants in the cell reaction. We know that the reaction Gibbs energy is related to the composition of the reaction mixture by eqn 7.11 ($\Delta_r G = \Delta_r G^\ominus + RT \ln Q$); it follows, on division of both sides by $-vF$, that

$$E = -\frac{\Delta_r G^\ominus}{vF} - \frac{RT}{vF} \ln Q$$

The first term on the right is written

$$E^\ominus = -\frac{\Delta_r G^\ominus}{vF} \quad [7.28]$$

and called the **standard emf** of the cell. That is, the standard emf is the standard reaction Gibbs energy expressed as a potential (in volts). It follows that

$$E = E^\ominus - \frac{RT}{\nu F} \ln Q \quad (7.29)$$

This equation for the emf in terms of the composition is called the **Nernst equation**; the dependence of cell potential on composition that it predicts is summarized in Fig. 7.15. One important application of the Nernst equation is to the determination of the pH of a solution and, with a suitable choice of electrodes, of the concentration of other ions (Section 7.9c).

We see from eqn 7.29 that the standard emf (which will shortly move to centre stage of the exposition) can be interpreted as the emf when all the reactants and products in the cell reaction are in their standard states, for then all activities are 1, so $Q = 1$ and $\ln Q = 0$. However, the fact that the standard emf is merely a disguised form of the standard reaction Gibbs energy (eqn 7.28) should always be kept in mind and underlies all its applications.

Fig. 7.15 The variation of cell emf with the value of the reaction quotient for the cell reaction for different values of ν (the number of electrons transferred). At 298 K, $RT/F = 25.69$ mV, so the vertical scale refers to multiples of this value.

Exploration Plot the variation of cell emf with the value of the reaction quotient for the cell reaction for different values of the temperature. Does the cell emf become more or less sensitive to composition as the temperature increases?

Illustration 7.10 Using the Nernst equation

Because $RT/F = 25.7$ mV at 25°C, a practical form of the Nernst equation is

$$E = E^\ominus - \frac{25.7 \text{ mV}}{\nu} \ln Q$$

It then follows that, for a reaction in which $\nu = 1$, if Q is increased by a factor of 10, then the emf decreases by 59.2 mV.

(b) Cells at equilibrium

A special case of the Nernst equation has great importance in electrochemistry and provides a link to the earlier part of the chapter. Suppose the reaction has reached equilibrium; then $Q = K$, where K is the equilibrium constant of the cell reaction. However, a chemical reaction at equilibrium cannot do work, and hence it generates zero potential difference between the electrodes of a galvanic cell. Therefore, setting $E = 0$ and $Q = K$ in the Nernst equation gives

$$\ln K = \frac{\nu FE^\ominus}{RT} \quad (7.30)$$

This very important equation (which could also have been obtained more directly by substituting eqn 7.29 into eqn 7.17) lets us predict equilibrium constants from measured standard cell potentials. However, before we use it extensively, we need to establish a further result.

Illustration 7.11 Calculating an equilibrium constant from a standard cell potential

Because the standard emf of the Daniell cell is +1.10 V, the equilibrium constant for the cell reaction $\text{Cu}^{2+}(\text{aq}) + \text{Zn}(\text{s}) \rightarrow \text{Cu}(\text{s}) + \text{Zn}^{2+}(\text{aq})$, for which $\nu = 2$, is $K = 1.5 \times 10^{37}$ at 298 K. We conclude that the displacement of copper by zinc goes virtually to completion. Note that an emf of about 1 V is easily measurable but corresponds to an equilibrium constant that would be impossible to measure by direct chemical analysis.

7.8 Standard potentials

A galvanic cell is a combination of two electrodes, and each one can be considered as making a characteristic contribution to the overall cell potential. Although it is not possible to measure the contribution of a single electrode, we can define the potential of one of the electrodes as zero and then assign values to others on that basis. The specially selected electrode is the **standard hydrogen electrode** (SHE):

at all temperatures. To achieve the standard conditions, the activity of the hydrogen ions must be 1 (that is, $\text{pH} = 0$) and the pressure (more precisely, the fugacity) of the hydrogen gas must be 1 bar. The **standard potential**, E° , of another couple is then assigned by constructing a cell in which it is the right-hand electrode and the standard hydrogen electrode is the left-hand electrode.

The procedure for measuring a standard potential can be illustrated by considering a specific case, the silver chloride electrode. The measurement is made on the ‘Harned cell’:

for which the Nernst equation is

$$E = E^\circ(\text{AgCl/Ag, Cl}^-) - \frac{RT}{F} \ln \frac{a_{\text{H}^+} a_{\text{Cl}^-}}{a_{\text{H}_2}^{1/2}}$$

We shall set $a_{\text{H}_2} = 1$ from now on, and for simplicity write the standard potential as E° ; then

$$E = E^\circ - \frac{RT}{F} \ln a_{\text{H}^+} a_{\text{Cl}^-}$$

The activities can be expressed in terms of the molality b of HCl(aq) through $a_{\text{H}^+} = \gamma_{\pm} b/b^\circ$ and $a_{\text{Cl}^-} = \gamma_{\pm} b/b^\circ$ as we saw in Section 5.9), so

$$E = E^\circ - \frac{RT}{F} \ln b^2 - \frac{RT}{F} \ln \gamma_{\pm}^2$$

where for simplicity we have replaced b/b° by b . This expression rearranges to

$$E + \frac{2RT}{F} \ln b = E^\circ - \frac{2RT}{F} \ln \gamma_{\pm} \quad [7.32]$$

From the Debye–Hückel limiting law for a 1,1-electrolyte (Section 5.9; a 1,1-electrolyte is a solution of singly charged M^+ and X^- ions), we know that $\ln \gamma_{\pm} \propto -b^{1/2}$. The natural logarithm used here is proportional to the common logarithm that appears in eqn 5.69 (because $\ln x = \ln 10 \log x = 2.303 \log x$). Therefore, with the constant of proportionality in this relation written as $(F/2RT)C$, eqn 7.32 becomes

$$E + \frac{2RT}{F} \ln b = E^\circ + Cb^{1/2} \quad [7.33]$$

The expression on the left is evaluated at a range of molalities, plotted against $b^{1/2}$, and extrapolated to $b = 0$. The intercept at $b^{1/2} = 0$ is the value of E° for the silver/silver-chloride electrode. In precise work, the $b^{1/2}$ term is brought to the left, and a higher-order correction term from the extended Debye–Hückel law is used on the right.

Illustration 7.12 Determining the standard emf of a cell

The emf of the cell $\text{Pt(s)} | \text{H}_2(\text{g}, p^\ominus) | \text{HCl}(\text{aq}, b) | \text{AgCl(s)} | \text{Ag(s)}$ at 25°C has the following values:

$b/(10^{-3} b^\ominus)$	3.215	5.619	9.138	25.63
E/V	0.52053	0.49257	0.46860	0.41824

To determine the standard emf of the cell we draw up the following table, using $2RT/F = 0.05139 \text{ V}$:

$b/(10^{-3} b^\ominus)$	3.215	5.619	9.138	25.63
$\{b/(10^{-3} b^\ominus)\}^{1/2}$	1.793	2.370	3.023	5.063
E/V	0.52053	0.49257	0.46860	0.41824
$E/\text{V} + 0.05139 \ln b$	0.2256	0.2263	0.2273	0.2299

The data are plotted in Fig. 7.16; as can be seen, they extrapolate to $E^\ominus = 0.2232 \text{ V}$.

Self-test 7.9 The data below are for the cell $\text{Pt(s)} | \text{H}_2(\text{g}, p^\ominus) | \text{HBr}(\text{aq}, b) | \text{AgBr(s)} | \text{Ag(s)}$ at 25°C . Determine the standard emf of the cell.

$b/(10^{-4} b^\ominus)$	4.042	8.444	37.19
E/V	0.47381	0.43636	0.36173
			[0.071 V]

Table 7.2 lists standard potentials at 298 K. An important feature of standard emf of cells and standard potentials of electrodes is that they are unchanged if the chemical equation for the cell reaction or a half-reaction is multiplied by a numerical factor. A numerical factor increases the value of the standard Gibbs energy for the reaction. However, it also increases the number of electrons transferred by the same factor, and by eqn 7.27 the value of $E^\ominus$ remains unchanged. A practical consequence is that a cell emf is independent of the physical size of the cell. In other words, cell emf is an intensive property.

The standard potentials in Table 7.2 may be combined to give values for couples that are not listed there. However, to do so, we must take into account the fact that different couples may correspond to the transfer of different numbers of electrons. The procedure is illustrated in the following *Example*.

Example 7.4 Evaluating a standard potential from two others

Given that the standard potentials of the Cu^{2+}/Cu and Cu^+/Cu couples are $+0.340 \text{ V}$ and $+0.522 \text{ V}$, respectively, evaluate $E^\ominus(\text{Cu}^{2+}, \text{Cu}^+)$.

Method First, we note that reaction Gibbs energies may be added (as in a Hess's law analysis of reaction enthalpies). Therefore, we should convert the $E^\ominus$ values to $\Delta G^\ominus$ values by using eqn 7.27, add them appropriately, and then convert the overall $\Delta G^\ominus$ to the required $E^\ominus$ by using eqn 7.27 again. This roundabout procedure is necessary because, as we shall see, although the factor F cancels, the factor ν in general does not.

Answer The electrode reactions are as follows:

Fig. 7.16 The plot and the extrapolation used for the experimental measurement of a standard cell emf. The intercept at $b^{1/2} = 0$ is $E^\ominus$.

Exploration Suppose that the procedure in *Illustration 7.12* results in a plot that deviates from linearity. What might be the cause of this behaviour? How might you modify the procedure to obtain a reliable value of the standard potential?

Synoptic Table 7.2* Standard potentials at 298 K

Couple	$E^\ominus/\text{V}$
$\text{Ce}^{4+}(\text{aq}) + \text{e}^- \rightarrow \text{Ce}^{3+}(\text{aq})$	+1.61
$\text{Cu}^{2+}(\text{aq}) + 2 \text{e}^- \rightarrow \text{Cu(s)}$	+0.34
$\text{H}^+(\text{aq}) + \text{e}^- \rightarrow \frac{1}{2} \text{H}_2(\text{g})$	0
$\text{AgCl(s)} + \text{e}^- \rightarrow \text{Ag(s)} + \text{Cl}^-(\text{aq})$	+0.22
$\text{Zn}^{2+}(\text{aq}) + 2 \text{e}^- \rightarrow \text{Zn(s)}$	-0.76
$\text{Na}^+(\text{aq}) + \text{e}^- \rightarrow \text{Na(s)}$	-2.71

* More values are given in the *Data section*.

The required reaction is

Because (c) = (a) – (b), the standard Gibbs energy of reaction (c) is

$$\Delta_r G^{\circ} = \Delta_r G^{\circ}(\text{a}) - \Delta_r G^{\circ}(\text{b}) = -(-0.158 \text{ V}) \times F$$

Therefore, $E^{\circ} = +0.158 \text{ V}$. Note that the generalization of the calculation we just performed is

$$\nu_c E^{\circ}(\text{c}) = \nu_a E^{\circ}(\text{a}) + \nu_b E^{\circ}(\text{b}) \quad (7.34)$$

A note on good practice Whenever combining standard potentials to obtain the standard potential of a third couple, always work via the Gibbs energies because they are additive, whereas, in general, standard potentials are not.

Self-test 7.10 Calculate the standard potential of the Fe^{3+}/Fe couple from the values for the $\text{Fe}^{3+}/\text{Fe}^{2+}$ and Fe^{2+}/Fe couples. [–0.037 V]

7.9 Applications of standard potentials

Cell emfs are a convenient source of data on equilibrium constants and the Gibbs energies, enthalpies, and entropies of reactions. In practice the standard values of these quantities are the ones normally determined.

(a) The electrochemical series

We have seen that for two redox couples, Ox_1/Red_1 and Ox_2/Red_2 , and the cell

that the cell reaction

is spontaneous as written if $E^{\circ} > 0$, and therefore if $E_2^{\circ} > E_1^{\circ}$. Because in the cell reaction Red_1 reduces Ox_2 , we can conclude that

More briefly: low reduces high.

Illustration 7.13 Using the electrochemical series

Because $E^{\circ}(\text{Zn}^{2+}, \text{Zn}) = -0.76 \text{ V} < E^{\circ}(\text{Cu}^{2+}, \text{Cu}) = +0.34 \text{ V}$, zinc has a thermodynamic tendency to reduce Cu^{2+} ions in aqueous solution.

Table 7.3 shows a part of the **electrochemical series**, the metallic elements (and hydrogen) arranged in the order of their reducing power as measured by their standard potentials in aqueous solution. A metal low in the series (with a lower standard potential) can reduce the ions of metals with higher standard potentials. This conclusion is qualitative. The quantitative value of K is obtained by doing the calculations we have described previously. For example, to determine whether zinc can displace magnesium from aqueous solutions at 298 K, we note that zinc lies above magnesium

in the electrochemical series, so zinc cannot reduce magnesium ions in aqueous solution. Zinc can reduce hydrogen ions, because hydrogen lies higher in the series. However, even for reactions that are thermodynamically favourable, there may be kinetic factors that result in very slow rates of reaction.

The reactions of the electron transport chains of respiration are good applications of this principle.

IMPACT ON BIOCHEMISTRY

17.2 Energy conversion in biological cells

The whole of life's activities depends on the coupling of exergonic and endergonic reactions, for the oxidation of food drives other reactions forward. In biological cells, the energy released by the oxidation of foods is stored in adenosine triphosphate (ATP, **1**). The essence of the action of ATP is its ability to lose its terminal phosphate group by hydrolysis and to form adenosine diphosphate (ADP):

where P_i^- denotes an inorganic phosphate group, such as H_2PO_4^- . The biological standard values for ATP hydrolysis at 37°C (310 K, blood temperature) are $\Delta_r G^\oplus = -31 \text{ kJ mol}^{-1}$, $\Delta_r H^\oplus = -20 \text{ kJ mol}^{-1}$, and $\Delta_r S^\oplus = +34 \text{ J K}^{-1} \text{ mol}^{-1}$. The hydrolysis is therefore exergonic ($\Delta_r G^\oplus < 0$) under these conditions and 31 kJ mol^{-1} is available for driving other reactions. Moreover, because the reaction entropy is large, the reaction Gibbs energy is sensitive to temperature. In view of its exergonicity the ADP—phosphate bond has been called a 'high-energy phosphate bond'. The name is intended to signify a high tendency to undergo reaction, and should not be confused with 'strong' bond. In fact, even in the biological sense it is not of very 'high energy'. The action of ATP depends on it being intermediate in activity. Thus ATP acts as a phosphate donor to a number of acceptors (for example, glucose), but is recharged by more powerful phosphate donors in a number of biochemical processes.

We now use the oxidation of glucose to CO_2 and H_2O by O_2 as an example of how the breakdown of foods is coupled to the formation of ATP in the cell. The process begins with *glycolysis*, a partial oxidation of glucose by nicotinamide adenine dinucleotide (NAD^+ , **2**) to pyruvate ion, $\text{CH}_3\text{COCO}_2^-$, continues with the *citric acid cycle*, which oxidizes pyruvate to CO_2 , and ends with *oxidative phosphorylation*, which reduces O_2 to H_2O . Glycolysis is the main source of energy during *anaerobic metabolism*, a form of metabolism in which inhaled O_2 does not play a role. The citric acid cycle and oxidative phosphorylation are the main mechanisms for the extraction of energy from carbohydrates during *aerobic metabolism*, a form of metabolism in which inhaled O_2 does play a role.

1 ATP

Glycolysis

Glycolysis occurs in the *cytosol*, the aqueous material encapsulated by the cell membrane, and consists of ten enzyme-catalysed reactions. At blood temperature, $\Delta_r G^\ominus = -147 \text{ kJ mol}^{-1}$ for the oxidation of glucose by NAD^+ to pyruvate ions. The oxidation of one glucose molecule is coupled to the conversion of two ADP molecules to two ATP molecules, so the net reaction of glycolysis is:

The standard reaction Gibbs energy is $(-147) - 2(-31) \text{ kJ mol}^{-1} = -85 \text{ kJ mol}^{-1}$. The reaction is exergonic, and therefore spontaneous: the oxidation of glucose is used to ‘recharge’ the ATP. In cells that are deprived of O_2 , pyruvate ion is reduced to lactate ion, $\text{CH}_3\text{C}(\text{OH})\text{CO}_2^-$, by NADH .² Very strenuous exercise, such as bicycle racing, can decrease sharply the concentration of O_2 in muscle cells and the condition known as muscle fatigue results from increased concentrations of lactate ion.

The citric acid cycle

The standard Gibbs energy of combustion of glucose is $-2880 \text{ kJ mol}^{-1}$, so terminating its oxidation at pyruvate is a poor use of resources. In the presence of O_2 , pyruvate is oxidized further during the citric acid cycle and oxidative phosphorylation, which occur in a special compartment of the cell called the *mitochondrion*. The citric acid cycle requires eight enzymes that couple the synthesis of ATP to the oxidation of pyruvate by NAD^+ and flavin adenine dinucleotide (FAD , **3**):

The NADH and FADH_2 go on to reduce O_2 during oxidative phosphorylation, which also produces ATP. The citric acid cycle and oxidative phosphorylation generate as many as 38 ATP molecules for each glucose molecule consumed. Each mole of ATP molecules extracts 31 kJ from the 2880 kJ supplied by 1 mol $\text{C}_6\text{H}_{12}\text{O}_6$ (180 g of

² In yeast, the terminal products are ethanol and CO_2 .

**3 FAD**

glucose), so 1178 kJ is stored for later use. Therefore, aerobic oxidation of glucose is much more efficient than glycolysis.

In the cell, each ATP molecule can be used to drive an endergonic reaction for which $\Delta_r G^\ominus$ does not exceed +31 kJ mol⁻¹. For example, the biosynthesis of sucrose from glucose and fructose can be driven by plant enzymes because the reaction is endergonic to the extent $\Delta_r G^\ominus = +23$ kJ mol⁻¹. The biosynthesis of proteins is strongly endergonic, not only on account of the enthalpy change but also on account of the large decrease in entropy that occurs when many amino acids are assembled into a precisely determined sequence. For instance, the formation of a peptide link is endergonic, with $\Delta_r G^\ominus = +17$ kJ mol⁻¹, but the biosynthesis occurs indirectly and is equivalent to the consumption of three ATP molecules for each link. In a moderately small protein like myoglobin, with about 150 peptide links, the construction alone requires 450 ATP molecules, and therefore about 12 mol of glucose molecules for 1 mol of protein molecules.

The respiratory chain

In the exergonic oxidation of glucose 24 electrons are transferred from each C₆H₁₂O₆ molecule to six O₂ molecules. The half-reactions for the oxidation of glucose and the reduction of O₂ are

The electrons do not flow directly from glucose to O₂. We have already seen that, in biological cells, glucose is oxidized to CO₂ by NAD⁺ and FAD during glycolysis and the citric acid cycle:

4 Coenzyme Q, Q

5 Heme c

In the *respiratory chain*, electrons from the powerful reducing agents NADH and FADH_2 pass through four membrane-bound protein complexes and two mobile electron carriers before reducing O_2 to H_2O . We shall see that the electron transfer reactions drive the synthesis of ATP at three of the membrane protein complexes.

The respiratory chain begins in complex I (NADH-Q oxidoreductase), where NADH is oxidized by coenzyme Q (Q, 4) in a two-electron reaction:

Additional Q molecules are reduced by FADH_2 in complex II (succinate-Q reductase):

Reduced Q migrates to complex III (Q-cytochrome *c* oxidoreductase), which catalyses the reduction of the protein cytochrome *c* (Cyt *c*). Cytochrome *c* contains the haem *c* group (5), the central iron ion of which can exist in oxidation states +3 and +2. The net reaction catalysed by complex III is

Reduced cytochrome *c* carries electrons from complex III to complex IV (cytochrome *c* oxidase), where O_2 is reduced to H_2O :

Fig. 7.17 The general features of a typical mitochondrion.

Oxidative phosphorylation

The reactions that occur in complexes I, III, and IV are sufficiently exergonic to drive the synthesis of ATP in the process called *oxidative phosphorylation*:

We saw above that the phosphorylation of ADP to ATP can be coupled to the exergonic dephosphorylation of other molecules. Indeed, this is the mechanism by which ATP is synthesized during glycolysis and the citric acid cycle. However, oxidative phosphorylation operates by a different mechanism.

The structure of a mitochondrion is shown in Fig. 7.17. The protein complexes associated with the electron transport chain span the inner membrane and phosphorylation takes place in the intermembrane space. The Gibbs energy of the reactions

in complexes I, III, and IV is first used to do the work of moving protons across the mitochondrial membrane. The complexes are oriented asymmetrically in the inner membrane so that the protons abstracted from one side of the membrane can be deposited on the other side. For example, the oxidation of NADH by Q in complex I is coupled to the transfer of four protons across the membrane. The coupling of electron transfer and proton pumping in complexes III and IV contribute further to a gradient of proton concentration across the membrane. Then the enzyme H^+ -ATPase uses the energy stored in the proton gradient to phosphorylate ADP to ATP. Experiments show that 11 molecules of ATP are made for every three molecules of NADH and one molecule of $FADH_2$ that are oxidized by the respiratory chain. The ATP is then hydrolysed on demand to perform useful biochemical work throughout the cell.

The *chemiosmotic theory* proposed by Peter Mitchell explains how H^+ -ATPases synthesize ATP from ADP. The energy stored in a transmembrane proton gradient come from two contributions. First, the difference in activity of H^+ ion results in a difference in molar Gibbs energy across the mitochondrial membrane

$$\Delta G_{m,1} = G_{m,in} - G_{m,out} = RT \ln \frac{a_{H^+,in}}{a_{H^+,out}}$$

Second, there is a membrane potential difference $\Delta\phi = \phi_{in} - \phi_{out}$ that arises from differences in Coulombic interactions on each side of the membrane. The charge difference across a membrane per mole of H^+ ions is $N_A e$, or F , where $F = eN_A$. It follows from *Justification 7.3*, that the molar Gibbs energy difference is then $\Delta G_{m,2} = F\Delta\phi$. Adding this contribution to $\Delta G_{m,1}$ gives the total Gibbs energy stored by the combination of an activity gradient and a membrane potential gradient:

$$\Delta G_m = RT \ln \frac{[H^+]_{in}}{[H^+]_{out}} + F\Delta\phi$$

where we have replaced activities by molar concentrations. This equation also provides an estimate of the Gibbs energy available for phosphorylation of ADP. After using $\ln [H^+] \approx \ln 10 \times \log [H^+]$ and substituting $\Delta pH = pH_{in} - pH_{out} = -\log [H^+]_{in} + \log [H^+]_{out}$, it follows that

$$\Delta G_m = F\Delta\phi - (RT \ln 10) \Delta pH$$

In the mitochondrion, $\Delta pH \approx -1.4$ and $\Delta\phi \approx 0.14$ V, so $\Delta G_m \approx +21.5$ kJ mol⁻¹. Because 31 kJ mol⁻¹ is needed for phosphorylation, we conclude that at least 2 mol H^+ (and probably more) must flow through the membrane for the phosphorylation of 1 mol ADP.

(b) The determination of activity coefficients

Once the standard potential of an electrode in a cell is known, we can use it to determine mean activity coefficients by measuring the cell emf with the ions at the concentration of interest. For example, the mean activity coefficient of the ions in hydrochloric acid of molality b is obtained from eqn 7.32 in the form

$$\ln \gamma_{\pm} = \frac{E^{\ominus} - E}{2RT/F} - \ln b \quad \{7.36\}$$

once E has been measured.

(c) The determination of equilibrium constants

The principal use for standard potentials is to calculate the standard emf of a cell formed from any two electrodes. To do so, we subtract the standard potential of the left-hand electrode from the standard potential of the right-hand electrode:

Fig. 7.18 The glass electrode. It is commonly used in conjunction with a calomel electrode that makes contact with the test solution through a salt bridge.

Fig. 7.19 A section through the wall of a glass electrode.

$$E^\circ = E^\circ(\text{right}) - E^\circ(\text{left}) \quad (7.37)$$

Because $\Delta G^\circ = -\nu FE^\circ$, it then follows that, if the result gives $E^\circ > 0$, then the corresponding cell reaction has $K > 1$.

Illustration 7.14 Calculating an equilibrium constant from standard potentials

A disproportionation is a reaction in which a species is both oxidized and reduced. To study the disproportionation $2 \text{Cu}^+(\text{aq}) \rightarrow \text{Cu}(\text{s}) + \text{Cu}^{2+}(\text{aq})$ we combine the following electrodes:

Right-hand electrode:

Left-hand electrode:

where the standard potentials are measured at 298 K. The standard emf of the cell is therefore

$$E^\circ = +0.52 \text{ V} - 0.16 \text{ V} = +0.36 \text{ V}$$

We can now calculate the equilibrium constant of the cell reaction. Because $\nu = 1$, from eqn 7.30

$$\ln K = \frac{0.36 \text{ V}}{0.025693 \text{ V}} = \frac{0.36}{0.025693}$$

Hence, $K = 1.2 \times 10^6$.

Self-test 7.11 Calculate the solubility constant (the equilibrium constant for the reaction $\text{Hg}_2\text{Cl}_2(\text{s}) \rightleftharpoons \text{Hg}_2^{2+}(\text{aq}) + 2 \text{Cl}^-(\text{aq})$) and the solubility of mercury(I) chloride at 298.15 K. *Hint.* The mercury(I) ion is the diatomic species Hg_2^{2+} .
[2.6×10^{-18} , $8.7 \times 10^{-7} \text{ mol kg}^{-1}$]

(d) Species-selective electrodes

An **ion-selective electrode** is an electrode that generates a potential in response to the presence of a solution of specific ions. An example is the **glass electrode** (Fig. 7.18), which is sensitive to hydrogen ion activity, and has a potential proportional to pH. It is filled with a phosphate buffer containing Cl^- ions, and conveniently has $E = 0$ when the external medium is at pH = 7. It is necessary to calibrate the glass electrode before use with solutions of known pH.

The responsiveness of a glass electrode to the hydrogen ion activity is a result of complex processes at the interface between the glass membrane and the solutions on either side of it. The membrane itself is permeable to Na^+ and Li^+ ions but not to H^+ ions. Therefore, the potential difference across the glass membrane must arise by a mechanism different from that responsible for biological transmembrane potentials (*Impact on biochemistry* 7.2). A clue to the mechanism comes from a detailed inspection of the glass membrane, for each face is coated with a thin layer of hydrated silica (Fig. 7.19). The hydrogen ions in the test solution modify this layer to an extent that depends on their activity in the solution, and the charge modification of the outside layer is transmitted to the inner layer by the Na^+ and Li^+ ions in the glass. The hydrogen ion activity gives rise to a membrane potential by this indirect mechanism.

Electrodes sensitive to hydrogen ions, and hence to pH, are typically glasses based on lithium silicate doped with heavy-metal oxides. The glass can also be made responsive to Na^+ , K^+ , and NH_4^+ ions by being doped with Al_2O_3 and B_2O_3 .

A suitably adapted glass electrode can be used to detect the presence of certain gases. A simple form of a **gas-sensing electrode** consists of a glass electrode contained in an outer sleeve filled with an aqueous solution and separated from the test solution by a membrane that is permeable to gas. When a gas such as sulfur dioxide or ammonia diffuses into the aqueous solution, it modifies its pH, which in turn affects the potential of the glass electrode. The presence of an enzyme that converts a compound, such as urea or an amino acid, into ammonia, which then affects the pH, can be used to detect these organic compounds.

Somewhat more sophisticated devices are used as ion-selective electrodes that give potentials according to the presence of specific ions present in a test solution. In one arrangement, a porous lipophilic (hydrocarbon-attracting) membrane is attached to a small reservoir of a hydrophobic (water-repelling) liquid, such as dioctylphenylphosphonate, that saturates it (Fig. 7.20). The liquid contains an agent, such as $(\text{RO})_2\text{PO}_2^-$ with R a C_8 to C_{18} chain, that acts as a kind of solubilizing agent for the ions with which it can form a complex. The complex's ions are able to migrate through the lipophilic membrane, and hence give rise to a transmembrane potential, which is detected by a silver/silver chloride electrode in the interior of the assembly. Electrodes of this construction can be designed to be sensitive to a variety of ionic species, including calcium, zinc, iron, lead, and copper ions.

In theory, the transmembrane potential should be determined entirely by differences in the activity of the species that the electrode was designed to detect. In practice, a small potential difference, called the **asymmetry potential**, is observed even when the activity of the test species is the same on both sides of the membrane. The asymmetry potential is due to the fact that it is not possible to manufacture a membrane material that has the same structure and the same chemical properties throughout. Furthermore, all species-selective electrodes are sensitive to more than one species. For example, a Na^+ selective electrode also responds, albeit less effectively, to the activity of K^+ ions in the test solution. As a result of these effects, the potential of an electrode sensitive to species X^+ that is also susceptible to interference by species Y^+ is given by a modified form of the Nernst equation:

$$E = E_{\text{ap}} + \beta \frac{RT}{F} \ln(a_{\text{X}^+} + k_{\text{X,Y}} a_{\text{Y}^+}) \quad (7.38)$$

where E_{ap} is the asymmetry potential, β is an experimental parameter that captures deviations from the Nernst equation, and $k_{\text{X,Y}}$ is the **selectivity coefficient** of the electrode and is related to the response of the electrode to the interfering species Y^+ . A value of $\beta = 1$ indicates that the electrode responds to the activity of ions in solution in a way that is consistent with the Nernst equation and, in practice, most species-selective electrodes of high quality have $\beta \approx 1$. The selectivity coefficient, and hence interference effects, can be minimized when designing and manufacturing a species-selective electrode. For precise work, it is necessary to calibrate the response of the electrode by measuring E_{ap} , β , and $k_{\text{X,Y}}$ before performing experiments on solutions of unknown concentration of X^+ .

(e) The determination of thermodynamic functions

The standard emf of a cell is related to the standard reaction Gibbs energy through eqn 7.28 ($\Delta_r G^\circ = -vFE^\circ$). Therefore, by measuring E° we can obtain this important thermodynamic quantity. Its value can then be used to calculate the Gibbs energy of formation of ions by using the convention explained in Section 3.6.

Fig. 7.20 The structure of an ion-selective electrode. Chelated ions are able to migrate through the lipophilic membrane.

Illustration 7.15 *Determining the Gibbs energy of formation of an ion electrochemically*

The cell reaction taking place in

is

Therefore, with $\nu = 1$, we find

$$\Delta_f G^\circ(\text{Ag}^+, \text{aq}) = -(-FE^\circ) = +77.15 \text{ kJ mol}^{-1}$$

which is in close agreement with the value in Table 2.6 of the *Data section*.

The temperature coefficient of the standard cell emf, dE°/dT , gives the standard entropy of the cell reaction. This conclusion follows from the thermodynamic relation $(\partial G/\partial T)_p = -S$ and eqn 7.27, which combine to give

$$\frac{dE^\circ}{dT} = \frac{\Delta_r S^\circ}{\nu F} \quad (7.39)$$

The derivative is complete because E° , like $\Delta_r G^\circ$, is independent of the pressure. Hence we have an electrochemical technique for obtaining standard reaction entropies and through them the entropies of ions in solution.

Finally, we can combine the results obtained so far and use them to obtain the standard reaction enthalpy:

$$\Delta_r H^\circ = \Delta_r G^\circ + T\Delta_r S^\circ = -\nu F \left(E^\circ - T \frac{dE^\circ}{dT} \right) \quad (7.40)$$

This expression provides a non-calorimetric method for measuring $\Delta_r H^\circ$ and, through the convention $\Delta_f H^\circ(\text{H}^+, \text{aq}) = 0$, the standard enthalpies of formation of ions in solution (Section 2.8). Thus, electrical measurements can be used to calculate all the thermodynamic properties with which this chapter began.

Example 7.5 *Using the temperature coefficient of the cell potential*

The standard emf of the cell $\text{Pt(s)} | \text{H}_2(\text{g}) | \text{HBr(aq)} | \text{AgBr(s)} | \text{Ag(s)}$ was measured over a range of temperatures, and the data were fitted to the following polynomial:

$$E^\circ/\text{V} = 0.07131 - 4.99 \times 10^{-4}(T/\text{K} - 298) - 3.45 \times 10^{-6}(T/\text{K} - 298)^2$$

Evaluate the standard reaction Gibbs energy, enthalpy, and entropy at 298 K.

Method The standard Gibbs energy of reaction is obtained by using eqn 7.28 after evaluating E° at 298 K and by using $1 \text{ V C} = 1 \text{ J}$. The standard entropy of reaction is obtained by using eqn 7.39, which involves differentiating the polynomial with respect to T and then setting $T = 298 \text{ K}$. The reaction enthalpy is obtained by combining the values of the standard Gibbs energy and entropy.

Answer At $T = 298 \text{ K}$, $E^\circ = +0.07131 \text{ V}$, so

$$\begin{aligned} \Delta_r G^\circ &= -\nu FE^\circ = -(1) \times (9.6485 \times 10^4 \text{ C mol}^{-1}) \times (+0.07131 \text{ V}) \\ &= -6.880 \times 10^3 \text{ V C mol}^{-1} = -6.880 \text{ kJ mol}^{-1} \end{aligned}$$

The temperature coefficient of the cell potential is

$$\frac{dE^\circ}{dT} = -4.99 \times 10^{-4} \text{ V K}^{-1} - 2(3.45 \times 10^{-6})(T/\text{K} - 298) \text{ V K}^{-1}$$

At $T = 298 \text{ K}$ this expression evaluates to

$$\frac{dE}{dT} = -4.99 \times 10^{-4} \text{ V K}^{-1}$$

So, from eqn 7.39, the reaction entropy is

$$\begin{aligned}\Delta_r S^\circ &= 1 \times (9.6485 \times 10^4 \text{ C mol}^{-1}) \times (-4.99 \times 10^{-4} \text{ V K}^{-1}) \\ &= -48.2 \text{ J K}^{-1} \text{ mol}^{-1}\end{aligned}$$

It then follows that

$$\begin{aligned}\Delta_r H^\circ &= \Delta_r G^\circ + T\Delta_r S^\circ = -6.880 \text{ kJ mol}^{-1} + (298 \text{ K}) \times (-0.0482 \text{ kJ K}^{-1} \text{ mol}^{-1}) \\ &= -21.2 \text{ kJ mol}^{-1}\end{aligned}$$

One difficulty with this procedure lies in the accurate measurement of small temperature coefficients of cell potential. Nevertheless, it is another example of the striking ability of thermodynamics to relate the apparently unrelated, in this case to relate electrical measurements to thermal properties.

Self-test 7.12 Predict the standard potential of the Harned cell at 303 K from tables of thermodynamic data. [+0.2222 V]

Checklist of key ideas

☐ 1. The extent of reaction (ξ) is defined such that, when the extent of reaction changes by a finite amount $\Delta\xi$, the amount of A present changes from $n_{A,0}$ to $n_{A,0} - \Delta\xi$. ☐ 2. The reaction Gibbs energy is the slope of the graph of the Gibbs energy plotted against the extent of reaction: $\Delta_r G = (\partial G / \partial \xi)_{p,T}$; at equilibrium, $\Delta_r G = 0$. ☐ 3. An exergonic reaction is a reaction for which $\Delta_r G < 0$; such a reaction can be used to drive another process. An endergonic reaction is a reaction for which $\Delta_r G > 0$. ☐ 4. The general expression for $\Delta_r G$ at an arbitrary stage of the reaction is $\Delta_r G = \Delta_r G^\circ + RT \ln Q$. ☐ 5. The equilibrium constant (K) may be written in terms of $\Delta_r G^\circ$ as $\Delta_r G^\circ = -RT \ln K$. ☐ 6. The standard reaction Gibbs energy may be calculated from standard Gibbs energies of formation, $\Delta_r G^\circ = \sum_{\text{Products}} \nu \Delta_f G^\circ - \sum_{\text{Reactants}} \nu \Delta_f G^\circ = \sum_j \nu_j \Delta_f G^\circ(j)$. ☐ 7. Thermodynamic equilibrium constant is an equilibrium constant K expressed in terms of activities (or fugacities): $K = \left(\prod_j a_j^{\nu_j} \right)_{\text{equilibrium}}.$	☐ 8. A catalyst does not affect the equilibrium constant. ☐ 9. Changes in pressure do not affect the equilibrium constant: $(\partial K / \partial p)_T = 0$. However, partial pressures and concentrations can change in response to a change in pressure. ☐ 10. Le Chatelier's principle states that a system at equilibrium, when subjected to a disturbance, responds in a way that tends to minimize the effect of the disturbance. ☐ 11. Increased temperature favours the reactants in exothermic reactions and the products in endothermic reactions. ☐ 12. The temperature dependence of the equilibrium constant is given by the van 't Hoff equation: $d \ln K / dT = \Delta_r H^\circ / RT^2$. To calculate K at one temperature in terms of its value at another temperature, and provided $\Delta_r H^\circ$ is independent of temperature, we use $\ln K_2 - \ln K_1 = -(\Delta_r H^\circ / R)(1/T_2 - 1/T_1)$. ☐ 13. A galvanic cell is an electrochemical cell that produces electricity as a result of the spontaneous reaction occurring inside it. An electrolytic cell is an electrochemical cell in which a non-spontaneous reaction is driven by an external source of current. ☐ 14. Oxidation is the removal of electrons from a species; reduction is the addition of electrons to a species; a redox

reaction is a reaction in which there is a transfer of electrons from one species to another.

- ☐ 15. The anode is the electrode at which oxidation occurs. The cathode is the electrode at which reduction occurs.
- ☐ 16. The electromotive force (emf) is the cell potential when it is balanced by an exactly opposing source of potential so that the cell reaction occurs reversibly, the composition is constant, and no current flows.
- ☐ 17. The cell potential and the reaction Gibbs energy are related by $-vFE = \Delta_r G$.
- ☐ 18. The standard emf is the standard reaction Gibbs energy expressed as a potential: $E^\circ = \Delta_r G^\circ / vF$.
- ☐ 19. The Nernst equation is the equation for the emf of a cell in terms of the composition: $E = E^\circ - (RT/vF) \ln Q$.
- ☐ 20. The equilibrium constant for a cell reaction is related to the standard emf by $\ln K = vFE^\circ / RT$.
- ☐ 21. The standard potential of a couple (E°) is the standard emf of a cell in which a couple forms the right-hand electrode and the standard hydrogen electrode is the left-hand electrode.
- ☐ 22. To calculate the standard emf, form the difference of electrode potentials: $E^\circ = E^\circ(\text{right}) - E^\circ(\text{left})$.
- ☐ 23. The temperature coefficient of cell potential is given by $dE^\circ/dT = \Delta_r S^\circ / vF$.
- ☐ 24. The standard reaction entropy and enthalpy are calculated from the temperature dependence of the standard emf by: $\Delta_r S^\circ = vF dE^\circ/dT$, $\Delta_r H^\circ = -v(FE^\circ - T dE^\circ/dT)$.

Discussion questions

- 7.1** Explain how the mixing of reactants and products affects the position of chemical equilibrium.
- 7.2** Suggest how the thermodynamic equilibrium constant may respond differently to changes in pressure and temperature from the equilibrium constant expressed in terms of partial pressures.
- 7.3** Account for Le Chatelier's principle in terms of thermodynamic quantities.
- 7.4** Explain the molecular basis of the van 't Hoff equation for the temperature dependence of K .
- 7.5** (a) How may an Ellingham diagram be used to decide whether one metal may be used to reduce the oxide of another metal? (b) Use the Ellingham diagram in Fig. 7.10 to identify the lowest temperature at which zinc oxide can be reduced to zinc metal by carbon.
- 7.6** Distinguish between cell potential and electromotive force and explain why the latter is related to thermodynamic quantities.
- 7.7** Describe the contributions to the emf of cells formed by combining the electrodes specified in Table 7.1.
- 7.8** Describe a method for the determination of a standard potential of a redox couple.
- 7.9** Devise a method for the determination of the pH of an aqueous solution.

Exercises

7.1(a) At 2257 K and 1.00 atm total pressure, water is 1.77 per cent dissociated at equilibrium by way of the reaction $2\text{H}_2\text{O}(\text{g}) \rightleftharpoons 2\text{H}_2(\text{g}) + \text{O}_2(\text{g})$. Calculate (a) K , (b) $\Delta_r G^\circ$, and (c) $\Delta_r G$ at this temperature.

7.1(b) For the equilibrium, $\text{N}_2\text{O}_4(\text{g}) \rightleftharpoons 2\text{NO}_2(\text{g})$, the degree of dissociation, α , at 298 K is 0.201 at 1.00 bar total pressure. Calculate (a) $\Delta_r G$, (2) K , and (3) $\Delta_r G^\circ$ at 298 K.

7.2(a) Dinitrogen tetroxide is 18.46 per cent dissociated at 25°C and 1.00 bar in the equilibrium $\text{N}_2\text{O}_4(\text{g}) \rightleftharpoons 2\text{NO}_2(\text{g})$. Calculate (a) K at 25°C, (b) $\Delta_r G^\circ$, (c) K at 100°C given that $\Delta_r H^\circ = +57.2\text{ kJ mol}^{-1}$ over the temperature range.

7.2(b) Molecular bromine is 24 per cent dissociated at 1600 K and 1.00 bar in the equilibrium $\text{Br}_2(\text{g}) \rightleftharpoons 2\text{Br}(\text{g})$. Calculate (a) K at 25°C, (b) $\Delta_r G^\circ$, (c) K at 2000°C given that $\Delta_r H^\circ = +112\text{ kJ mol}^{-1}$ over the temperature range.

7.3(a) From information in the *Data section*, calculate the standard Gibbs energy and the equilibrium constant at (a) 298 K and (b) 400 K for the reaction $\text{PbO}(\text{s}) + \text{CO}(\text{g}) \rightleftharpoons \text{Pb}(\text{s}) + \text{CO}_2(\text{g})$. Assume that the reaction enthalpy is independent of temperature.

7.3(b) From information in the *Data section*, calculate the standard Gibbs energy and the equilibrium constant at (a) 25°C and (b) 50°C for the reaction $\text{CH}_4(\text{g}) + 3\text{Cl}_2(\text{g}) \rightleftharpoons \text{CHCl}_3(\text{l}) + 3\text{HCl}(\text{g})$. Assume that the reaction enthalpy is independent of temperature.

7.4(a) In the gas-phase reaction $2\text{A} + \text{B} \rightleftharpoons 3\text{C} + 2\text{D}$, it was found that, when 1.00 mol A, 2.00 mol B, and 1.00 mol D were mixed and allowed to come to equilibrium at 25°C, the resulting mixture contained 0.90 mol C at a total pressure of 1.00 bar. Calculate (a) the mole fractions of each species at equilibrium, (b) K_x , (c) K , and (d) $\Delta_r G^\circ$.

7.4(b) In the gas-phase reaction $\text{A} + \text{B} \rightleftharpoons \text{C} + 2\text{D}$, it was found that, when 2.00 mol A, 1.00 mol B, and 3.00 mol D were mixed and allowed to come to equilibrium at 25°C, the resulting mixture contained 0.79 mol C at a total pressure of 1.00 bar. Calculate (a) the mole fractions of each species at equilibrium, (b) K_x , (c) K , and (d) $\Delta_r G^\circ$.

7.5(a) The standard reaction enthalpy of $\text{Zn}(\text{s}) + \text{H}_2\text{O}(\text{g}) \rightarrow \text{ZnO}(\text{s}) + \text{H}_2(\text{g})$ is approximately constant at $+224\text{ kJ mol}^{-1}$ from 920 K up to 1280 K. The standard reaction Gibbs energy is $+33\text{ kJ mol}^{-1}$ at 1280 K. Estimate the temperature at which the equilibrium constant becomes greater than 1.

7.5(b) The standard enthalpy of a certain reaction is approximately constant at $+125\text{ kJ mol}^{-1}$ from 800 K up to 1500 K. The standard reaction Gibbs energy is $+22\text{ kJ mol}^{-1}$ at 1120 K. Estimate the temperature at which the equilibrium constant becomes greater than 1.

7.6(a) The equilibrium constant of the reaction $2\text{C}_3\text{H}_6(\text{g}) \rightleftharpoons \text{C}_2\text{H}_4(\text{g}) + \text{C}_4\text{H}_8(\text{g})$ is found to fit the expression $\ln K = A + B/T + C/T^2$ between 300 K and 600 K, with $A = -1.04$, $B = -1088\text{ K}$, and $C = 1.51 \times 10^5\text{ K}^2$. Calculate the standard reaction enthalpy and standard reaction entropy at 400 K.

7.6(b) The equilibrium constant of a reaction is found to fit the expression $\ln K = A + B/T + C/T^3$ between 400 K and 500 K with $A = -2.04$, $B = -1176\text{ K}$, and $C = 2.1 \times 10^7\text{ K}^3$. Calculate the standard reaction enthalpy and standard reaction entropy at 450 K.

7.7(a) The standard reaction Gibbs energy of the isomerization of borneol ($\text{C}_{10}\text{H}_{17}\text{OH}$) to isoborneol in the gas phase at 503 K is $+9.4\text{ kJ mol}^{-1}$. Calculate the reaction Gibbs energy in a mixture consisting of 0.15 mol of borneol and 0.30 mol of isoborneol when the total pressure is 600 Torr.

7.7(b) The equilibrium pressure of H_2 over solid uranium and uranium hydride, UH_3 , at 500 K is 139 Pa. Calculate the standard Gibbs energy of formation of $\text{UH}_3(\text{s})$ at 500 K.

7.8(a) Calculate the percentage change in K_x for the reaction $\text{H}_2\text{CO}(\text{g}) \rightleftharpoons \text{CO}(\text{g}) + \text{H}_2(\text{g})$ when the total pressure is increased from 1.0 bar to 2.0 bar at constant temperature.

7.8(b) Calculate the percentage change in K_x for the reaction $\text{CH}_3\text{OH}(\text{g}) + \text{NOCl}(\text{g}) \rightleftharpoons \text{HCl}(\text{g}) + \text{CH}_3\text{NO}_2(\text{g})$ when the total pressure is increased from 1.0 bar to 2.0 bar at constant temperature.

7.9(a) The equilibrium constant for the gas-phase isomerization of borneol ($\text{C}_{10}\text{H}_{17}\text{OH}$) to isoborneol at 503 K is 0.106. A mixture consisting of 7.50 g of borneol and 14.0 g of isoborneol in a container of volume 5.0 dm^3 is heated to 503 K and allowed to come to equilibrium. Calculate the mole fractions of the two substances at equilibrium.

7.9(b) The equilibrium constant for the reaction $\text{N}_2(\text{g}) + \text{O}_2(\text{g}) \rightleftharpoons 2\text{NO}(\text{g})$ is 1.69×10^{-3} at 2300 K. A mixture consisting of 5.0 g of nitrogen and 2.0 g of oxygen in a container of volume 1.0 dm^3 is heated to 2300 K and allowed to come to equilibrium. Calculate the mole fraction of NO at equilibrium.

7.10(a) What is the standard enthalpy of a reaction for which the equilibrium constant is (a) doubled, (b) halved when the temperature is increased by 10 K at 298 K?

7.10(b) What is the standard enthalpy of a reaction for which the equilibrium constant is (a) doubled, (b) halved when the temperature is increased by 15 K at 310 K?

7.11(a) The standard Gibbs energy of formation of $\text{NH}_3(\text{g})$ is -16.5 kJ mol^{-1} at 298 K. What is the reaction Gibbs energy when the partial pressures of the N_2 , H_2 , and NH_3 (treated as perfect gases) are 3.0 bar, 1.0 bar, and 4.0 bar, respectively? What is the spontaneous direction of the reaction in this case?

7.11(b) The dissociation vapour pressure of NH_4Cl at 427°C is 608 kPa but at 459°C it has risen to 1115 kPa. Calculate (a) the equilibrium constant, (b) the standard reaction Gibbs energy, (c) the standard enthalpy, (d) the standard entropy of dissociation, all at 427°C. Assume that the vapour behaves as a perfect gas and that ΔH° and ΔS° are independent of temperature in the range given.

7.12(a) Estimate the temperature at which CaCO_3 (calcite) decomposes.

7.12(b) Estimate the temperature at which $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ undergoes dehydration.

7.13(a) For $\text{CaF}_2(\text{s}) \rightleftharpoons \text{Ca}^{2+}(\text{aq}) + 2\text{F}^{-}(\text{aq})$, $K = 3.9 \times 10^{-11}$ at 25°C and the standard Gibbs energy of formation of $\text{CaF}_2(\text{s})$ is -1167 kJ mol^{-1} . Calculate the standard Gibbs energy of formation of $\text{CaF}_2(\text{aq})$.

7.13(b) For $\text{PbI}_2(\text{s}) \rightleftharpoons \text{Pb}^{2+}(\text{aq}) + 2\text{I}^{-}(\text{aq})$, $K = 1.4 \times 10^{-8}$ at 25°C and the standard Gibbs energy of formation of $\text{PbI}_2(\text{s})$ is $-173.64\text{ kJ mol}^{-1}$. Calculate the standard Gibbs energy of formation of $\text{PbI}_2(\text{aq})$.

7.14(a) Write the cell reaction and electrode half-reactions and calculate the standard emf of each of the following cells:

- (a) $\text{Zn} | \text{ZnSO}_4(\text{aq}) || \text{AgNO}_3(\text{aq}) | \text{Ag}$
- (b) $\text{Cd} | \text{CdCl}_2(\text{aq}) || \text{HNO}_3(\text{aq}) | \text{H}_2(\text{g}) | \text{Pt}$
- (c) $\text{Pt} | \text{K}_3[\text{Fe}(\text{CN})_6](\text{aq}), \text{K}_4[\text{Fe}(\text{CN})_6](\text{aq}) || \text{CrCl}_3(\text{aq}) | \text{Cr}$

7.14(b) Write the cell reaction and electrode half-reactions and calculate the standard emf of each of the following cells:

- (a) $\text{Pt} | \text{Cl}_2(\text{g}) | \text{HCl}(\text{aq}) || \text{K}_2\text{CrO}_4(\text{aq}) | \text{Ag}_2\text{CrO}_4(\text{s}) | \text{Ag}$
- (b) $\text{Pt} | \text{Fe}^{3+}(\text{aq}), \text{Fe}^{2+}(\text{aq}) || \text{Sn}^{4+}(\text{aq}), \text{Sn}^{2+}(\text{aq}) | \text{Pt}$
- (c) $\text{Cu} | \text{Cu}^{2+}(\text{aq}) || \text{Mn}^{2+}(\text{aq}), \text{H}^{+}(\text{aq}) | \text{MnO}_2(\text{s}) | \text{Pt}$

7.15(a) Devise cells in which the following are the reactions and calculate the standard emf in each case:

- (a) $\text{Zn(s)} + \text{CuSO}_4(\text{aq}) \rightarrow \text{ZnSO}_4(\text{aq}) + \text{Cu(s)}$
- (b) $2 \text{AgCl(s)} + \text{H}_2(\text{g}) \rightarrow 2 \text{HCl(aq)} + 2 \text{Ag(s)}$
- (c) $2 \text{H}_2(\text{g}) + \text{O}_2(\text{g}) \rightarrow 2 \text{H}_2\text{O(l)}$

7.15(b) Devise cells in which the following are the reactions and calculate the standard emf in each case:

- (a) $2 \text{Na(s)} + 2 \text{H}_2\text{O(l)} \rightarrow 2 \text{NaOH(aq)} + \text{H}_2(\text{g})$
- (b) $\text{H}_2(\text{g}) + \text{I}_2(\text{g}) \rightarrow 2 \text{HI(aq)}$
- (c) $\text{H}_3\text{O}^+(\text{aq}) + \text{OH}^-(\text{aq}) \rightarrow 2 \text{H}_2\text{O(l)}$

7.16(a) Use the Debye–Hückel limiting law and the Nernst equation to estimate the potential of the cell $\text{Ag}|\text{AgBr(s)}|\text{KBr(aq, 0.050 mol kg}^{-1})||\text{Cd(NO}_3)_2(\text{aq, 0.010 mol kg}^{-1})|\text{Cd}$ at 25°C.

7.16(b) Consider the cell $\text{Pt}|\text{H}_2(\text{g, } p^\ominus)|\text{HCl(aq)}|\text{AgCl(s)}|\text{Ag}$, for which the cell reaction is $2 \text{AgCl(s)} + \text{H}_2(\text{g}) \rightarrow 2 \text{Ag(s)} + 2 \text{HCl(aq)}$. At 25°C and a molality of HCl of $0.010 \text{ mol kg}^{-1}$, $E = +0.4658 \text{ V}$. (a) Write the Nernst

equation for the cell reaction. (b) Calculate $\Delta_r G$ for the cell reaction.

(c) Assuming that the Debye–Hückel limiting law holds at this concentration, calculate $E^\ominus(\text{AgCl, Ag})$.

7.17(a) Calculate the equilibrium constants of the following reactions at 25°C from standard potential data:

- (a) $\text{Sn(s)} + \text{Sn}^{4+}(\text{aq}) \rightleftharpoons 2 \text{Sn}^{2+}(\text{aq})$
- (b) $\text{Sn(s)} + 2 \text{AgCl(s)} \rightleftharpoons \text{SnCl}_2(\text{aq}) + 2 \text{Ag(s)}$

7.17(b) Calculate the equilibrium constants of the following reactions at 25°C from standard potential data:

- (a) $\text{Sn(s)} + \text{CuSO}_4(\text{aq}) \rightleftharpoons \text{Cu(s)} + \text{SnSO}_4(\text{aq})$
- (b) $\text{Cu}^{2+}(\text{aq}) + \text{Cu(s)} \rightleftharpoons 2 \text{Cu}^+(\text{aq})$

7.18(a) The emf of the cell $\text{Ag}|\text{AgI(s)}|\text{AgI(aq)}|\text{Ag}$ is $+0.9509 \text{ V}$ at 25°C. Calculate (a) the solubility product of AgI and (b) its solubility.

7.18(b) The emf of the cell $\text{Bi}|\text{Bi}_2\text{S}_3(\text{s})|\text{Bi}_2\text{S}_3(\text{aq})|\text{Bi}$ is -0.96 V at 25°C. Calculate (a) the solubility product of Bi_2S_3 and (b) its solubility.

Problems*

Numerical problems

7.1 The equilibrium constant for the reaction, $\text{I}_2(\text{s}) + \text{Br}_2(\text{g}) \rightleftharpoons 2 \text{IBr(g)}$ is 0.164 at 25°C. (a) Calculate $\Delta_r G^\ominus$ for this reaction. (b) Bromine gas is introduced into a container with excess solid iodine. The pressure and temperature are held at 0.164 atm and 25°C, respectively. Find the partial pressure of IBr(g) at equilibrium. Assume that all the bromine is in the liquid form and that the vapour pressure of iodine is negligible. (c) In fact, solid iodine has a measurable vapour pressure at 25°C. In this case, how would the calculation have to be modified?

7.2 Consider the dissociation of methane, $\text{CH}_4(\text{g})$, into the elements $\text{H}_2(\text{g})$ and C(s, graphite) . (a) Given that $\Delta_f H^\ominus(\text{CH}_4, \text{g}) = -74.85 \text{ kJ mol}^{-1}$ and that $\Delta_f S^\ominus(\text{CH}_4, \text{g}) = -80.67 \text{ J K}^{-1} \text{ mol}^{-1}$ at 298 K, calculate the value of the equilibrium constant at 298 K. (b) Assuming that $\Delta_f H^\ominus$ is independent of temperature, calculate K at 50°C. (c) Calculate the degree of dissociation, α , of methane at 25°C and a total pressure of 0.010 bar. (d) Without doing any numerical calculations, explain how the degree of dissociation for this reaction will change as the pressure and temperature are varied.

7.3 The equilibrium pressure of H_2 over U(s) and $\text{UH}_3(\text{s})$ between 450 K and 715 K fits the expression $\ln(p/\text{Pa}) = A + B/T + C \ln(T/\text{K})$, with $A = 69.32$, $B = -1.464 \times 10^4 \text{ K}$, and $C = -5.65$. Find an expression for the standard enthalpy of formation of $\text{UH}_3(\text{s})$ and from it calculate $\Delta_r C_p^\ominus$.

7.4 The degree of dissociation, α , of $\text{CO}_2(\text{g})$ into CO(g) and $\text{O}_2(\text{g})$ at high temperatures was found to vary with temperature as follows:

T/K	1395	1443	1498
$\alpha/10^{-4}$	1.44	2.50	4.71

Assuming $\Delta_r H^\ominus$ to be constant over this temperature range, calculate K , $\Delta_r G^\ominus$, $\Delta_r H^\ominus$, and $\Delta_r S^\ominus$. Make any justifiable approximations.

7.5 The standard reaction enthalpy for the decomposition of $\text{CaCl}_2 \cdot \text{NH}_3(\text{s})$ into $\text{CaCl}_2(\text{s})$ and $\text{NH}_3(\text{g})$ is nearly constant at $+78 \text{ kJ mol}^{-1}$ between 350 K and 470 K. The equilibrium pressure of NH_3 in the presence of $\text{CaCl}_2 \cdot \text{NH}_3$ is

1.71 kPa at 400 K. Find an expression for the temperature dependence of $\Delta_r G^\ominus$ in the same range.

7.6 Calculate the equilibrium constant of the reaction $\text{CO(g)} + \text{H}_2(\text{g}) \rightleftharpoons \text{H}_2\text{CO(g)}$ given that, for the production of liquid formaldehyde, $\Delta_r G^\ominus = +28.95 \text{ kJ mol}^{-1}$ at 298 K and that the vapour pressure of formaldehyde is 1500 Torr at that temperature.

7.7 Acetic acid was evaporated in container of volume 21.45 cm^3 at 437 K and at an external pressure of 101.9 kPa, and the container was then sealed. The mass of acid present in the sealed container was 0.0519 g. The experiment was repeated with the same container but at 471 K, and it was found that 0.0380 g of acetic acid was present. Calculate the equilibrium constant for the dimerization of the acid in the vapour and the enthalpy of vaporization.

7.8 A sealed container was filled with 0.300 mol $\text{H}_2(\text{g})$, 0.400 mol $\text{I}_2(\text{g})$, and 0.200 mol HI(g) at 870 K and total pressure 1.00 bar. Calculate the amounts of the components in the mixture at equilibrium given that $K = 870$ for the reaction $\text{H}_2(\text{g}) + \text{I}_2(\text{g}) \rightleftharpoons 2 \text{HI(g)}$.

7.9 The dissociation of I_2 can be monitored by measuring the total pressure, and three sets of results are as follows:

T/K	973	1073	1173
100p/atm	6.244	7.500	9.181
$10^4 n_1$	2.4709	2.4555	2.4366

where n_1 is the amount of I atoms per mole of I_2 molecules in the mixture, which occupied 342.68 cm^3 . Calculate the equilibrium constants of the dissociation and the standard enthalpy of dissociation at the mean temperature.

7.10‡ Thorn *et al.* carried out a study of $\text{Cl}_2\text{O(g)}$ by photoelectron ionization (R.P. Thorn, L.J. Stief, S.-C. Kuo, and R.B. Klemm, *J. Phys. Chem.* **100**, 14178 (1996)). From their measurements, they report $\Delta_f H^\ominus(\text{Cl}_2\text{O}) = +77.2 \text{ kJ mol}^{-1}$. They combined this measurement with literature data on the reaction $\text{Cl}_2\text{O(g)} + \text{H}_2\text{O(g)} \rightarrow 2 \text{HOCl(g)}$, for which $K = 8.2 \times 10^{-2}$ and $\Delta_r S^\ominus =$

* Problems denoted with the symbol ‡ were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

+16.38 J K⁻¹ mol⁻¹, and with readily available thermodynamic data on water vapour to report a value for $\Delta_f H^\circ(\text{HOCl})$. Calculate that value. All quantities refer to 298 K.

7.11‡ The 1980s saw reports of $\Delta_f H^\circ(\text{SiH}_2)$ ranging from 243 to 289 kJ mol⁻¹. For example, the lower value was cited in the review article by R. Walsh (*Acc. Chem. Res.* **14**, 246 (1981)); Walsh later leaned towards the upper end of the range (H.M. Frey, R. Walsh, and I.M. Watts, *J. Chem. Soc., Chem. Commun.* 1189 (1986)). The higher value was reported in S.-K. Shin and J.L. Beauchamp, *J. Phys. Chem.* **90**, 1507 (1986). If the standard enthalpy of formation is uncertain by this amount, by what factor is the equilibrium constant for the formation of SiH₂ from its elements uncertain at (a) 298 K, (b) 700 K?

7.12 Fuel cells provide electrical power for spacecraft (as in the NASA space shuttles) and also show promise as power sources for automobiles. Hydrogen and carbon monoxide have been investigated for use in fuel cells, so their solubilities in molten salts are of interest. Their solubilities in a molten NaNO₃/KNO₃ mixture were examined (E. Desimoni and P.G. Zambonin, *J. Chem. Soc. Faraday Trans. 1*, 2014 (1973)) with the following results:

$$\log s_{\text{H}_2} = -5.39 - \frac{980}{T/\text{K}} \quad \log s_{\text{CO}} = -5.98 - \frac{980}{T/\text{K}}$$

where s is the solubility in mol cm⁻³ bar⁻¹. Calculate the standard molar enthalpies of solution of the two gases at 570 K.

7.13 Given that $\Delta_r G^\circ = -212.7$ kJ mol⁻¹ for the reaction in the Daniell cell at 25°C, and $b(\text{CuSO}_4) = 1.0 \times 10^{-3}$ mol kg⁻¹ and $b(\text{ZnSO}_4) = 3.0 \times 10^{-3}$ mol kg⁻¹, calculate (a) the ionic strengths of the solutions, (b) the mean ionic activity coefficients in the compartments, (c) the reaction quotient, (d) the standard cell potential, and (e) the cell potential. (Take $\gamma_+ = \gamma_- = \gamma_\pm$ in the respective compartments.)

7.14 A fuel cell develops an electric potential from the chemical reaction between reagents supplied from an outside source. What is the emf of a cell fuelled by (a) hydrogen and oxygen, (b) the combustion of butane at 1.0 bar and 298 K?

7.15 Although the hydrogen electrode may be conceptually the simplest electrode and is the basis for our reference state of electrical potential in electrochemical systems, it is cumbersome to use. Therefore, several substitutes for it have been devised. One of these alternatives is the quinhydrone electrode (quinhydrone, Q · QH₂, is a complex of quinone, C₆H₄O₂ = Q, and hydroquinone, C₆H₄O₂H₂ = QH₂). The electrode half-reaction is Q(aq) + 2 H⁺(aq) + 2 e⁻ → QH₂(aq), $E^\circ = +0.6994$ V. If the cell Hg|Hg₂Cl₂(s)|HCl(aq)|Q · QH₂|Au is prepared, and the measured cell potential is +0.190 V, what is the pH of the HCl solution? Assume that the Debye–Hückel limiting law is applicable.

7.16 Consider the cell, Zn(s)|ZnCl₂(0.0050 mol kg⁻¹)|Hg₂Cl₂(s)|Hg(l), for which the cell reaction is Hg₂Cl₂(s) + Zn(s) → 2 Hg(l) + 2 Cl⁻(aq) + Zn²⁺(aq). Given that $E^\circ(\text{Zn}^{2+}, \text{Zn}) = -0.7628$ V, $E^\circ(\text{Hg}_2\text{Cl}_2, \text{Hg}) = +0.2676$ V, and that the emf is +1.2272 V, (a) write the Nernst equation for the cell. Determine (b) the standard emf, (c) $\Delta_r G$, $\Delta_r G^\circ$, and K for the cell reaction, (d) the mean ionic activity and activity coefficient of ZnCl₂ from the measured cell potential, and (e) the mean ionic activity coefficient of ZnCl₂ from the Debye–Hückel limiting law. (f) Given that $(\partial E/\partial T)_p = -4.52 \times 10^{-4}$ V K⁻¹. Calculate ΔS and ΔH .

7.17 The emf of the cell Pt|H₂(g, p°)|HCl(aq, b)|Hg₂Cl₂(s)|Hg(l) has been measured with high precision (G.J. Hills and D.J.G. Ives, *J. Chem. Soc.*, 311 (1951)) with the following results at 25°C:

$b/(\text{mmol kg}^{-1})$	1.6077	3.0769	5.0403	7.6938	10.9474
E/V	0.60080	0.56825	0.54366	0.52267	0.50532

Determine the standard emf of the cell and the mean activity coefficient of HCl at these molalities. (Make a least-squares fit of the data to the best straight line.)

7.18 Careful measurements of the emf of the cell Pt|H₂(g, p°)|NaOH(aq, 0.0100 mol kg⁻¹), NaCl(aq, 0.01125 mol kg⁻¹)|AgCl(s)|Ag have been reported (C.P. Bezboruah, M.F.G.F.C. Camoes, A.K. Covington, and J.V. Dobson, *J. Chem. Soc. Faraday Trans. 1* **69**, 949 (1973)). Among the data is the following information:

$\theta/^\circ\text{C}$	20.0	25.0	30.0
E/V	1.04774	1.04864	1.04942

Calculate pK_w at these temperatures and the standard enthalpy and entropy of the autoprotolysis of water at 25.0°C.

7.19 Measurements of the emf of cells of the type Ag|AgX(s)MX(b_1)|M_xHg|MX(b_2)|AgX(s)|Ag, where M_xHg denotes an amalgam and the electrolyte is an alkali metal halide dissolved in ethylene glycol, have been reported (U. Sen, *J. Chem. Soc. Faraday Trans. 1* **69**, 2006 (1973)) and some values for LiCl are given below. Estimate the activity coefficient at the concentration marked * and then use this value to calculate activity coefficients from the measured cell potential at the other concentrations. Base your answer on the following version of the extended Debye–Hückel law:

$$\log \gamma = -\frac{AI^{1/2}}{1 - BI^{1/2}} + kI$$

with $A = 1.461$, $B = 1.70$, $k = 0.20$, and $I = b/b^\circ$. For $b_2 = 0.09141$ mol kg⁻¹:

$b_1/(\text{mol kg}^{-1})$	0.0555	0.09141*	0.1652	0.2171	1.040	1.350
E/V	-0.0220	0.0000	0.0263	0.0379	0.1156	0.1336

7.20 The standard potential of the AgCl/Ag, Cl⁻ couple has been measured very carefully over a range of temperature (R.G. Bates and V.E. Bowers, *J. Res. Nat. Bur. Stand.* **53**, 283 (1954)) and the results were found to fit the expression

$$E^\circ/\text{V} = 0.23659 - 4.8564 \times 10^{-4}(\theta/^\circ\text{C}) - 3.4205 \times 10^{-6}(\theta/^\circ\text{C})^2 + 5.869 \times 10^{-9}(\theta/^\circ\text{C})^3$$

Calculate the standard Gibbs energy and enthalpy of formation of Cl⁻(aq) and its entropy at 298 K.

7.21‡ (a) Derive a general relation for $(\partial E/\partial p)_{T,n}$ for electrochemical cells employing reactants in any state of matter. (b) E. Cohen and K. Piepenbroek (*Z. Physik. Chem.* **167A**, 365 (1933)) calculated the change in volume for the reaction $\text{TiCl(s)} + \text{CNS}^-(\text{aq}) \rightarrow \text{TiCNS(s)} + \text{Cl}^-(\text{aq})$ at 30°C from density data and obtained $\Delta_r V = -2.666 \pm 0.080$ cm³ mol⁻¹. They also measured the emf of the cell $\text{Ti(Hg)}|\text{TiCNS(s)}|\text{KCNS}:\text{KCl}|\text{TiCl}|\text{Ti(Hg)}$ at pressures up to 1500 atm. Their results are given in the following table:

p/atm	1.00	250	500	750	1000	1250	1500
E/mV	8.56	9.27	9.98	10.69	11.39	12.11	12.82

From this information, obtain $(\partial E/\partial p)_{T,n}$ at 30°C and compare to the value obtained from $\Delta_r V$. (c) Fit the data to a polynomial for E against p . How constant is $(\partial E/\partial p)_{T,n}$? (d) From the polynomial, estimate an effective isothermal compressibility for the cell as a whole.

7.22‡ The table below summarizes the emf observed for the cell $\text{Pd}|\text{H}_2(\text{g}, 1 \text{ bar})|\text{BH}(\text{aq}, b), \text{B}(\text{aq}, b)|\text{AgCl(s)}|\text{Ag}$. Each measurement is made at equimolar concentrations of 2-aminopyridinium chloride (BH) and 2-aminopyridine (B). The data are for 25°C and it is found that $E^\circ = 0.22251$ V. Use the data to determine pK_a for the acid at 25°C and the mean activity coefficient ($\gamma_\pm$) of BH as a function of molality (b) and ionic strength (I). Use the extended Debye–Hückel equation for the mean activity coefficient in the form

$$-\log \gamma_\pm = \frac{AI^{1/2}}{1 + BI^{1/2}} - kb$$

where $A = 0.5091$ and B and k are parameters that depend upon the ions. Draw a graph of the mean activity coefficient with $b = 0.04 \text{ mol kg}^{-1}$ and $0 \leq I \leq 0.1$.

$b/(\text{mol kg}^{-1})$	0.01	0.02	0.03	0.04	0.05
$E(25^\circ\text{C})/\text{V}$	0.74452	0.72853	0.71928	0.71314	0.70809
$b/(\text{mol kg}^{-1})$	0.06	0.07	0.08	0.09	0.10
$E(25^\circ\text{C})/\text{V}$	0.70380	0.70059	0.69790	0.69571	0.69338

Hint. Use mathematical software or a spreadsheet.

7.23 Superheavy elements are now of considerable interest, particularly because signs of stability are starting to emerge with element 114, which has recently been made. Shortly before it was (falsely) believed that the first superheavy element had been discovered, an attempt was made to predict the chemical properties of ununpentium (Uup, element 115, O.L. Keller, C.W. Nestor, and B. Fricke, *J. Phys. Chem.* **78**, 1945 (1974)). In one part of the paper the standard enthalpy and entropy of the reaction $\text{Uup}^+(\text{aq}) + \frac{1}{2}\text{H}_2(\text{g}) \rightarrow \text{Uup}(\text{s}) + \text{H}^+(\text{aq})$ were estimated from the following data: $\Delta_{\text{sub}}H^\circ(\text{Uup}) = +1.5 \text{ eV}$, $I(\text{Uup}) = 5.52 \text{ eV}$, $\Delta_{\text{hyd}}H^\circ(\text{Uup}^+, \text{aq}) = -3.22 \text{ eV}$, $S^\circ(\text{Uup}^+, \text{aq}) = +1.34 \text{ meV K}^{-1}$, $S^\circ(\text{Uup}, \text{s}) = 0.69 \text{ meV K}^{-1}$. Estimate the expected standard potential of the Uup^+/Uup couple.

7.24 Sodium fluoride is routinely added to public water supplies because it is known that fluoride ion can prevent tooth decay. In a fluoride-selective electrode used in the analysis of water samples a crystal of LaF_3 doped with Eu^{2+} , denoted as $\text{Eu}^{2+}:\text{LaF}_3$, provides a semipermeable barrier between the test solution and the solution inside the electrode (the filling solution), which contains $0.1 \text{ mol kg}^{-1} \text{ NaF}(\text{aq})$ and $0.1 \text{ mol kg}^{-1} \text{ NaCl}(\text{aq})$. A silver–silver chloride electrode immersed in the filling solution is connected to a potentiometer and the emf of the cell can be measured against an appropriate reference electrode. It follows that the half-cell for a fluoride-selective electrode is represented by

where b_1 and b_2 are the molalities of fluoride ion in the filling and test solutions, respectively. (a) Derive an expression for the emf of this half-cell. (b) The fluoride-selective electrode just described is not sensitive to $\text{HF}(\text{aq})$. Hydroxide ion is the only interfering species, with $k_{\text{F}^-, \text{OH}^-} = 0.1$. Use this information and the fact that K_a of HF is 3.5×10^{-4} at 298 K to specify a range of pH values in which the electrode responds accurately to the activity of F^- in the test solution at 298 K .

Theoretical problems

7.25 Express the equilibrium constant of a gas-phase reaction $\text{A} + 3 \text{B} \rightleftharpoons 2 \text{C}$ in terms of the equilibrium value of the extent of reaction, ξ , given that initially A and B were present in stoichiometric proportions. Find an expression for ξ as a function of the total pressure, p , of the reaction mixture and sketch a graph of the expression obtained.

7.26 Find an expression for the standard reaction Gibbs energy at a temperature T' in terms of its value at another temperature T and the coefficients a , b , and c in the expression for the molar heat capacity listed in Table 2.2. Evaluate the standard Gibbs energy of formation of $\text{H}_2\text{O}(\text{l})$ at 372 K from its value at 298 K .

7.27 Show that, if the ionic strength of a solution of the sparingly soluble salt MX and the freely soluble salt NX is dominated by the concentration C of the latter, and if it is valid to use the Debye–Hückel limiting law, the solubility S' in the mixed solution is given by

$$S' = \frac{K_s e^{4.606AC^{1/2}}}{C}$$

when K_s is small (in a sense to be specified).

Applications: to biology, environmental science, and chemical engineering

7.28 Here we investigate the molecular basis for the observation that the hydrolysis of ATP is exergonic at $\text{pH} = 7.0$ and 310 K . (a) It is thought that the exergonicity of ATP hydrolysis is due in part to the fact that the standard entropies of hydrolysis of polyphosphates are positive. Why would an increase in entropy accompany the hydrolysis of a triphosphate group into a diphosphate and a phosphate group? (b) Under identical conditions, the Gibbs energies of hydrolysis of H_4ATP and MgATP^{2-} , a complex between the Mg^{2+} ion and ATP^{4-} , are less negative than the Gibbs energy of hydrolysis of ATP^{4-} . This observation has been used to support the hypothesis that electrostatic repulsion between adjacent phosphate groups is a factor that controls the exergonicity of ATP hydrolysis. Provide a rationale for the hypothesis and discuss how the experimental evidence supports it. Do these electrostatic effects contribute to the $\Delta_r H$ or $\Delta_r S$ terms that determine the exergonicity of the reaction? *Hint.* In the MgATP^{2-} complex, the Mg^{2+} ion and ATP^{4-} anion form two bonds: one that involves a negatively charged oxygen belonging to the terminal phosphate group of ATP^{4-} and another that involves a negatively charged oxygen belonging to the phosphate group adjacent to the terminal phosphate group of ATP^{4-} .

7.29 To get a sense of the effect of cellular conditions on the ability of ATP to drive biochemical processes, compare the standard Gibbs energy of hydrolysis of ATP to ADP with the reaction Gibbs energy in an environment at 37°C in which $\text{pH} = 7.0$ and the ATP , ADP , and P_i concentrations are all $1.0 \mu\text{mol dm}^{-3}$.

7.30 Under biochemical standard conditions, aerobic respiration produces approximately 38 molecules of ATP per molecule of glucose that is completely oxidized. (a) What is the percentage efficiency of aerobic respiration under biochemical standard conditions? (b) The following conditions are more likely to be observed in a living cell: $p_{\text{CO}_2} = 5.3 \times 10^{-2} \text{ atm}$, $p_{\text{O}_2} = 0.132 \text{ atm}$, $[\text{glucose}] = 5.6 \times 10^{-2} \text{ mol dm}^{-3}$, $[\text{ATP}] = [\text{ADP}] = [\text{P}_i] = 1.0 \times 10^{-4} \text{ mol dm}^{-3}$, $\text{pH} = 7.4$, $T = 310 \text{ K}$. Assuming that activities can be replaced by the numerical values of molar concentrations, calculate the efficiency of aerobic respiration under these physiological conditions. (c) A typical diesel engine operates between $T_c = 873 \text{ K}$ and $T_h = 1923 \text{ K}$ with an efficiency that is approximately 75 per cent of the theoretical limit of $(1 - T_c/T_h)$ (see Section 3.2). Compare the efficiency of a typical diesel engine with that of aerobic respiration under typical physiological conditions (see part b). Why is biological energy conversion more or less efficient than energy conversion in a diesel engine?

7.31 In anaerobic bacteria, the source of carbon may be a molecule other than glucose and the final electron acceptor is some molecule other than O_2 . Could a bacterium evolve to use the ethanol/nitrate pair instead of the glucose/ O_2 pair as a source of metabolic energy?

7.32 If the mitochondrial electric potential between matrix and the intermembrane space were 70 mV , as is common for other membranes, how much ATP could be synthesized from the transport of 4 mol H^+ , assuming the pH difference remains the same?

7.33 The standard potentials of proteins are not commonly measured by the methods described in this chapter because proteins often lose their native structure and function when they react on the surfaces of electrodes. In an alternative method, the oxidized protein is allowed to react with an appropriate electron donor in solution. The standard potential of the protein is then determined from the Nernst equation, the equilibrium concentrations of all species in solution, and the known standard potential of the electron donor. We shall illustrate this method with the protein cytochrome *c*. The one-electron reaction between cytochrome *c*, cyt , and 2,6-dichloroindophenol, D , can be followed spectrophotometrically because each of the four species in solution has a distinct colour, or absorption spectrum. We write the reaction as $\text{cyt}_{\text{ox}} + \text{D}_{\text{red}} \rightleftharpoons \text{cyt}_{\text{red}} + \text{D}_{\text{ox}}$, where the

subscripts 'ox' and 'red' refer to oxidized and reduced states, respectively.

(a) Consider E_{cyt}° and E_D° to be the standard potentials of cytochrome *c* and D, respectively. Show that, at equilibrium ('eq'), a plot of $\ln([D_{\text{ox}}]_{\text{eq}}/[D_{\text{red}}]_{\text{eq}})$ versus $\ln([cyt_{\text{ox}}]_{\text{eq}}/[cyt_{\text{red}}]_{\text{eq}})$ is linear with slope of 1 and y -intercept $F(E_{\text{cyt}}^\circ - E_D^\circ)/RT$, where equilibrium activities are replaced by the numerical values of equilibrium molar concentrations. (b) The following data were obtained for the reaction between oxidized cytochrome *c* and reduced D in a pH 6.5 buffer at 298 K. The ratios $[D_{\text{ox}}]_{\text{eq}}/[D_{\text{red}}]_{\text{eq}}$ and $[cyt_{\text{ox}}]_{\text{eq}}/[cyt_{\text{red}}]_{\text{eq}}$ were adjusted by titrating a solution containing oxidized cytochrome *c* and reduced D with a solution of sodium ascorbate, which is a strong reductant. From the data and the standard potential of D of 0.237 V, determine the standard potential cytochrome *c* at pH 6.5 and 298K.

$[D_{\text{ox}}]_{\text{eq}}/[D_{\text{red}}]_{\text{eq}}$	0.00279	0.00843	0.0257	0.0497	0.0748	0.238	0.534
$[cyt_{\text{ox}}]_{\text{eq}}/[cyt_{\text{red}}]_{\text{eq}}$	0.0106	0.0230	0.0894	0.197	0.335	0.809	1.39

7.34† The dimerization of ClO in the Antarctic winter stratosphere is believed to play an important part in that region's severe seasonal depletion of ozone. The following equilibrium constants are based on measurements by R.A. Cox and C.A. Hayman (*Nature* **332**, 796 (1988)) on the reaction $2\text{ClO}(\text{g}) \rightarrow (\text{ClO})_2(\text{g})$.

T/K	233	248	258	268	273	280
K	4.13×10^8	5.00×10^7	1.45×10^7	5.37×10^6	3.20×10^6	9.62×10^5
T/K	288	295	303			
K	4.28×10^5	1.67×10^5	7.02×10^4			

(a) Derive the values of $\Delta_f H^\circ$ and $\Delta_f S^\circ$ for this reaction. (b) Compute the standard enthalpy of formation and the standard molar entropy of $(\text{ClO})_2$ given $\Delta_f H^\circ(\text{ClO}) = +101.8 \text{ kJ mol}^{-1}$ and $S_m^\circ(\text{ClO}) = 226.6 \text{ J K}^{-1} \text{ mol}^{-1}$ (*CRC Handbook* 2004).

7.35† Nitric acid hydrates have received much attention as possible catalysts for heterogeneous reactions that bring about the Antarctic ozone hole. Worsnop *et al.* investigated the thermodynamic stability of these hydrates under conditions typical of the polar winter stratosphere (D.R. Worsnop, L.E. Fox, M.S. Zahniser, and S.C. Wofsy, *Science* **259**, 71 (1993)). Standard reaction Gibbs energies can be computed for the following reactions at 190 K from their data:

Which solid is thermodynamically most stable at 190 K if $p_{\text{H}_2\text{O}} = 1.3 \times 10^{-7} \text{ bar}$ and $p_{\text{HNO}_3} = 4.1 \times 10^{-10} \text{ bar}$? *Hint.* Try computing $\Delta_r G$ for each reaction under the prevailing conditions; if more than one solid forms spontaneously, examine $\Delta_r G$ for the conversion of one solid to another.

7.36† Suppose that an iron catalyst at a particular manufacturing plant produces ammonia in the most cost-effective manner at 450°C when the pressure is such that $\Delta_r G$ for the reaction $\frac{1}{2} \text{N}_2(\text{g}) + \frac{3}{2} \text{H}_2(\text{g}) \rightarrow \text{NH}_3(\text{g})$ is equal to -500 J mol^{-1} . (a) What pressure is needed? (b) Now suppose that a new catalyst is developed that is most cost-effective at 400°C when the pressure gives the same value of $\Delta_r G$. What pressure is needed when the new catalyst is used? What are the advantages of the new catalyst? Assume that (i) all gases are perfect gases or that (ii) all gases are van der Waals gases. Isotherms of $\Delta_r G(T, p)$ in the pressure range $100 \text{ atm} \leq p \leq 400 \text{ atm}$ are needed to derive the answer. (c) Do the isotherms you plotted confirm Le Chatelier's principle concerning the response of equilibrium changes in temperature and pressure?

Quantum theory: introduction and principles

This chapter introduces some of the basic principles of quantum mechanics. First, it reviews the experimental results that overthrew the concepts of classical physics. These experiments led to the conclusion that particles may not have an arbitrary energy and that the classical concepts of ‘particle’ and ‘wave’ blend together. The overthrow of classical mechanics inspired the formulation of a new set of concepts and led to the formulation of quantum mechanics. In quantum mechanics, all the properties of a system are expressed in terms of a wavefunction that is obtained by solving the Schrödinger equation. We see how to interpret wavefunctions. Finally, we introduce some of the techniques of quantum mechanics in terms of operators, and see that they lead to the uncertainty principle, one of the most profound departures from classical mechanics.

It was once thought that the motion of atoms and subatomic particles could be expressed using **classical mechanics**, the laws of motion introduced in the seventeenth century by Isaac Newton, for these laws were very successful at explaining the motion of everyday objects and planets. However, towards the end of the nineteenth century, experimental evidence accumulated showing that classical mechanics failed when it was applied to particles as small as electrons, and it took until the 1920s to discover the appropriate concepts and equations for describing them. We describe the concepts of this new mechanics, which is called **quantum mechanics**, in this chapter, and apply them throughout the remainder of the text.

The origins of quantum mechanics

The basic principles of classical mechanics are reviewed in *Appendix 2*. In brief, they show that classical physics (1) predicts a precise trajectory for particles, with precisely specified locations and momenta at each instant, and (2) allows the translational, rotational, and vibrational modes of motion to be excited to any energy simply by controlling the forces that are applied. These conclusions agree with everyday experience. Everyday experience, however, does not extend to individual atoms, and careful experiments of the type described below have shown that classical mechanics fails when applied to the transfers of very small energies and to objects of very small mass.

We shall also investigate the properties of light. In classical physics, light is described as electromagnetic radiation, which is understood in terms of the **electromagnetic field**, an oscillating electric and magnetic disturbance that spreads as a harmonic wave through empty space, the vacuum. Such waves are generated by the acceleration of electric charge, as in the oscillating motion of electrons in the antenna of a radio transmitter. The wave travels at a constant speed called the *speed of light*, c , which

Fig. 8.1 The wavelength, λ , of a wave is the peak-to-peak distance. (b) The wave is shown travelling to the right at a speed c . At a given location, the instantaneous amplitude of the wave changes through a complete cycle (the four dots show half a cycle). The frequency, ν , is the number of cycles per second that occur at a given point.

Comment 8.1

Harmonic waves are waves with displacements that can be expressed as sine or cosine functions. The physics of waves is reviewed in *Appendix 3*.

is about $3 \times 10^8 \text{ m s}^{-1}$. As its name suggests, an electromagnetic field has two components, an **electric field** that acts on charged particles (whether stationary or moving) and a **magnetic field** that acts only on moving charged particles. The electromagnetic field is characterized by a **wavelength**, λ (lambda), the distance between the neighbouring peaks of the wave, and its **frequency**, ν (nu), the number of times per second at which its displacement at a fixed point returns to its original value (Fig. 8.1). The frequency is measured in *hertz*, where $1 \text{ Hz} = 1 \text{ s}^{-1}$. The wavelength and frequency of an electromagnetic wave are related by

$$\lambda \nu = c \quad (8.1)$$

Therefore, the shorter the wavelength, the higher the frequency. The characteristics of the wave are also reported by giving the **wavenumber**, $\tilde{\nu}$ (nu tilde), of the radiation, where

$$\tilde{\nu} = \frac{\nu}{c} = \frac{1}{\lambda} \quad [8.2]$$

Wavenumbers are normally reported in reciprocal centimetres (cm^{-1}).

Figure 8.2 summarizes the **electromagnetic spectrum**, the description and classification of the electromagnetic field according to its frequency and wavelength. White light is a mixture of electromagnetic radiation with wavelengths ranging from about 380 nm to about 700 nm ($1 \text{ nm} = 10^{-9} \text{ m}$). Our eyes perceive different wavelengths of radiation in this range as different colours, so it can be said that white light is a mixture of light of all different colours.

The wave model falls short of describing all the properties of radiation. So, just as our view of particles (and in particular small particles) needs to be adjusted, a new view of light also has to be developed.

8.1 The failures of classical physics

In this section we review some of the experimental evidence that showed that several concepts of classical mechanics are untenable. In particular, we shall see that observations of the radiation emitted by hot bodies, heat capacities, and the spectra of atoms and molecules indicate that systems can take up energy only in discrete amounts.

(a) Black-body radiation

A hot object emits electromagnetic radiation. At high temperatures, an appreciable proportion of the radiation is in the visible region of the spectrum, and a higher

Fig. 8.2 The electromagnetic spectrum and the classification of the spectral regions.

proportion of short-wavelength blue light is generated as the temperature is raised. This behaviour is seen when a heated iron bar glowing red hot becomes white hot when heated further. The dependence is illustrated in Fig. 8.3, which shows how the energy output varies with wavelength at several temperatures. The curves are those of an ideal emitter called a **black body**, which is an object capable of emitting and absorbing all frequencies of radiation uniformly. A good approximation to a black body is a pinhole in an empty container maintained at a constant temperature, because any radiation leaking out of the hole has been absorbed and re-emitted inside so many times that it has come to thermal equilibrium with the walls (Fig. 8.4).

The explanation of black-body radiation was a major challenge for nineteenth-century scientists, and in due course it was found to be beyond the capabilities of classical physics. The physicist Lord Rayleigh studied it theoretically from a classical viewpoint, and thought of the electromagnetic field as a collection of oscillators of all possible frequencies. He regarded the presence of radiation of frequency ν (and therefore of wavelength $\lambda = c/\nu$) as signifying that the electromagnetic oscillator of that frequency had been excited (Fig. 8.5). Rayleigh used the equipartition principle (Section 2.2) to calculate the average energy of each oscillator as kT . Then, with minor help from James Jeans, he arrived at the **Rayleigh–Jeans law** (see *Further reading* for its justification):

$$d\mathcal{E} = \rho d\lambda \quad \rho = \frac{8\pi kT}{\lambda^4} \quad (8.3)$$

where ρ (rho), the **density of states**, is the proportionality constant between $d\lambda$ and the energy density, $d\mathcal{E}$, in the range of wavelengths between λ and $\lambda + d\lambda$, k is Boltzmann's constant ($k = 1.381 \times 10^{-23} \text{ J K}^{-1}$). The units of ρ are typically joules per metre⁴ (J m^{-4}), to give an energy density $d\mathcal{E}$ in joules per cubic metre (J m^{-3}) when multiplied by a wavelength range $d\lambda$ in metres. A high density of states at the wavelength λ simply means that there is a lot of energy associated with wavelengths lying between λ and $\lambda + d\lambda$. The total energy density (in joules per cubic metre) in a region is obtained by integrating eqn 8.3 over all wavelengths between zero and infinity, and the total energy (in joules) within the region is obtained by multiplying that total energy density by the volume of the region.

Fig. 8.4 An experimental representation of a black-body is a pinhole in an otherwise closed container. The radiation is reflected many times within the container and comes to thermal equilibrium with the walls at a temperature T . Radiation leaking out through the pinhole is characteristic of the radiation within the container.

Fig. 8.3 The energy distribution in a black-body cavity at several temperatures. Note how the energy density increases in the region of shorter wavelengths as the temperature is raised, and how the peak shifts to shorter wavelengths. The total energy density (the area under the curve) increases as the temperature is increased (as T^4).

Fig. 8.5 The electromagnetic vacuum can be regarded as able to support oscillations of the electromagnetic field. When a high frequency, short wavelength oscillator (a) is excited, that frequency of radiation is present. The presence of low frequency, long wavelength radiation (b) signifies that an oscillator of the corresponding frequency has been excited.

Fig. 8.6 The Rayleigh–Jeans law (eqn 8.3) predicts an infinite energy density at short wavelengths. This approach to infinity is called the *ultraviolet catastrophe*.

Fig. 8.7 The Planck distribution (eqn 8.5) accounts very well for the experimentally determined distribution of black-body radiation. Planck's quantization hypothesis essentially quenches the contributions of high frequency, short wavelength oscillators. The distribution coincides with the Rayleigh–Jeans distribution at long wavelengths.

Exploration Plot the Planck distribution at several temperatures and confirm that eqn 8.5 predicts the behaviour summarized by Fig. 8.2.

Unfortunately (for Rayleigh, Jeans, and classical physics), although the Rayleigh–Jeans law is quite successful at long wavelengths (low frequencies), it fails badly at short wavelengths (high frequencies). Thus, as λ decreases, ρ increases without going through a maximum (Fig. 8.6). The equation therefore predicts that oscillators of very short wavelength (corresponding to ultraviolet radiation, X-rays, and even γ -rays) are strongly excited even at room temperature. This absurd result, which implies that a large amount of energy is radiated in the high-frequency region of the electromagnetic spectrum, is called the **ultraviolet catastrophe**. According to classical physics, even cool objects should radiate in the visible and ultraviolet regions, so objects should glow in the dark; there should in fact be no darkness.

(b) The Planck distribution

The German physicist Max Planck studied black-body radiation from the viewpoint of thermodynamics. In 1900 he found that he could account for the experimental observations by proposing that the energy of each electromagnetic oscillator is limited to discrete values and cannot be varied arbitrarily. This proposal is quite contrary to the viewpoint of classical physics (on which the equipartition principle used by Rayleigh is based), in which all possible energies are allowed. The limitation of energies to discrete values is called the **quantization of energy**. In particular, Planck found that he could account for the observed distribution of energy if he supposed that the permitted energies of an electromagnetic oscillator of frequency ν are integer multiples of $h\nu$:

$$E = nh\nu \quad n = 0, 1, 2, \dots \quad (8.4)$$

where h is a fundamental constant now known as **Planck's constant**. On the basis of this assumption, Planck was able to derive the **Planck distribution**:

$$dE = \rho d\lambda \quad \rho = \frac{8\pi hc}{\lambda^5 (e^{hc/\lambda kT} - 1)} \quad (8.5)$$

(For references to the derivation of this expression, see *Further reading*.) This expression fits the experimental curve very well at all wavelengths (Fig. 8.7), and the value of h , which is an undetermined parameter in the theory, may be obtained by varying its value until a best fit is obtained. The currently accepted value for h is 6.626×10^{-34} J s.

The Planck distribution resembles the Rayleigh–Jeans law (eqn 8.3) apart from the all-important exponential factor in the denominator. For short wavelengths, $hc/\lambda kT \gg 1$ and $e^{hc/\lambda kT} \rightarrow \infty$ faster than $\lambda^5 \rightarrow 0$; therefore $\rho \rightarrow 0$ as $\lambda \rightarrow 0$ or $\nu \rightarrow \infty$. Hence, the energy density approaches zero at high frequencies, in agreement with observation. For long wavelengths, $hc/\lambda kT \ll 1$, and the denominator in the Planck distribution can be replaced by

$$e^{hc/\lambda kT} - 1 = \left(1 + \frac{hc}{\lambda kT} + \dots \right) - 1 \approx \frac{hc}{\lambda kT}$$

When this approximation is substituted into eqn 8.5, we find that the Planck distribution reduces to the Rayleigh–Jeans law.

It is quite easy to see why Planck's approach was successful while Rayleigh's was not. The thermal motion of the atoms in the walls of the black body excites the oscillators of the electromagnetic field. According to classical mechanics, all the oscillators of the field share equally in the energy supplied by the walls, so even the highest frequencies are excited. The excitation of very high frequency oscillators results in the ultraviolet catastrophe. According to Planck's hypothesis, however, oscillators are excited only if

they can acquire an energy of at least $h\nu$. This energy is too large for the walls to supply in the case of the very high frequency oscillators, so the latter remain unexcited. The effect of quantization is to reduce the contribution from the high frequency oscillators, for they cannot be significantly excited with the energy available.

(c) Heat capacities

In the early nineteenth century, the French scientists Pierre-Louis Dulong and Alexis-Thérèse Petit determined the heat capacities of a number of monatomic solids. On the basis of some somewhat slender experimental evidence, they proposed that the molar heat capacities of all monatomic solids are the same and (in modern units) close to $25 \text{ J K}^{-1} \text{ mol}^{-1}$.

Dulong and Petit's law is easy to justify in terms of classical physics. If classical physics were valid, the equipartition principle could be used to calculate the heat capacity of a solid. According to this principle, the mean energy of an atom as it oscillates about its mean position in a solid is kT for each direction of displacement. As each atom can oscillate in three dimensions, the average energy of each atom is $3kT$; for N atoms the total energy is $3NkT$. The contribution of this motion to the molar internal energy is therefore

$$U_m = 3N_A kT = 3RT$$

because $N_A k = R$, the gas constant. The molar constant volume heat capacity (see *Comment 8.3*) is then predicted to be

$$C_{V,m} = \left(\frac{\partial U_m}{\partial T} \right)_V = 3R \quad (8.6)$$

This result, with $3R = 24.9 \text{ J K}^{-1} \text{ mol}^{-1}$, is in striking accord with Dulong and Petit's value.

Unfortunately (this time, for Dulong and Petit), significant deviations from their law were observed when advances in refrigeration techniques made it possible to measure heat capacities at low temperatures. It was found that the molar heat capacities of all monatomic solids are lower than $3R$ at low temperatures, and that the values approach zero as $T \rightarrow 0$. To account for these observations, Einstein (in 1905) assumed that each atom oscillated about its equilibrium position with a single frequency ν . He then invoked Planck's hypothesis to assert that the energy of oscillation is confined to discrete values, and specifically to $n h \nu$, where n is an integer. Einstein first calculated the contribution of the oscillations of the atoms to the total molar energy of the metal (by a method described in Section 16.4) and obtained

$$U_m = \frac{3N_A h \nu}{e^{h\nu/kT} - 1}$$

in place of the classical expression $3RT$. Then he found the molar heat capacity by differentiating U_m with respect to T . The resulting expression is now known as the **Einstein formula**:

$$C_{V,m} = 3Rf \quad f = \left(\frac{\theta_E}{T} \right)^2 \left(\frac{e^{\theta_E/2T}}{e^{\theta_E/T} - 1} \right)^2 \quad (8.7)$$

The **Einstein temperature**, $\theta_E = h\nu/k$, is a way of expressing the frequency of oscillation of the atoms as a temperature: a high frequency corresponds to a high Einstein temperature.

Comment 8.2

The series expansion of an exponential function is $e^x = 1 + x + \frac{1}{2}x^2 + \dots$. If $x \ll 1$, a good approximation is $e^x \approx 1 + x$. For example, $e^{0.01} = 1.010\,050\dots \approx 1 + 0.01$.

Comment 8.3

The internal energy, U , a concept from thermodynamics (Chapter 2), can be regarded as the total energy of the particles making up a sample of matter. The constant-volume heat capacity is defined as $C_V = (\partial U / \partial T)_V$. A small heat capacity indicates that a large rise in temperature results from a given transfer of energy.

Fig. 8.8 Experimental low-temperature molar heat capacities and the temperature dependence predicted on the basis of Einstein's theory. His equation (eqn 8.7) accounts for the dependence fairly well, but is everywhere too low.

Exploration Using eqn 8.7, plot $C_{V,m}$ against T for several values of the Einstein temperature θ_E . At low temperature, does an increase in θ_E result in an increase or decrease of $C_{V,m}$? Estimate the temperature at which the value of $C_{V,m}$ reaches the classical value given by eqn 8.6.

At high temperatures (when $T \gg \theta_E$) the exponentials in f can be expanded as $1 + \theta_E/T + \dots$ and higher terms ignored (see *Comment 8.2*). The result is

$$f = \left(\frac{\theta_E}{T} \right)^2 \left\{ \frac{1 + \theta_E/2T + \dots}{(1 + \theta_E/T + \dots) - 1} \right\}^2 \approx 1 \quad (8.8a)$$

Consequently, the classical result ($C_{V,m} = 3R$) is obtained at high temperatures. At low temperatures, when $T \ll \theta_E$,

$$f \approx \left(\frac{\theta_E}{T} \right)^2 \left(\frac{e^{\theta_E/2T}}{e^{\theta_E/T}} \right)^2 = \left(\frac{\theta_E}{T} \right)^2 e^{-\theta_E/T} \quad (8.8b)$$

The strongly decaying exponential function goes to zero more rapidly than $1/T$ goes to infinity; so $f \rightarrow 0$ as $T \rightarrow 0$, and the heat capacity therefore approaches zero too. We see that Einstein's formula accounts for the decrease of heat capacity at low temperatures. The physical reason for this success is that at low temperatures only a few oscillators possess enough energy to oscillate significantly. At higher temperatures, there is enough energy available for all the oscillators to become active: all $3N$ oscillators contribute, and the heat capacity approaches its classical value.

Figure 8.8 shows the temperature dependence of the heat capacity predicted by the Einstein formula. The general shape of the curve is satisfactory, but the numerical agreement is in fact quite poor. The poor fit arises from Einstein's assumption that all the atoms oscillate with the same frequency, whereas in fact they oscillate over a range of frequencies from zero up to a maximum value, ν_D . This complication is taken into account by averaging over all the frequencies present, the final result being the **Debye formula**:

$$C_{V,m} = 3Rf \quad f = 3 \left(\frac{T}{\theta_D} \right)^3 \int_0^{\theta_D/T} \frac{x^4 e^x}{(e^x - 1)^2} dx \quad (8.9)$$

where $\theta_D = h\nu_D/k$ is the **Debye temperature** (for a derivation, see *Further reading*). The integral in eqn 8.9 has to be evaluated numerically, but that is simple with mathematical software. The details of this modification, which, as Fig. 8.9 shows, gives improved agreement with experiment, need not distract us at this stage from the main conclusion, which is that quantization must be introduced in order to explain the thermal properties of solids.

Illustration 8.1 Assessing the heat capacity

The Debye temperature for lead is 105 K, corresponding to a vibrational frequency of 2.2×10^{12} Hz, whereas that for diamond and its much lighter, more rigidly bonded atoms, is 2230 K, corresponding to 4.6×10^{13} Hz. As we see from Fig. 8.9, $f \approx 1$ for $T > \theta_D$ and the heat capacity is almost classical. For lead at 25°C, corresponding to $T/\theta_D = 2.8$, $f = 0.99$ and the heat capacity has almost its classical value. For diamond at the same temperature, $T/\theta_D = 0.13$, corresponding to $f = 0.15$, and the heat capacity is only 15 per cent of its classical value.

(d) Atomic and molecular spectra

The most compelling evidence for the quantization of energy comes from **spectroscopy**, the detection and analysis of the electromagnetic radiation absorbed, emitted, or scattered by a substance. The record of the intensity of light intensity transmitted

Fig. 8.9 Debye's modification of Einstein's calculation (eqn 8.9) gives very good agreement with experiment. For copper, $T/\theta_D = 2$ corresponds to about 170 K, so the detection of deviations from Dulong and Petit's law had to await advances in low-temperature physics.

Exploration Starting with the Debye formula (eqn 8.9), plot $dC_{V,m}/dT$, the temperature coefficient of $C_{V,m}$, against T for $\theta_D = 400$ K. At what temperature is $C_{V,m}$ most sensitive to temperature?

Fig. 8.10 A region of the spectrum of radiation emitted by excited iron atoms consists of radiation at a series of discrete wavelengths (or frequencies).

Fig. 8.11 When a molecule changes its state, it does so by absorbing radiation at definite frequencies. This spectrum is part of that due to the electronic, vibrational, and rotational excitation of sulfur dioxide (SO_2) molecules. This observation suggests that molecules can possess only discrete energies, not an arbitrary energy.

or scattered by a molecule as a function of frequency (ν), wavelength (λ), or wavenumber ($\tilde{\nu} = \nu/c$) is called its **spectrum** (from the Latin word for appearance).

A typical atomic spectrum is shown in Fig. 8.10, and a typical molecular spectrum is shown in Fig. 8.11. The obvious feature of both is that radiation is emitted or absorbed at a series of discrete frequencies. This observation can be understood if the energy of the atoms or molecules is also confined to discrete values, for then energy can be discarded or absorbed only in discrete amounts (Fig. 8.12). Then, if the energy of an atom decreases by ΔE , the energy is carried away as radiation of frequency ν , and an emission 'line', a sharply defined peak, appears in the spectrum. We say that a molecule undergoes a **spectroscopic transition**, a change of state, when the **Bohr frequency condition**

$$\Delta E = h\nu \quad (8.10)$$

is fulfilled. We develop the principles and applications of atomic spectroscopy in Chapter 10 and of molecular spectroscopy in Chapters 13–15.

8.2 Wave–particle duality

At this stage we have established that the energies of the electromagnetic field and of oscillating atoms are quantized. In this section we shall see the experimental evidence that led to the revision of two other basic concepts concerning natural phenomena. One experiment shows that electromagnetic radiation—which classical physics treats as wave-like—actually also displays the characteristics of particles. Another experiment shows that electrons—which classical physics treats as particles—also display the characteristics of waves.

Fig. 8.12 Spectroscopic transitions, such as those shown above, can be accounted for if we assume that a molecule emits a photon as it changes between discrete energy levels. Note that high-frequency radiation is emitted when the energy change is large.

(a) The particle character of electromagnetic radiation

The observation that electromagnetic radiation of frequency ν can possess only the energies $0, h\nu, 2h\nu, \dots$ suggests that it can be thought of as consisting of $0, 1, 2, \dots$ particles, each particle having an energy $h\nu$. Then, if one of these particles is present, the energy is $h\nu$, if two are present the energy is $2h\nu$, and so on. These particles of electromagnetic radiation are now called **photons**. The observation of discrete spectra from atoms and molecules can be pictured as the atom or molecule generating a photon of energy $h\nu$ when it discards an energy of magnitude ΔE , with $\Delta E = h\nu$.

Example 8.1 *Calculating the number of photons*

Calculate the number of photons emitted by a 100 W yellow lamp in 1.0 s. Take the wavelength of yellow light as 560 nm and assume 100 per cent efficiency.

Method Each photon has an energy $h\nu$, so the total number of photons needed to produce an energy E is $E/h\nu$. To use this equation, we need to know the frequency of the radiation (from $\nu = c/\lambda$) and the total energy emitted by the lamp. The latter is given by the product of the power (P , in watts) and the time interval for which the lamp is turned on ($E = P\Delta t$).

Answer The number of photons is

$$N = \frac{E}{h\nu} = \frac{P\Delta t}{h(c/\lambda)} = \frac{\lambda P\Delta t}{hc}$$

Substitution of the data gives

$$N = \frac{(5.60 \times 10^{-7} \text{ m}) \times (100 \text{ J s}^{-1}) \times (1.0 \text{ s})}{(6.626 \times 10^{-34} \text{ J s}) \times (2.998 \times 10^8 \text{ m s}^{-1})} = 2.8 \times 10^{20}$$

Note that it would take nearly 40 min to produce 1 mol of these photons.

A note on good practice To avoid rounding and other numerical errors, it is best to carry out algebraic manipulations first, and to substitute numerical values into a single, final formula. Moreover, an analytical result may be used for other data without having to repeat the entire calculation.

Self-test 8.1 How many photons does a monochromatic (single frequency) infrared rangefinder of power 1 mW and wavelength 1000 nm emit in 0.1 s?
[5×10^{14}]

Further evidence for the particle-like character of radiation comes from the measurement of the energies of electrons produced in the **photoelectric effect**. This effect is the ejection of electrons from metals when they are exposed to ultraviolet radiation. The experimental characteristics of the photoelectric effect are as follows:

- 1 No electrons are ejected, regardless of the intensity of the radiation, unless its frequency exceeds a threshold value characteristic of the metal.
- 2 The kinetic energy of the ejected electrons increases linearly with the frequency of the incident radiation but is independent of the intensity of the radiation.
- 3 Even at low light intensities, electrons are ejected immediately if the frequency is above the threshold.

Fig. 8.13 In the photoelectric effect, it is found that no electrons are ejected when the incident radiation has a frequency below a value characteristic of the metal and, above that value, the kinetic energy of the photoelectrons varies linearly with the frequency of the incident radiation.

Exploration Calculate the value of Planck's constant given that the following kinetic energies were observed for photoejected electrons irradiated by radiation of the wavelengths noted.

λ_i/nm	320	330	345	360	385
E_K/eV	1.17	1.05	0.885	0.735	0.511

Fig. 8.14 The photoelectric effect can be explained if it is supposed that the incident radiation is composed of photons that have energy proportional to the frequency of the radiation. (a) The energy of the photon is insufficient to drive an electron out of the metal. (b) The energy of the photon is more than enough to eject an electron, and the excess energy is carried away as the kinetic energy of the photoelectron (the ejected electron).

Figure 8.13 illustrates the first and second characteristics.

These observations strongly suggest that the photoelectric effect depends on the ejection of an electron when it is involved in a collision with a particle-like projectile that carries enough energy to eject the electron from the metal. If we suppose that the projectile is a photon of energy $h\nu$, where ν is the frequency of the radiation, then the conservation of energy requires that the kinetic energy of the ejected electron should obey

$$\frac{1}{2}m_e v^2 = h\nu - \Phi \quad (8.11)$$

In this expression Φ is a characteristic of the metal called its **work function**, the energy required to remove an electron from the metal to infinity (Fig. 8.14), the analogue of the ionization energy of an individual atom or molecule. Photoejection cannot occur if $h\nu < \Phi$ because the photon brings insufficient energy: this conclusion accounts for observation (1). Equation 8.11 predicts that the kinetic energy of an ejected electron should increase linearly with frequency, in agreement with observation (2). When a photon collides with an electron, it gives up all its energy, so we should expect electrons to appear as soon as the collisions begin, provided the photons have sufficient energy;

Fig. 8.15 The Davisson–Germer experiment. The scattering of an electron beam from a nickel crystal shows a variation of intensity characteristic of a diffraction experiment in which waves interfere constructively and destructively in different directions.

Comment 8.4

A characteristic property of waves is that they interfere with one another, giving a greater displacement where peaks or troughs coincide, leading to constructive interference, and a smaller displacement where peaks coincide with troughs, leading to destructive interference (see the illustration: (a) constructive, (b) destructive).

this conclusion agrees with observation (3). A practical application of eqn 8.11 is that it provides a technique for the determination of Planck's constant, for the slopes of the lines in Fig. 8.13 are all equal to h .

(b) The wave character of particles

Although contrary to the long-established wave theory of light, the view that light consists of particles had been held before, but discarded. No significant scientist, however, had taken the view that matter is wave-like. Nevertheless, experiments carried out in 1925 forced people to consider that possibility. The crucial experiment was performed by the American physicists Clinton Davisson and Lester Germer, who observed the diffraction of electrons by a crystal (Fig. 8.15). Diffraction is the interference caused by an object in the path of waves. Depending on whether the interference is constructive or destructive, the result is a region of enhanced or diminished intensity of the wave. Davisson and Germer's success was a lucky accident, because a chance rise of temperature caused their polycrystalline sample to anneal, and the ordered planes of atoms then acted as a diffraction grating. At almost the same time, G.P. Thomson, working in Scotland, showed that a beam of electrons was diffracted when passed through a thin gold foil. Electron diffraction is the basis for special techniques in microscopy used by biologists and materials scientists (*Impact 18.1* and Section 20.4).

The Davisson–Germer experiment, which has since been repeated with other particles (including α particles and molecular hydrogen), shows clearly that particles have wave-like properties, and the diffraction of neutrons is a well-established technique for investigating the structures and dynamics of condensed phases (see Chapter 20). We have also seen that waves of electromagnetic radiation have particle-like properties. Thus we are brought to the heart of modern physics. When examined on an atomic scale, the classical concepts of particle and wave melt together, particles taking on the characteristics of waves, and waves the characteristics of particles.

Some progress towards coordinating these properties had already been made by the French physicist Louis de Broglie when, in 1924, he suggested that any particle, not only photons, travelling with a linear momentum p should have (in some sense) a wavelength given by the **de Broglie relation**:

$$\lambda = \frac{h}{p} \quad (8.12)$$

That is, a particle with a high linear momentum has a short wavelength (Fig. 8.16). Macroscopic bodies have such high momenta (because their mass is so great), even when they are moving slowly, that their wavelengths are undetectably small, and the wave-like properties cannot be observed.

Example 8.2 Estimating the de Broglie wavelength

Estimate the wavelength of electrons that have been accelerated from rest through a potential difference of 40 kV.

Method To use the de Broglie relation, we need to know the linear momentum, p , of the electrons. To calculate the linear momentum, we note that the energy acquired by an electron accelerated through a potential difference V is eV , where e is the magnitude of its charge. At the end of the period of acceleration, all the acquired energy is in the form of kinetic energy, $E_K = p^2/2m_e$, so we can determine p by setting $p^2/2m_e$ equal to eV . As before, carry through the calculation algebraically before substituting the data.

Answer The expression $p^2/2m_e = eV$ solves to $p = (2m_e eV)^{1/2}$; then, from the de Broglie relation $\lambda = h/p$,

$$\lambda = \frac{h}{(2m_e eV)^{1/2}}$$

Substitution of the data and the fundamental constants (from inside the front cover) gives

$$\lambda = \frac{6.626 \times 10^{-34} \text{ J s}}{\{2 \times (9.109 \times 10^{-31} \text{ kg}) \times (1.609 \times 10^{-19} \text{ C}) \times (4.0 \times 10^4 \text{ V})\}^{1/2}} \\ = 6.1 \times 10^{-12} \text{ m}$$

where we have used $1 \text{ V C} = 1 \text{ J}$ and $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$. The wavelength of 6.1 pm is shorter than typical bond lengths in molecules (about 100 pm). Electrons accelerated in this way are used in the technique of electron diffraction for the determination of molecular structure (see Section 20.4).

Self-test 8.2 Calculate (a) the wavelength of a neutron with a translational kinetic energy equal to kT at 300 K, (b) a tennis ball of mass 57 g travelling at 80 km/h.
[(a) 178 pm, (b) $5.2 \times 10^{-34} \text{ m}$]

We now have to conclude that, not only has electromagnetic radiation the character classically ascribed to particles, but electrons (and all other particles) have the characteristics classically ascribed to waves. This joint particle and wave character of matter and radiation is called **wave–particle duality**. Duality strikes at the heart of classical physics, where particles and waves are treated as entirely distinct entities. We have also seen that the energies of electromagnetic radiation and of matter cannot be varied continuously, and that for small objects the discreteness of energy is highly significant. In classical mechanics, in contrast, energies could be varied continuously. Such total failure of classical physics for small objects implied that its basic concepts were false. A new mechanics had to be devised to take its place.

IMPACT ON BIOLOGY

18.1 Electron microscopy

The basic approach of illuminating a small area of a sample and collecting light with a microscope has been used for many years to image small specimens. However, the *resolution* of a microscope, the minimum distance between two objects that leads to two distinct images, is on the order of the wavelength of light used as a probe (see *Impact I13.1*). Therefore, conventional microscopes employing visible light have resolutions in the micrometre range and are blind to features on a scale of nanometres.

There is great interest in the development of new experimental probes of very small specimens that cannot be studied by traditional light microscopy. For example, our understanding of biochemical processes, such as enzymatic catalysis, protein folding, and the insertion of DNA into the cell's nucleus, will be enhanced if it becomes possible to image individual biopolymers—with dimensions much smaller than visible wavelengths—at work. One technique that is often used to image nanometre-sized objects is *electron microscopy*, in which a beam of electrons with a well defined de Broglie wavelength replaces the lamp found in traditional light microscopes. Instead of glass or quartz lenses, magnetic fields are used to focus the beam. In *transmission electron microscopy* (TEM), the electron beam passes through the specimen and the

Fig. 8.16 An illustration of the de Broglie relation between momentum and wavelength. The wave is associated with a particle (shortly this wave will be seen to be the wavefunction of the particle). A particle with high momentum has a wavefunction with a short wavelength, and vice versa.

Fig. 8.17 A TEM image of a cross-section of a plant cell showing chloroplasts, organelles responsible for the reactions of photosynthesis (Chapter 23). Chloroplasts are typically 5 μm long. (Image supplied by Brian Bowes.)

image is collected on a screen. In *scanning electron microscopy* (SEM), electrons scattered back from a small irradiated area of the sample are detected and the electrical signal is sent to a video screen. An image of the surface is then obtained by scanning the electron beam across the sample.

As in traditional light microscopy, the wavelength of and the ability to focus the incident beam—in this case a beam of electrons—govern the resolution. Electron wavelengths in typical electron microscopes can be as short as 10 pm, but it is not possible to focus electrons well with magnetic lenses so, in the end, typical resolutions of TEM and SEM instruments are about 2 nm and 50 nm, respectively. It follows that electron microscopes cannot resolve individual atoms (which have diameters of about 0.2 nm). Furthermore, only certain samples can be observed under certain conditions. The measurements must be conducted under high vacuum. For TEM observations, the samples must be very thin cross-sections of a specimen and SEM observations must be made on dry samples. A consequence of these requirements is that neither technique can be used to study living cells. In spite of these limitations, electron microscopy is very useful in studies of the internal structure of cells (Fig. 8.17).

The dynamics of microscopic systems

Quantum mechanics acknowledges the wave–particle duality of matter by supposing that, rather than travelling along a definite path, a particle is distributed through space like a wave. This remark may seem mysterious: it will be interpreted more fully shortly. The mathematical representation of the wave that in quantum mechanics replaces the classical concept of trajectory is called a **wavefunction**, ψ (psi).

8.3 The Schrödinger equation

In 1926, the Austrian physicist Erwin Schrödinger proposed an equation for finding the wavefunction of any system. The **time-independent Schrödinger equation** for a particle of mass m moving in one dimension with energy E is

$$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} + V(x)\psi = E\psi \quad (8.13)$$

The factor $V(x)$ is the potential energy of the particle at the point x ; because the total energy E is the sum of potential and kinetic energies, the first term must be related (in a manner we explore later) to the kinetic energy of the particle; $\hbar$ (which is read *h*-cross or *h*-bar) is a convenient modification of Planck's constant:

$$\hbar = \frac{h}{2\pi} = 1.054\,57 \times 10^{-34} \text{ J s} \quad (8.14)$$

For a partial justification of the form of the Schrödinger equation, see the *Justification* below. The discussions later in the chapter will help to overcome the apparent arbitrariness of this complicated expression. For the present, treat the equation as a quantum-mechanical postulate. Various ways of expressing the Schrödinger equation, of incorporating the time-dependence of the wavefunction, and of extending it to more dimensions, are collected in Table 8.1. In Chapter 9 we shall solve the equation for a number of important cases; in this chapter we are mainly concerned with its significance, the interpretation of its solutions, and seeing how it implies that energy is quantized.

Table 8.1 The Schrödinger equation

For one-dimensional systems:

$$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} + V(x)\psi = E\psi$$

Where $V(x)$ is the potential energy of the particle and E is its total energy. For three-dimensional systems

$$-\frac{\hbar^2}{2m} \nabla^2\psi + V\psi = E\psi$$

where V may depend on position and ∇^2 ('del squared') is

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$$

In systems with spherical symmetry three equivalent forms are

$$\begin{aligned}\nabla^2 &= \frac{1}{r} \frac{\partial^2}{\partial r^2} r + \frac{1}{r^2} \Lambda^2 \\ &= \frac{1}{r^2} \frac{\partial}{\partial r} r^2 \frac{\partial}{\partial r} + \frac{1}{r^2} \Lambda^2 \\ &= \frac{\partial^2}{\partial r^2} + \frac{2}{r} \frac{\partial}{\partial r} + \frac{1}{r^2} \Lambda^2\end{aligned}$$

where

$$\Lambda^2 = \frac{1}{\sin^2\theta} \frac{\partial^2}{\partial \phi^2} + \frac{1}{\sin\theta} \frac{\partial}{\partial \theta} \sin\theta \frac{\partial}{\partial \theta}$$

In the general case the Schrodinger equation is written

$$\hat{H}\psi = E\psi$$

where $\hat{H}$ is the hamiltonian operator for the system:

$$\hat{H} = -\frac{\hbar^2}{2m} \nabla^2 + V$$

For the evolution of a system with time, it is necessary to solve the time-dependent Schrödinger equation:

$$\hat{H}\Psi = i\hbar \frac{\partial \Psi}{\partial t}$$

Justification 8.1 *Using the Schrödinger equation to develop the de Broglie relation*

Although the Schrödinger equation should be regarded as a postulate, like Newton's equations of motion, it can be seen to be plausible by noting that it implies the de Broglie relation for a freely moving particle in a region with constant potential energy V . After making the substitution $V(x) = V$, we can rearrange eqn 8.13 into

$$\frac{d^2\psi}{dx^2} = -\frac{2m}{\hbar^2} (E - V) \psi$$

General strategies for solving differential equations of this and other types that occur frequently in physical chemistry are treated in *Appendix 2*. In the case at hand, we note that a solution is

$$\psi = e^{ikx} \quad k = \left\{ \frac{2m(E - V)}{\hbar^2} \right\}^{1/2}$$

Comment 8.5

Complex numbers and functions are discussed in *Appendix 2*. Complex numbers have the form $z = x + iy$, where $i = (-1)^{1/2}$ and the real numbers x and y are the real and imaginary parts of z , denoted $\text{Re}(z)$ and $\text{Im}(z)$, respectively. Similarly, a complex function of the form $f = g + ih$, where g and h are functions of real arguments, has a real part $\text{Re}(f) = g$ and an imaginary part $\text{Im}(f) = h$.

Fig. 8.18 The real (purple) and imaginary (blue) parts of a free particle wavefunction corresponding to motion towards positive x (as shown by the arrow).

Fig. 8.19 The wavefunction ψ is a probability amplitude in the sense that its square modulus ($\psi^* \psi$ or $|\psi|^2$) is a probability density. The probability of finding a particle in the region dx located at x is proportional to $|\psi|^2 dx$. We represent the probability density by the density of shading in the superimposed band.

Comment 8.6

To form the complex conjugate, ψ^* , of a complex function, replace i wherever it occurs by $-i$. For instance, the complex conjugate of e^{ikx} is e^{-ikx} . If the wavefunction is real, $|\psi|^2 = \psi^2$.

In quantum mechanics, a wavefunction that describes the spatial distribution of a particle (a ‘spatial wavefunction’) is complex if the particle it describes has a net motion. In the present case, we can use the relation $e^{i\theta} = \cos \theta + i \sin \theta$ to write

$$\psi = \cos kx + i \sin kx$$

The real and imaginary parts of ψ are drawn in Fig. 8.18, and we see that the imaginary component $\text{Im}(\psi) = \sin kx$ is shifted in the direction of the particle’s motion. That is, both the real and imaginary parts of the wavefunction are ‘real’, in the sense of being present, and we express ψ as a complex function simply to help with the visualization of the motion of the particle the wavefunction describes.

Now we recognize that $\cos kx$ (or $\sin kx$) is a wave of wavelength $\lambda = 2\pi/k$, as can be seen by comparing $\cos kx$ with the standard form of a harmonic wave, $\cos(2\pi x/\lambda)$. The quantity $E - V$ is equal to the kinetic energy of the particle, E_K , so $k = (2mE_K/\hbar^2)^{1/2}$, which implies that $E_K = k^2 \hbar^2 / 2m$. Because $E_K = p^2 / 2m$, it follows that

$$p = k\hbar$$

Therefore, the linear momentum is related to the wavelength of the wavefunction by

$$p = \frac{2\pi}{\lambda} \times \frac{h}{2\pi} = \frac{h}{\lambda}$$

which is the de Broglie relation.

8.4 The Born interpretation of the wavefunction

A principal tenet of quantum mechanics is that *the wavefunction contains all the dynamical information about the system it describes*. Here we concentrate on the information it carries about the location of the particle.

The interpretation of the wavefunction in terms of the location of the particle is based on a suggestion made by Max Born. He made use of an analogy with the wave theory of light, in which the square of the amplitude of an electromagnetic wave in a region is interpreted as its intensity and therefore (in quantum terms) as a measure of the probability of finding a photon present in the region. The **Born interpretation** of the wavefunction focuses on the square of the wavefunction (or the square modulus, $|\psi|^2 = \psi^* \psi$, if ψ is complex). It states that the value of $|\psi|^2$ at a point is proportional to the probability of finding the particle in a region around that point. Specifically, for a one-dimensional system (Fig. 8.19):

If the wavefunction of a particle has the value ψ at some point x , then the probability of finding the particle between x and $x + dx$ is proportional to $|\psi|^2 dx$.

Thus, $|\psi|^2$ is the **probability density**, and to obtain the probability it must be multiplied by the length of the infinitesimal region dx . The wavefunction ψ itself is called the **probability amplitude**. For a particle free to move in three dimensions (for example, an electron near a nucleus in an atom), the wavefunction depends on the point $\mathbf{r}$ with coordinates x , y , and z , and the interpretation of $\psi(\mathbf{r})$ is as follows (Fig. 8.20):

If the wavefunction of a particle has the value ψ at some point $\mathbf{r}$, then the probability of finding the particle in an infinitesimal volume $d\tau = dx dy dz$ at that point is proportional to $|\psi|^2 d\tau$.

The Born interpretation does away with any worry about the significance of a negative (and, in general, complex) value of ψ because $|\psi|^2$ is real and never negative. There is no *direct* significance in the negative (or complex) value of a wavefunction: only the square modulus, a positive quantity, is directly physically significant, and both negative and positive regions of a wavefunction may correspond to a high

probability of finding a particle in a region (Fig. 8.21). However, later we shall see that the presence of positive and negative regions of a wavefunction is of great *indirect* significance, because it gives rise to the possibility of constructive and destructive interference between different wavefunctions.

Example 8.3 Interpreting a wavefunction

We shall see in Chapter 12 that the wavefunction of an electron in the lowest energy state of a hydrogen atom is proportional to e^{-r/a_0} , with a_0 a constant and r the distance from the nucleus. (Notice that this wavefunction depends only on this distance, not the angular position relative to the nucleus.) Calculate the relative probabilities of finding the electron inside a region of volume 1.0 pm^3 , which is small even on the scale of the atom, located at (a) the nucleus, (b) a distance a_0 from the nucleus.

Method The region of interest is so small on the scale of the atom that we can ignore the variation of ψ within it and write the probability, P , as proportional to the probability density (ψ^2 ; note that ψ is real) evaluated at the point of interest multiplied by the volume of interest, δV . That is, $P \propto \psi^2 \delta V$, with $\psi^2 \propto e^{-2r/a_0}$.

Answer In each case $\delta V = 1.0 \text{ pm}^3$. (a) At the nucleus, $r = 0$, so

$$P \propto e^0 \times (1.0 \text{ pm}^3) = (1.0) \times (1.0 \text{ pm}^3)$$

(b) At a distance $r = a_0$ in an arbitrary direction,

$$P \propto e^{-2} \times (1.0 \text{ pm}^3) = (0.14) \times (1.0 \text{ pm}^3)$$

Therefore, the ratio of probabilities is $1.0/0.14 = 7.1$. Note that it is more probable (by a factor of 7) that the electron will be found at the nucleus than in a volume element of the same size located at a distance a_0 from the nucleus. The negatively charged electron is attracted to the positively charged nucleus, and is likely to be found close to it.

A note on good practice The square of a wavefunction is not a probability: it is a probability density, and (in three dimensions) has the dimensions of $1/\text{length}^3$. It becomes a (unitless) probability when multiplied by a volume. In general, we have to take into account the variation of the amplitude of the wavefunction over the volume of interest, but here we are supposing that the volume is so small that the variation of ψ in the region can be ignored.

Self-test 8.3 The wavefunction for the electron in its lowest energy state in the ion He^+ is proportional to e^{-2r/a_0} . Repeat the calculation for this ion. Any comment?

[55; more compact wavefunction]

Fig. 8.20 The Born interpretation of the wavefunction in three-dimensional space implies that the probability of finding the particle in the volume element $d\tau = dx dy dz$ at some location r is proportional to the product of $d\tau$ and the value of $|\psi|^2$ at that location.

Fig. 8.21 The sign of a wavefunction has no direct physical significance: the positive and negative regions of this wavefunction both correspond to the same probability distribution (as given by the square modulus of ψ and depicted by the density of shading).

(a) Normalization

A mathematical feature of the Schrödinger equation is that, if ψ is a solution, then so is $N\psi$, where N is any constant. This feature is confirmed by noting that ψ occurs in every term in eqn 8.13, so any constant factor can be cancelled. This freedom to vary the wavefunction by a constant factor means that it is always possible to find a **normalization constant**, N , such that the proportionality of the Born interpretation becomes an equality.

We find the normalization constant by noting that, for a normalized wavefunction $N\psi$, the probability that a particle is in the region dx is equal to $(N\psi^*)(N\psi)dx$ (we are taking N to be real). Furthermore, the sum over all space of these individual probabilities must be 1 (the probability of the particle being somewhere is 1). Expressed mathematically, the latter requirement is

$$N^2 \int_{-\infty}^{\infty} \psi^* \psi dx = 1 \quad (8.15)$$

Almost all wavefunctions go to zero at sufficiently great distances so there is rarely any difficulty with the evaluation of this integral, and wavefunctions for which the integral in eqn 8.15 exists (in the sense of having a finite value) are said to be ‘square-integrable’. It follows that

$$N = \frac{1}{\left(\int_{-\infty}^{\infty} \psi^* \psi dx \right)^{1/2}} \quad (8.16)$$

Therefore, by evaluating the integral, we can find the value of N and hence ‘normalize’ the wavefunction. From now on, unless we state otherwise, we always use wavefunctions that have been normalized to 1; that is, from now on we assume that ψ already includes a factor that ensures that (in one dimension)

$$\int_{-\infty}^{\infty} \psi^* \psi dx = 1 \quad (8.17a)$$

In three dimensions, the wavefunction is normalized if

$$\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \psi^* \psi dx dy dz = 1 \quad (8.17b)$$

or, more succinctly, if

$$\int \psi^* \psi d\tau = 1 \quad (8.17c)$$

where $d\tau = dx dy dz$ and the limits of this definite integral are not written explicitly: in all such integrals, the integration is over all the space accessible to the particle. For systems with spherical symmetry it is best to work in **spherical polar coordinates** r , θ , and ϕ (Fig. 8.22): $x = r \sin \theta \cos \phi$, $y = r \sin \theta \sin \phi$, $z = r \cos \theta$. The volume element in spherical polar coordinates is $d\tau = r^2 \sin \theta dr d\theta d\phi$. To cover all space, the radius r ranges from 0 to ∞ , the colatitude, θ , ranges from 0 to π , and the azimuth, ϕ , ranges from 0 to 2π (Fig. 8.23), so the explicit form of eqn 6.17c is

$$\int_0^{\infty} \int_0^{\pi} \int_0^{2\pi} \psi^* \psi r^2 \sin \theta dr d\theta d\phi = 1 \quad (8.17d)$$

Example 8.4 Normalizing a wavefunction

Normalize the wavefunction used for the hydrogen atom in Example 8.3.

Method We need to find the factor N that guarantees that the integral in eqn 8.17c is equal to 1. Because the system is spherical, it is most convenient to use spherical coordinates and to carry out the integrations specified in eqn 8.17d. Note that the

Fig. 8.22 The spherical polar coordinates used for discussing systems with spherical symmetry.

Fig. 8.23 The surface of a sphere is covered by allowing θ to range from 0 to π , and then sweeping that arc around a complete circle by allowing ϕ to range from 0 to 2π .

limits on the first integral sign refer to r , those on the second to θ , and those on the third to ϕ . A useful integral for calculations on atomic wavefunctions is

$$\int_0^\infty x^n e^{-ax} dx = \frac{n!}{a^{n+1}}$$

where $n!$ denotes a factorial: $n! = n(n-1)(n-2) \dots 1$.

Answer The integration required is the product of three factors:

$$\int \psi^* \psi d\tau = N^2 \int_0^\infty \overbrace{r^2}^{\frac{1}{4}a_0^3} \overbrace{e^{-2r/a_0}}^2 dr \int_0^\pi \sin \theta d\theta \int_0^{2\pi} d\phi = \pi a_0^3 N^2$$

Therefore, for this integral to equal 1, we must set

$$N = \left(\frac{1}{\pi a_0^3} \right)^{1/2}$$

and the normalized wavefunction is

$$\psi = \left(\frac{1}{\pi a_0^3} \right)^{1/2} e^{-r/a_0}$$

Note that, because a_0 is a length, the dimensions of ψ are $1/\text{length}^{3/2}$ and therefore those of ψ^2 are $1/\text{length}^3$ (for instance, $1/\text{m}^3$) as is appropriate for a probability density.

If Example 8.3 is now repeated, we can obtain the actual probabilities of finding the electron in the volume element at each location, not just their relative values. Given (from Section 10.1) that $a_0 = 52.9$ pm, the results are (a) 2.2×10^{-6} , corresponding to 1 chance in about 500 000 inspections of finding the electron in the test volume, and (b) 2.9×10^{-7} , corresponding to 1 chance in 3.4 million.

Self-test 8.4 Normalize the wavefunction given in Self-test 8.3.

$$[N = (8/\pi a_0^3)^{1/2}]$$

(b) Quantization

The Born interpretation puts severe restrictions on the acceptability of wavefunctions. The principal constraint is that ψ must not be infinite anywhere. If it were, the integral in eqn 8.17 would be infinite (in other words, ψ would not be square-integrable) and the normalization constant would be zero. The normalized function would then be zero everywhere, except where it is infinite, which would be unacceptable. The requirement that ψ is finite everywhere rules out many possible solutions of the Schrödinger equation, because many mathematically acceptable solutions rise to infinity and are therefore physically unacceptable. We shall meet several examples shortly.

The requirement that ψ is finite everywhere is not the only restriction implied by the Born interpretation. We could imagine (and in Section 9.6a will meet) a solution of the Schrödinger equation that gives rise to more than one value of $|\psi|^2$ at a single point. The Born interpretation implies that such solutions are unacceptable, because it would be absurd to have more than one probability that a particle is at the same point. This restriction is expressed by saying that the wavefunction must be *single-valued*; that is, have only one value at each point of space.

Comment 8.7

Infinitely sharp spikes are acceptable provided they have zero width, so it is more appropriate to state that the wavefunction must not be infinite over any finite region. In elementary quantum mechanics the simpler restriction, to finite ψ , is sufficient.

Fig. 8.24 The wavefunction must satisfy stringent conditions for it to be acceptable. (a) Unacceptable because it is not continuous; (b) unacceptable because its slope is discontinuous; (c) unacceptable because it is not single-valued; (d) unacceptable because it is infinite over a finite region.

Comment 8.8

There are cases, and we shall meet them, where acceptable wavefunctions have kinks. These cases arise when the potential energy has peculiar properties, such as rising abruptly to infinity. When the potential energy is smoothly well-behaved and finite, the slope of the wavefunction must be continuous; if the potential energy becomes infinite, then the slope of the wavefunction need not be continuous. There are only two cases of this behaviour in elementary quantum mechanics, and the peculiarity will be mentioned when we meet them.

The Schrödinger equation itself also implies some mathematical restrictions on the type of functions that will occur. Because it is a second-order differential equation, the second derivative of ψ must be well-defined if the equation is to be applicable everywhere. We can take the second derivative of a function only if it is continuous (so there are no sharp steps in it, Fig. 8.24) and if its first derivative, its slope, is continuous (so there are no kinks).

At this stage we see that ψ must be continuous, have a continuous slope, be single-valued, and be square-integrable. An acceptable wavefunction cannot be zero everywhere, because the particle it describes must be somewhere. These are such severe restrictions that acceptable solutions of the Schrödinger equation do not in general exist for arbitrary values of the energy E . In other words, a particle may possess only certain energies, for otherwise its wavefunction would be physically unacceptable. That is, *the energy of a particle is quantized*. We can find the acceptable energies by solving the Schrödinger equation for motion of various kinds, and selecting the solutions that conform to the restrictions listed above. That is the task of the next chapter.

Quantum mechanical principles

We have claimed that a wavefunction contains all the information it is possible to obtain about the dynamical properties of the particle (for example, its location and momentum). We have seen that the Born interpretation tells us as much as we can know about location, but how do we find any additional information?

8.5 The information in a wavefunction

The Schrödinger equation for a particle of mass m free to move parallel to the x -axis with zero potential energy is obtained from eqn 8.13 by setting $V = 0$, and is

$$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} = E\psi \quad (8.18)$$

The solutions of this equation have the form

$$\psi = Ae^{ikx} + Be^{-ikx} \quad E = \frac{k^2\hbar^2}{2m} \quad (8.19)$$

where A and B are constants. To verify that ψ is a solution of eqn 8.18, we simply substitute it into the left-hand side of the equation and confirm that we obtain $E\psi$:

$$\begin{aligned} -\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} &= -\frac{\hbar^2}{2m} \frac{d^2}{dx^2} (Ae^{ikx} + Be^{-ikx}) \\ &= -\frac{\hbar^2}{2m} \{A(ik)^2 e^{ikx} + B(-ik)^2 e^{-ikx}\} \\ &= \frac{\hbar^2 k^2}{2m} (Ae^{ikx} + Be^{-ikx}) = E\psi \end{aligned}$$

(a) The probability density

We shall see later what determines the values of A and B ; for the time being we can treat them as arbitrary constants. Suppose that $B = 0$ in eqn 8.19, then the wavefunction is simply

$$\psi = Ae^{ikx} \quad (8.20)$$

Where is the particle? To find out, we calculate the probability density:

$$|\psi|^2 = (Ae^{ikx})^*(Ae^{ikx}) = (A^*e^{-ikx})(Ae^{ikx}) = |A|^2 \quad (8.21)$$

This probability density is independent of x ; so, wherever we look along the x -axis, there is an equal probability of finding the particle (Fig. 8.25a). In other words, if the wavefunction of the particle is given by eqn 8.20, then we cannot predict where we will find the particle. The same would be true if the wavefunction in eqn 8.19 had $A = 0$; then the probability density would be $|B|^2$, a constant.

Now suppose that in the wavefunction $A = B$. Then eqn 8.19 becomes

$$\psi = A(e^{ikx} + e^{-ikx}) = 2A \cos kx \quad (8.22)$$

The probability density now has the form

$$|\psi|^2 = (2A \cos kx)^*(2A \cos kx) = 4|A|^2 \cos^2 kx \quad (8.23)$$

This function is illustrated in Fig. 8.25b. As we see, the probability density periodically varies between 0 and $4|A|^2$. The locations where the probability density is zero correspond to *nodes* in the wavefunction: particles will never be found at the nodes. Specifically, a **node** is a point where a wavefunction passes *through* zero. The location where a wavefunction approaches zero without actually passing through zero is not a node. Nodes are defined in terms of the probability amplitude, the wavefunction itself. The probability density, of course, never passes through zero because it cannot be negative.

(b) Operators, eigenvalues, and eigenfunctions

To formulate a systematic way of extracting information from the wavefunction, we first note that any Schrödinger equation (such as those in eqns 8.13 and 8.18) may be written in the succinct form

$$\hat{H}\psi = E\psi \quad (8.24a)$$

with (in one dimension)

$$\hat{H} = -\frac{\hbar^2}{2m} \frac{d^2}{dx^2} + V(x) \quad (8.24b)$$

The quantity $\hat{H}$ is an **operator**, something that carries out a mathematical operation on the function ψ . In this case, the operation is to take the second derivative of ψ and (after multiplication by $-\hbar^2/2m$) to add the result to the outcome of multiplying ψ by V . The operator $\hat{H}$ plays a special role in quantum mechanics, and is called the **hamiltonian operator** after the nineteenth century mathematician William Hamilton, who developed a form of classical mechanics that, it subsequently turned out, is well suited to the formulation of quantum mechanics. The hamiltonian operator is the operator corresponding to the total energy of the system, the sum of the kinetic and potential energies. Consequently, we can infer—as we anticipated in Section 8.3—that the first term in eqn 8.24b (the term proportional to the second derivative) must be the operator for the kinetic energy. When the Schrödinger equation is written as in eqn 8.24a, it is seen to be an **eigenvalue equation**, an equation of the form

$$(\text{Operator})(\text{function}) = (\text{constant factor}) \times (\text{same function}) \quad (8.25a)$$

If we denote a general operator by $\hat{\Omega}$ (where Ω is uppercase omega) and a constant factor by ω (lowercase omega), then an eigenvalue equation has the form

$$\hat{\Omega}\psi = \omega\psi \quad (8.25b)$$

Fig. 8.25 (a) The square modulus of a wavefunction corresponding to a definite state of linear momentum is a constant; so it corresponds to a uniform probability of finding the particle anywhere. (b) The probability distribution corresponding to the superposition of states of equal magnitude of linear momentum but opposite direction of travel.

Comment 8.9

If the probability density of a particle is a constant, then it follows that, with x ranging from $-\infty$ to $+\infty$, the normalization constants, A or B , are 0. To avoid this embarrassing problem, x is allowed to range from $-L$ to $+L$, and L is allowed to go to infinity at the end of all calculations. We ignore this complication here.

The factor ω is called the **eigenvalue** of the operator $\hat{\Omega}$. The eigenvalue in eqn 8.24a is the energy. The function ψ in an equation of this kind is called an **eigenfunction** of the operator $\hat{\Omega}$ and is different for each eigenvalue. The eigenfunction in eqn 8.24a is the wavefunction corresponding to the energy E . It follows that another way of saying ‘solve the Schrödinger equation’ is to say ‘find the eigenvalues and eigenfunctions of the hamiltonian operator for the system’. The wavefunctions are the eigenfunctions of the hamiltonian operator, and the corresponding eigenvalues are the allowed energies.

Example 8.5 *Identifying an eigenfunction*

Show that e^{ax} is an eigenfunction of the operator d/dx , and find the corresponding eigenvalue. Show that e^{ax^2} is not an eigenfunction of d/dx .

Method We need to operate on the function with the operator and check whether the result is a constant factor times the original function.

Answer For $\hat{\Omega} = d/dx$ and $\psi = e^{ax}$:

$$\hat{\Omega}\psi = \frac{d}{dx}e^{ax} = ae^{ax} = a\psi$$

Therefore e^{ax} is indeed an eigenfunction of d/dx , and its eigenvalue is a . For $\psi = e^{ax^2}$,

$$\hat{\Omega}\psi = \frac{d}{dx}e^{ax^2} = 2axe^{ax^2} = 2ax \times \psi$$

which is not an eigenvalue equation even though the same function ψ occurs on the right, because ψ is now multiplied by a variable factor ($2ax$), not a constant factor. Alternatively, if the right-hand side is written $2a(xe^{ax^2})$, we see that it is a constant ($2a$) times a *different* function.

Self-test 8.5 Is the function $\cos ax$ an eigenfunction of (a) d/dx , (b) d^2/dx^2 ?
[(a) No, (b) yes]

The importance of eigenvalue equations is that the pattern

$$(\text{Energy operator})\psi = (\text{energy}) \times \psi$$

exemplified by the Schrödinger equation is repeated for other **observables**, or measurable properties of a system, such as the momentum or the electric dipole moment. Thus, it is often the case that we can write

$$(\text{Operator corresponding to an observable})\psi = (\text{value of observable}) \times \psi$$

The symbol $\hat{\Omega}$ in eqn 8.25b is then interpreted as an operator (for example, the hamiltonian, $\hat{H}$) corresponding to an observable (for example, the energy), and the eigenvalue ω is the value of that observable (for example, the value of the energy, E). Therefore, if we know both the wavefunction ψ and the operator $\hat{\Omega}$ corresponding to the observable Ω of interest, and the wavefunction is an eigenfunction of the operator $\hat{\Omega}$, then we can predict the outcome of an observation of the property Ω (for example, an atom’s energy) by picking out the factor ω in the eigenvalue equation, eqn 8.25b.

A basic postulate of quantum mechanics tells us how to set up the operator corresponding to a given observable:

Observables, Ω , are represented by operators, $\hat{\Omega}$, built from the following position and momentum operators:

$$\hat{x} = x \times \quad \hat{p}_x = \frac{\hbar}{i} \frac{d}{dx} \quad [8.26]$$

That is, the operator for location along the x -axis is multiplication (of the wavefunction) by x and the operator for linear momentum parallel to the x -axis is proportional to taking the derivative (of the wavefunction) with respect to x .

Comment 8.10

The rules summarized by eqn 8.26 apply to observables that depend on spatial variables; intrinsic properties, such as spin (see Section 9.8) are treated differently.

Example 8.6 Determining the value of an observable

What is the linear momentum of a particle described by the wavefunction in eqn 8.19 with (a) $B = 0$, (b) $A = 0$?

Method We operate on ψ with the operator corresponding to linear momentum (eqn 8.26), and inspect the result. If the outcome is the original wavefunction multiplied by a constant (that is, we generate an eigenvalue equation), then the constant is identified with the value of the observable.

Answer (a) With the wavefunction given in eqn 8.19 with $B = 0$,

$$\hat{p}_x \psi = \frac{\hbar}{i} \frac{d\psi}{dx} = \frac{\hbar}{i} A \frac{de^{ikx}}{dx} = \frac{\hbar}{i} B \times ike^{ikx} = k\hbar Be^{-ikx} = k\hbar \psi$$

This is an eigenvalue equation, and by comparing it with eqn 8.25b we find that $p_x = +k\hbar$. (b) For the wavefunction with $A = 0$,

$$\hat{p}_x \psi = \frac{\hbar}{i} \frac{d\psi}{dx} = \frac{\hbar}{i} B \frac{de^{-ikx}}{dx} = \frac{\hbar}{i} B \times (-ik)e^{-ikx} = -k\hbar Be^{-ikx} = -k\hbar \psi$$

The magnitude of the linear momentum is the same in each case ($k\hbar$), but the signs are different: In (a) the particle is travelling to the right (positive x) but in (b) it is travelling to the left (negative x).

Self-test 8.6 The operator for the angular momentum of a particle travelling in a circle in the xy -plane is $\hat{L}_z = (\hbar/i)d/d\phi$, where ϕ is its angular position. What is the angular momentum of a particle described by the wavefunction $e^{-2i\phi}$?

$$[L_z = -2\hbar]$$

We use the definitions in eqn 8.26 to construct operators for other spatial observables. For example, suppose we wanted the operator for a potential energy of the form $V = \frac{1}{2}kx^2$, with k a constant (later, we shall see that this potential energy describes the vibrations of atoms in molecules). Then it follows from eqn 8.26 that the operator corresponding to V is multiplication by x^2 :

$$\hat{V} = \frac{1}{2}kx^2 \times \quad (8.27)$$

In normal practice, the multiplication sign is omitted. To construct the operator for kinetic energy, we make use of the classical relation between kinetic energy and linear

Fig. 8.26 Even if a wavefunction does not have the form of a periodic wave, it is still possible to infer from it the average kinetic energy of a particle by noting its average curvature. This illustration shows two wavefunctions: the sharply curved function corresponds to a higher kinetic energy than the less sharply curved function.

Comment 8.11

We are using the term ‘curvature’ informally: the precise technical definition of the curvature of a function f is $(d^2f/dx^2)/\{1 + (df/dx)^2\}^{3/2}$.

Fig. 8.27 The observed kinetic energy of a particle is an average of contributions from the entire space covered by the wavefunction. Sharply curved regions contribute a high kinetic energy to the average; slightly curved regions contribute only a small kinetic energy.

momentum, which in one dimension is $E_K = p_x^2/2m$. Then, by using the operator for p_x in eqn 8.26 we find:

$$\hat{E}_K = \frac{1}{2m} \left(\frac{\hbar}{i} \frac{d}{dx} \right) \left(\frac{\hbar}{i} \frac{d}{dx} \right) = -\frac{\hbar^2}{2m} \frac{d^2}{dx^2} \quad (8.28)$$

It follows that the operator for the total energy, the hamiltonian operator, is

$$\hat{H} = \hat{E}_K + \hat{V} = -\frac{\hbar^2}{2m} \frac{d^2}{dx^2} + \hat{V} \quad (8.29)$$

with $\hat{V}$ the multiplicative operator in eqn 8.27 (or some other relevant potential energy).

The expression for the kinetic energy operator, eqn 8.28, enables us to develop the point made earlier concerning the interpretation of the Schrödinger equation. In mathematics, the second derivative of a function is a measure of its curvature: a large second derivative indicates a sharply curved function (Fig. 8.26). It follows that a sharply curved wavefunction is associated with a high kinetic energy, and one with a low curvature is associated with a low kinetic energy. This interpretation is consistent with the de Broglie relation, which predicts a short wavelength (a sharply curved wavefunction) when the linear momentum (and hence the kinetic energy) is high. However, it extends the interpretation to wavefunctions that do not spread through space and resemble those shown in Fig. 8.26. The curvature of a wavefunction in general varies from place to place. Wherever a wavefunction is sharply curved, its contribution to the total kinetic energy is large (Fig. 8.27). Wherever the wavefunction is not sharply curved, its contribution to the overall kinetic energy is low. As we shall shortly see, the observed kinetic energy of the particle is an integral of all the contributions of the kinetic energy from each region. Hence, we can expect a particle to have a high kinetic energy if the average curvature of its wavefunction is high. Locally there can be both positive and negative contributions to the kinetic energy (because the curvature can be either positive, $\smile$, or negative, $\frown$), but the average is always positive (see Problem 8.22).

The association of high curvature with high kinetic energy will turn out to be a valuable guide to the interpretation of wavefunctions and the prediction of their shapes. For example, suppose we need to know the wavefunction of a particle with a given total energy and a potential energy that decreases with increasing x (Fig. 8.28). Because the difference $E - V = E_K$ increases from left to right, the wavefunction must become more sharply curved as x increases: its wavelength decreases as the local contributions to its kinetic energy increase. We can therefore guess that the wavefunction will look like the function sketched in the illustration, and more detailed calculation confirms this to be so.

(c) Hermitian operators

All the quantum mechanical operators that correspond to observables have a very special mathematical property: they are ‘hermitian’. An **hermitian operator** is one for which the following relation is true:

$$\text{Hermiticity: } \int \psi_i^* \hat{Q} \psi_j dx = \left\{ \int \psi_j^* \hat{Q} \psi_i dx \right\}^* \quad [8.30]$$

It is easy to confirm that the position operator ($x \times$) is hermitian because we are free to change the order of the factors in the integrand:

$$\int_{-\infty}^{\infty} \psi_i^* x \psi_j dx = \int_{-\infty}^{\infty} \psi_j x \psi_i^* dx = \left\{ \int_{-\infty}^{\infty} \psi_j^* x \psi_i dx \right\}^*$$

The demonstration that the linear momentum operator is hermitian is more involved because we cannot just alter the order of functions we differentiate, but it is hermitian, as we show in the following *Justification*.

Justification 8.2 *The hermiticity of the linear momentum operator*

Our task is to show that

$$\int_{-\infty}^{\infty} \psi_i^* \hat{p}_x \psi_j dx = \left\{ \int_{-\infty}^{\infty} \psi_j^* \hat{p}_x \psi_i dx \right\}^*$$

with $\hat{p}_x$ given in eqn 8.26. To do so, we use ‘integration by parts’, the relation

$$\int f \frac{dg}{dx} dx = fg - \int g \frac{df}{dx} dx$$

In the present case we write

$$\begin{aligned} \int_{-\infty}^{\infty} \psi_i^* \hat{p}_x \psi_j dx &= \frac{\hbar}{i} \int_{-\infty}^{\infty} \psi_i^* \frac{d\psi_j}{dx} dx \\ &= \frac{\hbar}{i} \psi_i^* \psi_j \Big|_{-\infty}^{\infty} - \frac{\hbar}{i} \int_{-\infty}^{\infty} \psi_j \frac{d\psi_i^*}{dx} dx \end{aligned}$$

The first term on the right is zero, because all wavefunctions are zero at infinity in either direction, so we are left with

$$\begin{aligned} \int_{-\infty}^{\infty} \psi_i^* \hat{p}_x \psi_j dx &= -\frac{\hbar}{i} \int_{-\infty}^{\infty} \psi_j \frac{d\psi_i^*}{dx} dx = \left\{ \frac{\hbar}{i} \int_{-\infty}^{\infty} \psi_j^* \frac{d\psi_i}{dx} dx \right\}^* \\ &= \left\{ \int_{-\infty}^{\infty} \psi_j^* \hat{p}_x \psi_i dx \right\}^* \end{aligned}$$

as we set out to prove.

Fig. 8.28 The wavefunction of a particle in a potential decreasing towards the right and hence subjected to a constant force to the right. Only the real part of the wavefunction is shown, the imaginary part is similar, but displaced to the right.

Self-test 8.7 Confirm that the operator d^2/dx^2 is hermitian.

Hermitian operators are enormously important by virtue of two properties: their eigenvalues are real (as we prove in the *Justification* below), and their eigenfunctions are ‘orthogonal’. All observables have real values (in the mathematical sense, such as $x = 2$ m and $E = 10$ J), so all observables are represented by hermitian operators. To say that two different functions ψ_i and ψ_j are **orthogonal** means that the integral (over all space) of their product is zero:

$$\text{Orthogonality: } \int \psi_i^* \psi_j d\tau = 0 \quad [8.31]$$

For example, the hamiltonian operator is hermitian (it corresponds to an observable, the energy). Therefore, if ψ_1 corresponds to one energy, and ψ_2 corresponds to a different energy, then we know at once that the two functions are orthogonal and that the integral of their product is zero.

Justification 8.3 *The reality of eigenvalues*

For a wavefunction ψ that is normalized and is an eigenfunction of an hermitian operator $\hat{Q}$ with eigenvalue ω , we can write

$$\int \psi^* \hat{Q} \psi d\tau = \int \psi^* \omega \psi d\tau = \omega \int \psi^* \psi d\tau = \omega$$

However, by taking the complex conjugate we can write

$$\omega^* = \left\{ \int \psi^* \hat{Q} \psi d\tau \right\}^* = \int \psi^* \hat{Q} \psi d\tau = \omega$$

where in the second equality we have used the hermiticity of $\hat{Q}$. The conclusion that $\omega^* = \omega$ confirms that ω is real.

Fig. 8.29 The integral of the function $f(x) = \sin x \sin 2x$ is equal to the area (tinted) below the brown curve, and is zero, as can be inferred by symmetry. The function—and the value of the integral—repeats itself for all replications of the section between 0 and 2π , so the integral from $-\infty$ to ∞ is zero.

Illustration 8.2 *Confirming orthogonality*

The wavefunctions $\sin x$ and $\sin 2x$ are eigenfunctions of the hermitian operator d^2/dx^2 , with eigenvalues -1 and -4 , respectively. To verify that the two wavefunctions are mutually orthogonal, we integrate the product $(\sin x)(\sin 2x)$ over all space, which we may take to span from $x = 0$ to $x = 2\pi$, because both functions repeat themselves outside that range. Hence proving that the integral of their product is zero within that range implies that the integral over the whole of space is also integral (Fig. 8.29). A useful integral for this calculation is

$$\int \sin ax \sin bx dx = \frac{\sin(a-b)x}{2(a-b)} - \frac{\sin(a+b)x}{2(a+b)} + \text{constant}, \quad \text{if } a^2 \neq b^2$$

It follows that, for $a = 1$ and $b = 2$, and given the fact that $\sin 0 = 0$, $\sin 2\pi = 0$, and $\sin 6\pi = 0$,

$$\int_0^{2\pi} (\sin x)(\sin 2x) dx = 0$$

and the two functions are mutually orthogonal.

Self-test 8.8 Confirm that the functions $\sin x$ and $\sin 3x$ are mutually orthogonal.

$$\left[\int_{-\infty}^{\infty} \sin x \sin 3x dx = 0 \right]$$

(d) Superpositions and expectation values

Suppose now that the wavefunction is the one given in eqn 8.19 (with $A = B$). What is the linear momentum of the particle it describes? We quickly run into trouble if we use the operator technique. When we operate with p_x , we find

$$\frac{\hbar}{i} \frac{d\psi}{dx} = \frac{2\hbar}{i} A \frac{d \cos kx}{dx} = -\frac{2k\hbar}{i} A \sin kx \quad (8.32)$$

This expression is not an eigenvalue equation, because the function on the right ($\sin kx$) is different from that on the left ($\cos kx$).

When the wavefunction of a particle is not an eigenfunction of an operator, the property to which the operator corresponds does not have a definite value. However, in the current example the momentum is not completely indefinite because the cosine wavefunction is a **linear combination**, or sum, of e^{ikx} and e^{-ikx} , and these two functions, as we have seen, individually correspond to definite momentum states. We say that the total wavefunction is a **superposition** of more than one wavefunction. Symbolically we can write the superposition as

$$\psi = \psi_{\rightarrow} + \psi_{\leftarrow}$$

Particle with linear momentum $+k\hbar$	+	Particle with linear momentum $-k\hbar$

The interpretation of this composite wavefunction is that, if the momentum of the particle is repeatedly measured in a long series of observations, then its magnitude will be found to be $k\hbar$ in all the measurements (because that is the value for each component of the wavefunction). However, because the two component wavefunctions occur equally in the superposition, half the measurements will show that the particle is moving to the right ($p_x = +k\hbar$), and half the measurements will show that it is moving to the left ($p_x = -k\hbar$). According to quantum mechanics, we cannot predict in which direction the particle will in fact be found to be travelling; all we can say is that, in a long series of observations, if the particle is described by this wavefunction, then there are equal probabilities of finding the particle travelling to the right and to the left.

The same interpretation applies to any wavefunction written as a linear combination of eigenfunctions of an operator. Thus, suppose the wavefunction is known to be a superposition of many different linear momentum eigenfunctions and written as the linear combination

$$\psi = c_1\psi_1 + c_2\psi_2 + \cdots = \sum_k c_k\psi_k \quad (8.33)$$

where the c_k are numerical (possibly complex) coefficients and the ψ_k correspond to different momentum states. The functions ψ_k are said to form a **complete set** in the sense that any arbitrary function can be expressed as a linear combination of them. Then according to quantum mechanics:

- 1 When the momentum is measured, in a single observation one of the eigenvalues corresponding to the ψ_k that contribute to the superposition will be found.
- 2 The probability of measuring a particular eigenvalue in a series of observations is proportional to the square modulus ($|c_k|^2$) of the corresponding coefficient in the linear combination.
- 3 The average value of a large number of observations is given by the expectation value, $\langle\Omega\rangle$, of the operator $\hat{\Omega}$ corresponding to the observable of interest.

The **expectation value** of an operator $\hat{\Omega}$ is defined as

$$\langle\Omega\rangle = \int \psi^* \hat{\Omega} \psi d\tau \quad [8.34]$$

This formula is valid only for normalized wavefunctions. As we see in the *Justification* below, an expectation value is the weighted average of a large number of observations of a property.

Comment 8.12

In general, a linear combination of two functions f and g is $c_1f + c_2g$, where c_1 and c_2 are numerical coefficients, so a linear combination is a more general term than ‘sum’. In a sum, $c_1 = c_2 = 1$. A linear combination might have the form $0.567f + 1.234g$, for instance, so it is more general than the simple sum $f + g$.

Justification 8.4 *The expectation value of an operator*

If ψ is an eigenfunction of $\hat{\Omega}$ with eigenvalue ω , the expectation value of $\hat{\Omega}$ is

$$\langle \Omega \rangle = \int \overbrace{\psi^* \hat{\Omega} \psi}^{\omega \psi} d\tau = \int \psi^* \omega \psi d\tau = \omega \int \psi^* \psi d\tau = \omega$$

because ω is a constant and may be taken outside the integral, and the resulting integral is equal to 1 for a normalized wavefunction. The interpretation of this expression is that, because every observation of the property Ω results in the value ω (because the wavefunction is an eigenfunction of $\hat{\Omega}$), the mean value of all the observations is also ω .

A wavefunction that is not an eigenfunction of the operator of interest can be written as a linear combination of eigenfunctions. For simplicity, suppose the wavefunction is the sum of two eigenfunctions (the general case, eqn 8.33, can easily be developed). Then

$$\begin{aligned} \langle \Omega \rangle &= \int (c_1 \psi_1 + c_2 \psi_2)^* \hat{\Omega} (c_1 \psi_1 + c_2 \psi_2) d\tau \\ &= \int (c_1 \psi_1 + c_2 \psi_2)^* (c_1 \hat{\Omega} \psi_1 + c_2 \hat{\Omega} \psi_2) d\tau \\ &= \int (c_1 \psi_1 + c_2 \psi_2)^* (c_1 \omega_1 \psi_1 + c_2 \omega_2 \psi_2) d\tau \\ &= c_1^* c_1 \omega_1 \overbrace{\int \psi_1^* \psi_1 d\tau}^1 + c_2^* c_2 \omega_2 \overbrace{\int \psi_2^* \psi_2 d\tau}^1 \\ &\quad + c_2^* c_1 \omega_1 \overbrace{\int \psi_2^* \psi_1 d\tau}^0 + c_1^* c_2 \omega_2 \overbrace{\int \psi_1^* \psi_2 d\tau}^0 \end{aligned}$$

The first two integrals on the right are both equal to 1 because the wavefunctions are individually normalized. Because ψ_1 and ψ_2 correspond to different eigenvalues of an hermitian operator, they are orthogonal, so the third and fourth integrals on the right are zero. We can conclude that

$$\langle \Omega \rangle = |c_1|^2 \omega_1 + |c_2|^2 \omega_2$$

This expression shows that the expectation value is the sum of the two eigenvalues weighted by the probabilities that each one will be found in a series of measurements. Hence, the expectation value is the weighted mean of a series of observations.

Example 8.7 *Calculating an expectation value*

Calculate the average value of the distance of an electron from the nucleus in the hydrogen atom in its state of lowest energy.

Method The average radius is the expectation value of the operator corresponding to the distance from the nucleus, which is multiplication by r . To evaluate $\langle r \rangle$, we need to know the normalized wavefunction (from Example 8.4) and then evaluate the integral in eqn 8.34.

Answer The average value is given by the expectation value

$$\langle r \rangle = \int \psi^* r \psi d\tau$$

which we evaluate by using spherical polar coordinates. Using the normalized function in Example 8.4 gives

$$\langle r \rangle = \frac{1}{\pi a_0^3} \int_0^\infty \overbrace{r^3}^{3!a_0^3/2^4} e^{-2r/a_0} dr \int_0^\pi \overbrace{\sin \theta}^2 d\theta \int_0^{2\pi} \overbrace{d\phi}^{2\pi} = \frac{3}{2} a_0$$

Because $a_0 = 52.9$ pm (see Section 10.1), $\langle r \rangle = 79.4$ pm. This result means that, if a very large number of measurements of the distance of the electron from the nucleus are made, then their mean value will be 79.4 pm. However, each different observation will give a different and unpredictable individual result because the wavefunction is not an eigenfunction of the operator corresponding to r .

Self-test 8.9 Evaluate the root mean square distance, $\langle r^2 \rangle^{1/2}$, of the electron from the nucleus in the hydrogen atom. $[3^{1/2}a_0 = 91.6$ pm]

The mean kinetic energy of a particle in one dimension is the expectation value of the operator given in eqn 8.28. Therefore, we can write

$$\langle E_K \rangle = \int \psi^* \hat{E}_K \psi d\tau = -\frac{\hbar^2}{2m} \int \psi^* \frac{d^2\psi}{dx^2} d\tau \quad (8.35)$$

This conclusion confirms the previous assertion that the kinetic energy is a kind of average over the curvature of the wavefunction: we get a large contribution to the observed value from regions where the wavefunction is sharply curved (so $d^2\psi/dx^2$ is large) and the wavefunction itself is large (so that ψ^* is large too).

8.6 The uncertainty principle

We have seen that, if the wavefunction is Ae^{ikx} , then the particle it describes has a definite state of linear momentum, namely travelling to the right with momentum $p_x = +k\hbar$. However, we have also seen that the position of the particle described by this wavefunction is completely unpredictable. In other words, if the momentum is specified precisely, it is impossible to predict the location of the particle. This statement is one-half of a special case of the **Heisenberg uncertainty principle**, one of the most celebrated results of quantum mechanics:

It is impossible to specify simultaneously, with arbitrary precision, both the momentum and the position of a particle.

Before discussing the principle further, we must establish its other half: that, if we know the position of a particle exactly, then we can say nothing about its momentum. The argument draws on the idea of regarding a wavefunction as a superposition of eigenfunctions, and runs as follows.

If we know that the particle is at a definite location, its wavefunction must be large there and zero everywhere else (Fig. 8.30). Such a wavefunction can be created by superimposing a large number of harmonic (sine and cosine) functions, or, equivalently, a number of e^{ikx} functions. In other words, we can create a sharply localized

Fig. 8.30 The wavefunction for a particle at a well-defined location is a sharply spiked function that has zero amplitude everywhere except at the particle's position.

Fig. 8.31 The wavefunction for a particle with an ill-defined location can be regarded as the superposition of several wavefunctions of definite wavelength that interfere constructively in one place but destructively elsewhere. As more waves are used in the superposition (as given by the numbers attached to the curves), the location becomes more precise at the expense of uncertainty in the particle's momentum. An infinite number of waves is needed to construct the wavefunction of a perfectly localized particle.

Exploration Use mathematical software or an electronic spreadsheet to construct superpositions of cosine functions as

$$\psi(x) = \sum_{k=1}^N (1/N) \cos(k\pi x), \text{ where the}$$

constant $1/N$ is introduced to keep the superpositions with the same overall magnitude. Explore how the probability density $\psi^2(x)$ changes with the value of N .

wavefunction, called a **wave packet**, by forming a linear combination of wavefunctions that correspond to many different linear momenta. The superposition of a few harmonic functions gives a wavefunction that spreads over a range of locations (Fig. 8.31). However, as the number of wavefunctions in the superposition increases, the wave packet becomes sharper on account of the more complete interference between the positive and negative regions of the individual waves. When an infinite number of components is used, the wave packet is a sharp, infinitely narrow spike, which corresponds to perfect localization of the particle. Now the particle is perfectly localized. However, we have lost all information about its momentum because, as we saw above, a measurement of the momentum will give a result corresponding to any one of the infinite number of waves in the superposition, and which one it will give is unpredictable. Hence, if we know the location of the particle precisely (implying that its wavefunction is a superposition of an infinite number of momentum eigenfunctions), then its momentum is completely unpredictable.

A quantitative version of this result is

$$\Delta p \Delta q \geq \frac{1}{2} \hbar \quad (8.36a)$$

In this expression Δp is the 'uncertainty' in the linear momentum parallel to the axis q , and Δq is the uncertainty in position along that axis. These 'uncertainties' are precisely defined, for they are the root mean square deviations of the properties from their mean values:

$$\Delta p = \{\langle p^2 \rangle - \langle p \rangle^2\}^{1/2} \quad \Delta q = \{\langle q^2 \rangle - \langle q \rangle^2\}^{1/2} \quad (8.36b)$$

If there is complete certainty about the position of the particle ($\Delta q = 0$), then the only way that eqn 8.36a can be satisfied is for $\Delta p = \infty$, which implies complete uncertainty about the momentum. Conversely, if the momentum parallel to an axis is known exactly ($\Delta p = 0$), then the position along that axis must be completely uncertain ($\Delta q = \infty$).

The p and q that appear in eqn 8.36 refer to the same direction in space. Therefore, whereas simultaneous specification of the position on the x -axis and momentum parallel to the x -axis are restricted by the uncertainty relation, simultaneous location of position on x and motion parallel to y or z are not restricted. The restrictions that the uncertainty principle implies are summarized in Table 8.2.

Example 8.8 Using the uncertainty principle

Suppose the speed of a projectile of mass 1.0 g is known to within $1 \mu\text{m s}^{-1}$. Calculate the minimum uncertainty in its position.

Method Estimate Δp from $m\Delta v$, where Δv is the uncertainty in the speed; then use eqn 8.36a to estimate the minimum uncertainty in position, Δq .

Answer The minimum uncertainty in position is

$$\begin{aligned} \Delta q &= \frac{\hbar}{2m\Delta v} \\ &= \frac{1.055 \times 10^{-34} \text{ J s}}{2 \times (1.0 \times 10^{-3} \text{ kg}) \times (1 \times 10^{-6} \text{ m s}^{-1})} = 5 \times 10^{-26} \text{ m} \end{aligned}$$

where we have used $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$. The uncertainty is completely negligible for all practical purposes concerning macroscopic objects. However, if the mass is that of an electron, then the same uncertainty in speed implies an uncertainty in

position far larger than the diameter of an atom (the analogous calculation gives $\Delta q = 60$ m); so the concept of a trajectory, the simultaneous possession of a precise position and momentum, is untenable.

Self-test 8.10 Estimate the minimum uncertainty in the speed of an electron in a one-dimensional region of length $2a_0$. [500 km s⁻¹]

The Heisenberg uncertainty principle is more general than eqn 8.36 suggests. It applies to any pair of observables called **complementary observables**, which are defined in terms of the properties of their operators. Specifically, two observables $\hat{\Omega}_1$ and $\hat{\Omega}_2$ are complementary if

$$\hat{\Omega}_1(\hat{\Omega}_2\psi) \neq \hat{\Omega}_2(\hat{\Omega}_1\psi) \quad (8.37)$$

When the effect of two operators depends on their order (as this equation implies), we say that they do not **commute**. The different outcomes of the effect of applying $\hat{\Omega}_1$ and $\hat{\Omega}_2$ in a different order are expressed by introducing the **commutator** of the two operators, which is defined as

$$[\hat{\Omega}_1, \hat{\Omega}_2] = \hat{\Omega}_1\hat{\Omega}_2 - \hat{\Omega}_2\hat{\Omega}_1 \quad (8.38)$$

We can conclude from *Illustration 8.3* that the commutator of the operators for position and linear momentum is

$$[\hat{x}, \hat{p}_x] = i\hbar \quad (8.39)$$

Table 8.2* Constraints of the uncertainty principle

Variable 2	Variable 1					
	x	y	z	p_x	p_y	p_z
x						
y						
z						
p_x						
p_y						
p_z						

* Pairs of observables that cannot be determined simultaneously with arbitrary precision are marked with a white rectangle; all others are unrestricted.

Illustration 8.3 Evaluating a commutator

To show that the operators for position and momentum do not commute (and hence are complementary observables) we consider the effect of $\hat{x}\hat{p}_x$ (that is, the effect of $\hat{p}_x$ followed by the effect on the outcome of multiplication by x) on a wavefunction ψ :

$$\hat{x}\hat{p}_x\psi = x \times \frac{\hbar}{i} \frac{d\psi}{dx}$$

Next, we consider the effect of $\hat{p}_x\hat{x}$ on the same function (that is, the effect of multiplication by x followed by the effect of $\hat{p}_x$ on the outcome):

$$\hat{p}_x\hat{x}\psi = \frac{\hbar}{i} \frac{d}{dx} x\psi = \frac{\hbar}{i} \left(\psi + x \frac{d\psi}{dx} \right)$$

For this step we have used the standard rule about differentiating a product of functions. The second expression is clearly different from the first, so the two operators do not commute. Subtraction of the second expression from the first gives eqn 8.39.

Comment 8.13

For two functions f and g ,
 $d(fg) = fdg + gdf$.

The commutator in eqn 8.39 is of such vital significance in quantum mechanics that it is taken as a fundamental distinction between classical mechanics and quantum mechanics. In fact, this commutator may be taken as a postulate of quantum mechanics, and is used to justify the choice of the operators for position and linear momentum given in eqn 8.26.

Comment 8.14

The ‘modulus’ notation $|\dots|$ means take the magnitude of the term the bars enclose: for a real quantity x , $|x|$ is the magnitude of x (its value without its sign); for an imaginary quantity iy , $|iy|$ is the magnitude of y ; and—most generally—for a complex quantity $z = x + iy$, $|z|$ is the value of $(z^*z)^{1/2}$. For example, $|-2| = 2$, $|3i| = 3$, and $|-2 + 3i| = \{(-2 - 3i)(-2 + 3i)\}^{1/2} = 13^{1/2}$. Physically, the modulus on the right of eqn 8.40 ensures that the product of uncertainties has a real, non-negative value.

With the concept of commutator established, the Heisenberg uncertainty principle can be given its most general form. For *any* two pairs of observables, Ω_1 and Ω_2 , the uncertainties (to be precise, the root mean square deviations of their values from the mean) in simultaneous determinations are related by

$$\Delta\Omega_1\Delta\Omega_2 \geq \frac{1}{2} |\langle [\hat{\Omega}_1, \hat{\Omega}_2] \rangle| \quad (8.40)$$

We obtain the special case of eqn 8.36a when we identify the observables with x and p_x and use eqn 8.39 for their commutator.

Complementary observables are observables with non-commuting operators. With the discovery that some pairs of observables are complementary (we meet more examples in the next chapter), we are at the heart of the difference between classical and quantum mechanics. Classical mechanics supposed, falsely as we now know, that the position and momentum of a particle could be specified simultaneously with arbitrary precision. However, quantum mechanics shows that position and momentum are complementary, and that we have to make a choice: we can specify position at the expense of momentum, or momentum at the expense of position.

The realization that some observables are complementary allows us to make considerable progress with the calculation of atomic and molecular properties, but it does away with some of the most cherished concepts of classical physics.

8.7 The postulates of quantum mechanics

For convenience, we collect here the postulates on which quantum mechanics is based and which have been introduced in the course of this chapter.

The wavefunction. All dynamical information is contained in the wavefunction ψ for the system, which is a mathematical function found by solving the Schrödinger equation for the system. In one dimension:

$$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} + V(x)\psi = E\psi$$

The Born interpretation. If the wavefunction of a particle has the value ψ at some point $\mathbf{r}$, then the probability of finding the particle in an infinitesimal volume $d\tau = dx dy dz$ at that point is proportional to $|\psi|^2 d\tau$.

Acceptable wavefunctions. An acceptable wavefunction must be continuous, have a continuous first derivative, be single-valued, and be square-integrable.

Observables. Observables, Ω , are represented by operators, $\hat{\Omega}$, built from position and momentum operators of the form

$$\hat{x} = x \times \quad \hat{p}_x = \frac{\hbar}{i} \frac{d}{dx}$$

or, more generally, from operators that satisfy the commutation relation $[\hat{x}, \hat{p}_x] = i\hbar$.

The Heisenberg uncertainty principle. It is impossible to specify simultaneously, with arbitrary precision, both the momentum and the position of a particle and, more generally, any pair of observable with operators that do not commute.

Checklist of key ideas

- ☐ 1. In classical physics, radiation is described in terms of an oscillating electromagnetic disturbance that travels through vacuum at a constant speed $c = \lambda\nu$.
- ☐ 2. A black body is an object that emits and absorbs all frequencies of radiation uniformly.
- ☐ 3. The variation of the energy output of a black body with wavelength is explained by invoking quantization of energy, the limitation of energies to discrete values, which in turn leads to the Planck distribution, eqn 8.5.
- ☐ 4. The variation of the molar heat capacity of a solid with temperature is explained by invoking quantization of energy, which leads to the Einstein and Debye formulas, eqns 8.7 and 8.9.
- ☐ 5. Spectroscopic transitions are changes in populations of quantized energy levels of a system involving the absorption, emission, or scattering of electromagnetic radiation, $\Delta E = h\nu$.
- ☐ 6. The photoelectric effect is the ejection of electrons from metals when they are exposed to ultraviolet radiation: $\frac{1}{2}m_e v^2 = h\nu - \Phi$, where Φ is the work function, the energy required to remove an electron from the metal to infinity.
- ☐ 7. The photoelectric effect and electron diffraction are phenomena that confirm wave–particle duality, the joint particle and wave character of matter and radiation.
- ☐ 8. The de Broglie relation, $\lambda = h/p$, relates the momentum of a particle with its wavelength.
- ☐ 9. A wavefunction is a mathematical function obtained by solving the Schrödinger equation and which contains all the dynamical information about a system.
- ☐ 10. The time-independent Schrödinger equation in one dimension is $-(\hbar^2/2m)(d^2\psi/dx^2) + V(x)\psi = E\psi$.
- ☐ 11. The Born interpretation of the wavefunction states that the value of $|\psi|^2$, the probability density, at a point is proportional to the probability of finding the particle at that point.
- ☐ 12. Quantization is the confinement of a dynamical observable to discrete values.
- ☐ 13. An acceptable wavefunction must be continuous, have a continuous first derivative, be single-valued, and be square-integrable.
- ☐ 14. An operator is something that carries out a mathematical operation on a function. The position and momentum operators are $\hat{x} = x \times$ and $\hat{p}_x = (\hbar/i)d/dx$, respectively.
- ☐ 15. The hamiltonian operator is the operator for the total energy of a system, $\hat{H}\psi = E\psi$ and is the sum of the operators for kinetic energy and potential energy.
- ☐ 16. An eigenvalue equation is an equation of the form $\hat{\Omega}\psi = \omega\psi$. The eigenvalue is the constant ω in the eigenvalue equation; the eigenfunction is the function ψ in the eigenvalue equation.
- ☐ 17. The expectation value of an operator is $\langle\Omega\rangle = \int \psi^* \hat{\Omega} \psi d\tau$.
- ☐ 18. An hermitian operator is one for which $\int \psi_i^* \hat{\Omega} \psi_j dx = (\int \psi_j^* \hat{\Omega} \psi_i dx)^*$. The eigenvalues of hermitian operators are real and correspond to observables, measurable properties of a system. The eigenfunctions of hermitian operations are orthogonal, meaning that $\int \psi_i^* \psi_j d\tau = 0$.
- ☐ 19. The Heisenberg uncertainty principle states that it is impossible to specify simultaneously, with arbitrary precision, both the momentum and the position of a particle; $\Delta p \Delta q \geq \frac{1}{2}\hbar$.
- ☐ 20. Two operators commute when $[\hat{\Omega}_1, \hat{\Omega}_2] = \hat{\Omega}_1 \hat{\Omega}_2 - \hat{\Omega}_2 \hat{\Omega}_1 = 0$.
- ☐ 21. Complementary observables are observables corresponding to non-commuting operators.
- ☐ 22. The general form of the Heisenberg uncertainty principle is $\Delta\Omega_1 \Delta\Omega_2 \geq \frac{1}{2} |\langle [\hat{\Omega}_1, \hat{\Omega}_2] \rangle|$.

- 8.14b** Determine the commutators of the operators a and $a^\dagger$, where $a = (\hat{x} + i\hat{p})/2^{1/2}$ and $a^\dagger = (\hat{x} - i\hat{p})/2^{1/2}$.

Problems*

Numerical problems

8.1 The Planck distribution gives the energy in the wavelength range $d\lambda$ at the wavelength λ . Calculate the energy density in the range 650 nm to 655 nm inside a cavity of volume 100 cm^3 when its temperature is (a) 25°C , (b) 3000°C .

8.2 For a black body, the temperature and the wavelength of emission maximum, λ_{max} , are related by Wien's law, $\lambda_{\text{max}} T = \frac{1}{5} c_2$, where $c_2 = hc/k$ (see Problem 8.10). Values of λ_{max} from a small pinhole in an electrically heated container were determined at a series of temperatures, and the results are given below. Deduce a value for Planck's constant.

$\theta/^\circ\text{C}$	1000	1500	2000	2500	3000	3500
$\lambda_{\text{max}}/\text{nm}$	2181	1600	1240	1035	878	763

8.3 The Einstein frequency is often expressed in terms of an equivalent temperature θ_E , where $\theta_E = h\nu/k$. Confirm that θ_E has the dimensions of temperature, and express the criterion for the validity of the high-temperature form of the Einstein equation in terms of it. Evaluate θ_E for (a) diamond, for which $\nu = 46.5 \text{ THz}$ and (b) for copper, for which $\nu = 7.15 \text{ THz}$. What fraction of the Dulong and Petit value of the heat capacity does each substance reach at 25°C ?

8.4 The ground-state wavefunction for a particle confined to a one-dimensional box of length L is

$$\psi = \left(\frac{2}{L}\right)^{1/2} \sin\left(\frac{\pi x}{L}\right)$$

Suppose the box is 10.0 nm long. Calculate the probability that the particle is (a) between $x = 4.95 \text{ nm}$ and 5.05 nm , (b) between $x = 1.95 \text{ nm}$ and 2.05 nm , (c) between $x = 9.90 \text{ nm}$ and 10.00 nm , (d) in the right half of the box, (e) in the central third of the box.

8.5 The ground-state wavefunction of a hydrogen atom is

$$\psi = \left(\frac{1}{\pi a_0^3}\right)^{1/2} e^{-r/a_0}$$

where $a_0 = 53 \text{ pm}$ (the Bohr radius). (a) Calculate the probability that the electron will be found somewhere within a small sphere of radius 1.0 pm centred on the nucleus. (b) Now suppose that the same sphere is located at $r = a_0$. What is the probability that the electron is inside it?

8.6 The normalized wavefunctions for a particle confined to move on a circle are $\psi(\phi) = (1/2\pi)^{1/2} e^{-im\phi}$, where $m = 0, \pm 1, \pm 2, \pm 3, \dots$ and $0 \leq \phi \leq 2\pi$. Determine $\langle \phi \rangle$.

8.7 A particle is in a state described by the wavefunction $\psi(x) = (2a/\pi)^{1/4} e^{-ax^2}$, where a is a constant and $-\infty \leq x \leq \infty$. Verify that the value of the product $\Delta p \Delta x$ is consistent with the predictions from the uncertainty principle.

8.8 A particle is in a state described by the wavefunction $\psi(x) = a^{1/2} e^{-ax}$, where a is a constant and $0 \leq x \leq \infty$. Determine the expectation value of the commutator of the position and momentum operators.

Theoretical problems

8.9 Demonstrate that the Planck distribution reduces to the Rayleigh–Jeans law at long wavelengths.

8.10 Derive Wien's law, that $\lambda_{\text{max}} T$ is a constant, where λ_{max} is the wavelength corresponding to maximum in the Planck distribution at the temperature T , and deduce an expression for the constant as a multiple of the second radiation constant, $c_2 = hc/k$.

8.11 Use the Planck distribution to deduce the Stefan–Boltzmann law that the total energy density of black-body radiation is proportional to T^4 , and find the constant of proportionality.

8.12† Prior to Planck's derivation of the distribution law for black-body radiation, Wien found empirically a closely related distribution function which is very nearly but not exactly in agreement with the experimental results, namely, $\rho = (a/\lambda^5) e^{-b/\lambda kT}$. This formula shows small deviations from Planck's at long wavelengths. (a) By fitting Wien's empirical formula to Planck's at short wavelengths determine the constants a and b . (b) Demonstrate that Wien's formula is consistent with Wien's law (Problem 8.10) and with the Stefan–Boltzmann law (Problem 8.11).

8.13 Normalize the following wavefunctions: (a) $\sin(n\pi x/L)$ in the range $0 \leq x \leq L$, where $n = 1, 2, 3, \dots$, (b) a constant in the range $-L \leq x \leq L$, (c) $e^{-r/a}$ in three-dimensional space, (d) $x e^{-r/2a}$ in three-dimensional space. *Hint:* The volume element in three dimensions is $d\tau = r^2 dr \sin \theta d\theta d\phi$, with $0 \leq r < \infty$, $0 \leq \theta \leq \pi$, $0 \leq \phi \leq 2\pi$. Use the integral in Example 8.4.

8.14 (a) Two (unnormalized) excited state wavefunctions of the H atom are

$$(i) \psi = \left(2 - \frac{r}{a_0}\right) e^{-r/a_0} \quad (ii) \psi = r \sin \theta \cos \phi e^{-r/2a_0}$$

Normalize both functions to 1. (b) Confirm that these two functions are mutually orthogonal.

8.15 Identify which of the following functions are eigenfunctions of the operator d/dx : (a) e^{ikx} , (b) $\cos kx$, (c) k , (d) kx , (e) $e^{-\alpha x^2}$. Give the corresponding eigenvalue where appropriate.

8.16 Determine which of the following functions are eigenfunctions of the inversion operator $\hat{i}$ (which has the effect of making the replacement $x \rightarrow -x$): (a) $x^3 - kx$, (b) $\cos kx$, (c) $x^2 + 3x - 1$. State the eigenvalue of $\hat{i}$ when relevant.

8.17 Which of the functions in Problem 8.15 are (a) also eigenfunctions of d^2/dx^2 and (b) only eigenfunctions of d^2/dx^2 ? Give the eigenvalues where appropriate.

8.18 A particle is in a state described by the wavefunction $\psi = (\cos \chi) e^{ikx} + (\sin \chi) e^{-ikx}$, where χ (chi) is a parameter. What is the probability that the particle will be found with a linear momentum (a) $+\hbar k$, (b) $-\hbar k$? What form would the wavefunction have if it were 90 per cent certain that the particle had linear momentum $+\hbar k$?

8.19 Evaluate the kinetic energy of the particle with wavefunction given in Problem 8.18.

8.20 Calculate the average linear momentum of a particle described by the following wavefunctions: (a) e^{ikx} , (b) $\cos kx$, (c) $e^{-\alpha x^2}$, where in each one x ranges from $-\infty$ to $+\infty$.

8.21 Evaluate the expectation values of r and r^2 for a hydrogen atom with wavefunctions given in Problem 8.14.

8.22 Calculate (a) the mean potential energy and (b) the mean kinetic energy of an electron in the ground state of a hydrogenic atom.

* Problems denoted with the symbol † were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

8.23 Use mathematical software to construct superpositions of cosine functions and determine the probability that a given momentum will be observed. If you plot the superposition (which you should), set $x = 0$ at the centre of the screen and build the superposition there. Evaluate the root mean square location of the packet, $\langle x^2 \rangle^{1/2}$.

8.24 Show that the expectation value of an operator that can be written as the square of an hermitian operator is positive.

8.25 (a) Given that any operators used to represent observables must satisfy the commutation relation in eqn 8.38, what would be the operator for position if the choice had been made to represent linear momentum parallel to the x -axis by multiplication by the linear momentum? These different choices are all valid ‘representations’ of quantum mechanics. (b) With the identification of $\hat{x}$ in this representation, what would be the operator for $1/x$? *Hint.* Think of $1/x$ as x^{-1} .

Applications: to biology, environmental science, and astrophysics

8.26† The temperature of the Sun’s surface is approximately 5800 K. On the assumption that the human eye evolved to be most sensitive at the wavelength of light corresponding to the maximum in the Sun’s radiant energy distribution, determine the colour of light to which the eye is most sensitive. *Hint:* See Problem 8.10.

8.27 We saw in *Impact I8.1* that electron microscopes can obtain images with several hundredfold higher resolution than optical microscopes because of the short wavelength obtainable from a beam of electrons. For electrons moving at speeds close to c , the speed of light, the expression for the de Broglie wavelength (eqn 8.12) needs to be corrected for relativistic effects:

$$\lambda = \frac{h}{\left\{ 2m_e eV \left(1 + \frac{eV}{2m_e c^2} \right) \right\}^{1/2}}$$

where c is the speed of light in vacuum and V is the potential difference through which the electrons are accelerated. (a) Use the expression above to calculate the de Broglie wavelength of electrons accelerated through 50 kV. (b) Is the relativistic correction important?

8.28† Solar energy strikes the top of the Earth’s atmosphere at a rate of 343 W m^{-2} . About 30 per cent of this energy is reflected directly back into space by the Earth or the atmosphere. The Earth–atmosphere system absorbs the remaining energy and re-radiates it into space as black-body radiation. What is the average black-body temperature of the Earth? What is the wavelength of the most plentiful of the Earth’s black-body radiation? *Hint.* Use Wien’s law, Problem 8.10.

8.29† A star too small and cold to shine has been found by S. Kulkarni, K. Matthews, B.R. Oppenheimer, and T. Nakajima (*Science* **270**, 1478 (1995)). The spectrum of the object shows the presence of methane, which, according to the authors, would not exist at temperatures much above 1000 K. The mass of the star, as determined from its gravitational effect on a companion star, is roughly 20 times the mass of Jupiter. The star is considered to be a brown dwarf, the coolest ever found. (a) From available thermodynamic data, test the stability of methane at temperatures above 1000 K. (b) What is λ_{max} for this star? (c) What is the energy density of the star relative to that of the Sun (6000 K)? (d) To determine whether the star will shine, estimate the fraction of the energy density of the star in the visible region of the spectrum.

Quantum theory: techniques and applications

To find the properties of systems according to quantum mechanics we need to solve the appropriate Schrödinger equation. This chapter presents the essentials of the solutions for three basic types of motion: translation, vibration, and rotation. We shall see that only certain wavefunctions and their corresponding energies are acceptable. Hence, quantization emerges as a natural consequence of the equation and the conditions imposed on it. The solutions bring to light a number of highly nonclassical, and therefore surprising, features of particles, especially their ability to tunnel into and through regions where classical physics would forbid them to be found. We also encounter a property of the electron, its spin, that has no classical counterpart. The chapter concludes with an introduction to the experimental techniques used to probe the quantization of energy in molecules.

The three basic modes of motion—translation (motion through space), vibration, and rotation—all play an important role in chemistry because they are ways in which molecules store energy. Gas-phase molecules, for instance, undergo translational motion and their kinetic energy is a contribution to the total internal energy of a sample. Molecules can also store energy as rotational kinetic energy and transitions between their rotational energy states can be observed spectroscopically. Energy is also stored as molecular vibration and transitions between vibrational states are responsible for the appearance of infrared and Raman spectra.

Translational motion

Section 8.5 introduced the quantum mechanical description of free motion in one dimension. We saw there that the Schrödinger equation is

$$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} = E\psi \quad (9.1a)$$

or more succinctly

$$\hat{H}\psi = E\psi \quad \hat{H} = -\frac{\hbar^2}{2m} \frac{d^2}{dx^2} \quad (9.1b)$$

The general solutions of eqn 9.1 are

$$\psi_k = Ae^{ikx} + Be^{-ikx} \quad E_k = \frac{k^2\hbar^2}{2m} \quad (9.2)$$

Note that we are now labelling both the wavefunctions and the energies (that is, the eigenfunctions and eigenvalues of $\hat{H}$) with the index k . We can verify that these

Problems

Fig. 9.1 A particle in a one-dimensional region with impenetrable walls. Its potential energy is zero between $x = 0$ and $x = L$, and rises abruptly to infinity as soon as it touches the walls.

functions are solutions by substituting ψ_k into the left-hand side of eqn 9.1a and showing that the result is equal to $E_k \psi_k$. In this case, all values of k , and therefore all values of the energy, are permitted. It follows that the translational energy of a free particle is not quantized.

We saw in Section 8.5b that a wavefunction of the form e^{ikx} describes a particle with linear momentum $p_x = +k\hbar$, corresponding to motion towards positive x (to the right), and that a wavefunction of the form e^{-ikx} describes a particle with the same magnitude of linear momentum but travelling towards negative x (to the left). That is, e^{ikx} is an eigenfunction of the operator $\hat{p}_x$ with eigenvalue $+k\hbar$, and e^{-ikx} is an eigenfunction with eigenvalue $-k\hbar$. In either state, $|\psi|^2$ is independent of x , which implies that the position of the particle is completely unpredictable. This conclusion is consistent with the uncertainty principle because, if the momentum is certain, then the position cannot be specified (the operators $\hat{x}$ and $\hat{p}_x$ do not commute, Section 8.6).

9.1 A particle in a box

In this section, we consider a **particle in a box**, in which a particle of mass m is confined between two walls at $x = 0$ and $x = L$: the potential energy is zero inside the box but rises abruptly to infinity at the walls (Fig. 9.1). This model is an idealization of the potential energy of a gas-phase molecule that is free to move in a one-dimensional container. However, it is also the basis of the treatment of the electronic structure of metals (Chapter 20) and of a primitive treatment of conjugated molecules. The particle in a box is also used in statistical thermodynamics in assessing the contribution of the translational motion of molecules to their thermodynamic properties (Chapter 16).

(a) The acceptable solutions

The Schrödinger equation for the region between the walls (where $V = 0$) is the same as for a free particle (eqn 9.1), so the general solutions given in eqn 9.2 are also the same. However, we can use $e^{\pm ikx} = \cos kx \pm i \sin kx$ to write

$$\begin{aligned}\psi_k &= Ae^{ikx} + Be^{-ikx} = A(\cos kx + i \sin kx) + B(\cos kx - i \sin kx) \\ &= (A + B) \cos kx + (A - B)i \sin kx\end{aligned}$$

If we absorb all numerical factors into two new coefficients C and D , then the general solutions take the form

$$\psi_k(x) = C \sin kx + D \cos kx \quad E_k = \frac{k^2 \hbar^2}{2m} \quad (9.3)$$

For a free particle, any value of E_k corresponds to an acceptable solution. However, when the particle is confined within a region, the acceptable wavefunctions must satisfy certain **boundary conditions**, or constraints on the function at certain locations. As we shall see when we discuss penetration into barriers, a wavefunction decays exponentially with distance inside a barrier, such as a wall, and the decay is infinitely fast when the potential energy is infinite. This behaviour is consistent with the fact that it is physically impossible for the particle to be found with an infinite potential energy. We conclude that the wavefunction must be zero where V is infinite, at $x < 0$ and $x > L$. The continuity of the wavefunction then requires it to vanish just inside the well at $x = 0$ and $x = L$. That is, the boundary conditions are $\psi_k(0) = 0$ and $\psi_k(L) = 0$. These boundary conditions imply quantization, as we show in the following *Justification*.

Justification 9.1 *The energy levels and wavefunctions of a particle in a one-dimensional box*

For an informal demonstration of quantization, we consider each wavefunction to be a de Broglie wave that must fit within the container. The permitted wavelengths satisfy

$$L = n \times \frac{1}{2} \lambda \quad n = 1, 2, \dots$$

and therefore

$$\lambda = \frac{2L}{n} \quad \text{with } n = 1, 2, \dots$$

According to the de Broglie relation, these wavelengths correspond to the momenta

$$p = \frac{h}{\lambda} = \frac{nh}{2L}$$

The particle has only kinetic energy inside the box (where $V = 0$), so the permitted energies are

$$E = \frac{p^2}{2m} = \frac{n^2 h^2}{8mL^2} \quad \text{with } n = 1, 2, \dots$$

A more formal and widely applicable approach is as follows. Consider the wall at $x = 0$. According to eqn 9.3, $\psi(0) = D$ (because $\sin 0 = 0$ and $\cos 0 = 1$). But because $\psi(0) = 0$ we must have $D = 0$. It follows that the wavefunction must be of the form $\psi_k(x) = C \sin kx$. The value of ψ at the other wall (at $x = L$) is $\psi_k(L) = C \sin kL$, which must also be zero. Taking $C = 0$ would give $\psi_k(x) = 0$ for all x , which would conflict with the Born interpretation (the particle must be somewhere). Therefore, kL must be chosen so that $\sin kL = 0$, which is satisfied by

$$kL = n\pi \quad n = 1, 2, \dots$$

The value $n = 0$ is ruled out, because it implies $k = 0$ and $\psi_k(x) = 0$ everywhere (because $\sin 0 = 0$), which is unacceptable. Negative values of n merely change the sign of $\sin kL$ (because $\sin(-x) = -\sin x$). The wavefunctions are therefore

$$\psi_n(x) = C \sin(n\pi x/L) \quad n = 1, 2, \dots$$

(At this point we have started to label the solutions with the index n instead of k .) Because k and E_k are related by eqn 9.3, and k and n are related by $kL = n\pi$, it follows that the energy of the particle is limited to $E_n = n^2 h^2 / 8mL^2$, the values obtained by the informal procedure.

We conclude that the energy of the particle in a one-dimensional box is quantized and that this quantization arises from the boundary conditions that ψ must satisfy if it is to be an acceptable wavefunction. This is a general conclusion: *the need to satisfy boundary conditions implies that only certain wavefunctions are acceptable, and hence restricts observables to discrete values*. So far, only energy has been quantized; shortly we shall see that other physical observables may also be quantized.

(b) Normalization

Before discussing the solution in more detail, we shall complete the derivation of the wavefunctions by finding the normalization constant (here written C and regarded as real, that is, does not contain i). To do so, we look for the value of C that ensures that the integral of ψ^2 over all the space available to the particle (that is, from $x = 0$ to $x = L$) is equal to 1:

$$\int_0^L \psi^2 dx = C^2 \int_0^L \sin^2 \frac{n\pi x}{L} dx = C^2 \times \frac{L}{2} = 1, \quad \text{so } C = \left(\frac{2}{L}\right)^{1/2}$$

Fig. 9.2 The allowed energy levels for a particle in a box. Note that the energy levels increase as n^2 , and that their separation increases as the quantum number increases.

Fig. 9.3 The first five normalized wavefunctions of a particle in a box. Each wavefunction is a standing wave, and successive functions possess one more half wave and a correspondingly shorter wavelength.

Exploration Plot the probability density for a particle in a box with $n = 1, 2, \dots, 5$ and $n = 50$. How do your plots illustrate the correspondence principle?

Comment 9.1

It is sometimes useful to write

$$\cos x = (e^{ix} + e^{-ix})/2 \quad \sin x = (e^{ix} - e^{-ix})/2i$$

for all n . Therefore, the complete solution to the problem is

$$E_n = \frac{n^2 h^2}{8mL^2} \quad n = 1, 2, \dots \quad (9.4a)$$

$$\psi_n(x) = \left(\frac{2}{L}\right)^{1/2} \sin\left(\frac{n\pi x}{L}\right) \quad \text{for } 0 \leq x \leq L \quad (9.4b)$$

Self-test 9.1 Provide the intermediate steps for the determination of the normalization constant C . *Hint.* Use the standard integral $\int \sin^2 ax \, dx = \frac{1}{2}x - \left(\frac{1}{4a}\right) \sin 2ax + \text{constant}$ and the fact that $\sin 2m\pi = 0$, with $m = 0, 1, 2, \dots$

The energies and wavefunctions are labelled with the ‘quantum number’ n . A **quantum number** is an integer (in some cases, as we shall see, a half-integer) that labels the state of the system. For a particle in a box there is an infinite number of acceptable solutions, and the quantum number n specifies the one of interest (Fig. 9.2). As well as acting as a label, a quantum number can often be used to calculate the energy corresponding to the state and to write down the wavefunction explicitly (in the present example, by using eqn 9.4).

(c) The properties of the solutions

Figure 9.3 shows some of the wavefunctions of a particle in a box: they are all sine functions with the same amplitude but different wavelengths. Shortening the wavelength results in a sharper average curvature of the wavefunction and therefore an increase in the kinetic energy of the particle. Note that the number of nodes (points where the wavefunction passes through zero) also increases as n increases, and that the wavefunction ψ_n has $n - 1$ nodes. Increasing the number of nodes between walls of a given separation increases the average curvature of the wavefunction and hence the kinetic energy of the particle.

The linear momentum of a particle in a box is not well defined because the wavefunction $\sin kx$ is a standing wave and, like the example of $\cos kx$ treated in Section 8.5d, not an eigenfunction of the linear momentum operator. However, each wavefunction is a superposition of momentum eigenfunctions:

$$\psi_n = \left(\frac{2}{L}\right)^{1/2} \sin \frac{n\pi x}{L} = \frac{1}{2i} \left(\frac{2}{L}\right)^{1/2} (e^{ikx} - e^{-ikx}) \quad k = \frac{n\pi}{L} \quad (9.5)$$

It follows that measurement of the linear momentum will give the value $+k\hbar$ for half the measurements of momentum and $-k\hbar$ for the other half. This detection of opposite directions of travel with equal probability is the quantum mechanical version of the classical picture that a particle in a box rattles from wall to wall, and in any given period spends half its time travelling to the left and half travelling to the right.

Self-test 9.2 What is (a) the average value of the linear momentum of a particle in a box with quantum number n , (b) the average value of p^2 ?

$$[(a) \langle p \rangle = 0, (b) \langle p^2 \rangle = n^2 h^2 / 4L^2]$$

Because n cannot be zero, the lowest energy that the particle may possess is not zero (as would be allowed by classical mechanics, corresponding to a stationary particle) but

$$E_1 = \frac{h^2}{8mL^2} \quad (9.6)$$

This lowest, irremovable energy is called the **zero-point energy**. The physical origin of the zero-point energy can be explained in two ways. First, the uncertainty principle requires a particle to possess kinetic energy if it is confined to a finite region: the location of the particle is not completely indefinite, so its momentum cannot be precisely zero. Hence it has nonzero kinetic energy. Second, if the wavefunction is to be zero at the walls, but smooth, continuous, and not zero everywhere, then it must be curved, and curvature in a wavefunction implies the possession of kinetic energy.

The separation between adjacent energy levels with quantum numbers n and $n + 1$ is

$$E_{n+1} - E_n = \frac{(n+1)^2 h^2}{8mL^2} - \frac{n^2 h^2}{8mL^2} = (2n+1) \frac{h^2}{8mL^2} \quad (9.7)$$

This separation decreases as the length of the container increases, and is very small when the container has macroscopic dimensions. The separation of adjacent levels becomes zero when the walls are infinitely far apart. Atoms and molecules free to move in normal laboratory-sized vessels may therefore be treated as though their translational energy is not quantized. The translational energy of completely free particles (those not confined by walls) is not quantized.

Illustration 9.1 Accounting for the electronic absorption spectra of polyenes

β -Carotene (**1**) is a linear polyene in which 10 single and 11 double bonds alternate along a chain of 22 carbon atoms. If we take each CC bond length to be about 140 pm, then the length L of the molecular box in β -carotene is $L = 0.294$ nm. For reasons that will be familiar from introductory chemistry, each C atom contributes one p -electron to the π orbitals and, in the lowest energy state of the molecule, each level up to $n = 11$ is occupied by two electrons. From eqn 9.7 it follows that the separation in energy between the ground state and the state in which one electron is promoted from $n = 11$ to $n = 12$ is

$$\begin{aligned} \Delta E = E_{12} - E_{11} &= (2 \times 11 + 1) \frac{(6.626 \times 10^{-34} \text{ J s})^2}{8 \times (9.110 \times 10^{-31} \text{ kg}) \times (2.94 \times 10^{-10} \text{ m})^2} \\ &= 1.60 \times 10^{-19} \text{ J} \end{aligned}$$

It follows from the Bohr frequency condition (eqn 8.10, $\Delta E = h\nu$) that the frequency of radiation required to cause this transition is

$$\nu = \frac{\Delta E}{h} = \frac{1.60 \times 10^{-19} \text{ J}}{6.626 \times 10^{-34} \text{ J s}} = 2.41 \times 10^{14} \text{ s}^{-1}$$

The experimental value is $\nu = 6.03 \times 10^{14} \text{ s}^{-1}$ ($\lambda = 497$ nm), corresponding to radiation in the visible range of the electromagnetic spectrum.

Self-test 9.3 Estimate a typical nuclear excitation energy by calculating the first excitation energy of a proton confined to a square well with a length equal to the diameter of a nucleus (approximately 1 fm). [0.6 GeV]

Fig. 9.4 (a) The first two wavefunctions, (b) the corresponding probability distributions, and (c) a representation of the probability distribution in terms of the darkness of shading.

The probability density for a particle in a box is

$$\psi^2(x) = \frac{2}{L} \sin^2 \frac{n\pi x}{L} \quad (9.8)$$

and varies with position. The nonuniformity is pronounced when n is small (Fig. 9.4), but—provided we ignore the increasingly rapid oscillations— $\psi^2(x)$ becomes more uniform as n increases. The distribution at high quantum numbers reflects the classical result that a particle bouncing between the walls spends, on the average, equal times at all points. That the quantum result corresponds to the classical prediction at high quantum numbers is an illustration of the **correspondence principle**, which states that classical mechanics emerges from quantum mechanics as high quantum numbers are reached.

Example 9.1 Using the particle in a box solutions

The wavefunctions of an electron in a conjugated polyene can be approximated by particle-in-a-box wavefunctions. What is the probability, P , of locating the electron between $x = 0$ (the left-hand end of a molecule) and $x = 0.2$ nm in its lowest energy state in a conjugated molecule of length 1.0 nm?

Method The value of $\psi^2 dx$ is the probability of finding the particle in the small region dx located at x ; therefore, the total probability of finding the electron in the specified region is the integral of $\psi^2 dx$ over that region. The wavefunction of the electron is given in eqn 9.4b with $n = 1$.

Answer The probability of finding the particle in a region between $x = 0$ and $x = l$ is

$$P = \int_0^l \psi_n^2 dx = \frac{2}{L} \int_0^l \sin^2 \frac{n\pi x}{L} dx = \frac{l}{L} - \frac{1}{2n\pi} \sin \frac{2n\pi l}{L}$$

We then set $n = 1$ and $l = 0.2$ nm, which gives $P = 0.05$. The result corresponds to a chance of 1 in 20 of finding the electron in the region. As n becomes infinite, the sine term, which is multiplied by $1/n$, makes no contribution to P and the classical result, $P = l/L$, is obtained.

Self-test 9.4 Calculate the probability that an electron in the state with $n = 1$ will be found between $x = 0.25L$ and $x = 0.75L$ in a conjugated molecule of length L (with $x = 0$ at the left-hand end of the molecule). [0.82]

(d) Orthogonality

We can now illustrate a property of wavefunctions first mentioned in Section 8.5. Two wavefunctions are **orthogonal** if the integral of their product vanishes. Specifically, the functions ψ_n and $\psi_{n'}$ are orthogonal if

$$\int \psi_n^* \psi_{n'} d\tau = 0 \quad (9.9)$$

where the integration is over all space. A general feature of quantum mechanics, which we prove in the *Justification* below, is that *wavefunctions corresponding to different energies are orthogonal*; therefore, we can be confident that all the wavefunctions of a particle in a box are mutually orthogonal. A more compact notation for integrals of this kind is described in *Further information 9.1*.

Justification 9.2 *The orthogonality of wavefunctions*

Suppose we have two wavefunctions ψ_n and ψ_m corresponding to two different energies E_n and E_m , respectively. Then we can write

$$\hat{H}\psi_n = E_n\psi_n \quad \hat{H}\psi_m = E_m\psi_m$$

Now multiply the first of these two Schrödinger equations by ψ_m^* and the second by ψ_n^* and integrate over all space:

$$\int \psi_m^* \hat{H}\psi_n d\tau = E_n \int \psi_m^* \psi_n d\tau \quad \int \psi_n^* \hat{H}\psi_m d\tau = E_m \int \psi_n^* \psi_m d\tau$$

Next, noting that the energies themselves are real, form the complex conjugate of the second expression (for the state m) and subtract it from the first expression (for the state n):

$$\int \psi_m^* \hat{H}\psi_n d\tau - \left(\int \psi_n^* \hat{H}\psi_m d\tau \right)^* = E_n \int \psi_m^* \psi_n d\tau - E_m \int \psi_n^* \psi_m d\tau$$

By the hermiticity of the hamiltonian (Section 8.5c), the two terms on the left are equal, so they cancel and we are left with

$$0 = (E_n - E_m) \int \psi_m^* \psi_n d\tau$$

However, the two energies are different; therefore the integral on the right must be zero, which confirms that two wavefunctions belonging to different energies are orthogonal.

Fig. 9.5 Two functions are orthogonal if the integral of their product is zero. Here the calculation of the integral is illustrated graphically for two wavefunctions of a particle in a square well. The integral is equal to the total area beneath the graph of the product, and is zero.

Illustration 9.2 *Verifying the orthogonality of the wavefunctions for a particle in a box*

We can verify the orthogonality of wavefunctions of a particle in a box with $n = 1$ and $n = 3$ (Fig. 9.5):

$$\int_0^L \psi_1^* \psi_3 dx = \frac{2}{L} \int_0^L \sin \frac{\pi x}{L} \sin \frac{3\pi x}{L} dx = 0$$

We have used the standard integral given in *Illustration 8.2*.

The property of orthogonality is of great importance in quantum mechanics because it enables us to eliminate a large number of integrals from calculations. Orthogonality plays a central role in the theory of chemical bonding (Chapter 11) and spectroscopy (Chapter 14). Sets of functions that are normalized and mutually orthogonal are called **orthonormal**. The wavefunctions in eqn 9.4b are orthonormal.

9.2 Motion in two and more dimensions

Next, we consider a two-dimensional version of the particle in a box. Now the particle is confined to a rectangular surface of length L_1 in the x -direction and L_2 in the y -direction; the potential energy is zero everywhere except at the walls, where it is infinite (Fig. 9.6). The wavefunction is now a function of both x and y and the Schrödinger equation is

$$-\frac{\hbar^2}{2m} \left(\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} \right) = E\psi \quad (9.10)$$

Fig. 9.6 A two-dimensional square well. The particle is confined to the plane bounded by impenetrable walls. As soon as it touches the walls, its potential energy rises to infinity.

We need to see how to solve this *partial* differential equation, an equation in more than one variable.

(a) Separation of variables

Some partial differential equations can be simplified by the **separation of variables technique**, which divides the equation into two or more ordinary differential equations, one for each variable. An important application of this procedure, as we shall see, is the separation of the Schrödinger equation for the hydrogen atom into equations that describe the radial and angular variation of the wavefunction. The technique is particularly simple for a two-dimensional square well, as can be seen by testing whether a solution of eqn 9.10 can be found by writing the wavefunction as a product of functions, one depending only on x and the other only on y :

$$\psi(x, y) = X(x)Y(y)$$

With this substitution, we show in the *Justification* below that eqn 9.10 separates into two ordinary differential equations, one for each coordinate:

$$-\frac{\hbar^2}{2m} \frac{d^2X}{dx^2} = E_X X \quad -\frac{\hbar^2}{2m} \frac{d^2Y}{dy^2} = E_Y Y \quad E = E_X + E_Y \quad (9.11)$$

The quantity E_X is the energy associated with the motion of the particle parallel to the x -axis, and likewise for E_Y and motion parallel to the y -axis.

Justification 9.3 *The separation of variables technique applied to the particle in a two-dimensional box*

The first step in the justification of the separability of the wavefunction into the product of two functions X and Y is to note that, because X is independent of y and Y is independent of x , we can write

$$\frac{\partial^2 \psi}{\partial x^2} = \frac{\partial^2 XY}{\partial x^2} = Y \frac{d^2 X}{dx^2} \quad \frac{\partial^2 \psi}{\partial y^2} = \frac{\partial^2 XY}{\partial y^2} = X \frac{d^2 Y}{dy^2}$$

Then eqn 9.10 becomes

$$-\frac{\hbar^2}{2m} \left(Y \frac{d^2 X}{dx^2} + X \frac{d^2 Y}{dy^2} \right) = EXY$$

When both sides are divided by XY , we can rearrange the resulting equation into

$$\frac{1}{X} \frac{d^2 X}{dx^2} + \frac{1}{Y} \frac{d^2 Y}{dy^2} = -\frac{2mE}{\hbar^2}$$

The first term on the left is independent of y , so if y is varied only the second term can change. But the sum of these two terms is a constant given by the right-hand side of the equation; therefore, even the second term cannot change when y is changed. In other words, the second term is a constant, which we write $-2mE_Y/\hbar^2$. By a similar argument, the first term is a constant when x changes, and we write it $-2mE_X/\hbar^2$, and $E = E_X + E_Y$. Therefore, we can write

$$\frac{1}{X} \frac{d^2 X}{dx^2} = -\frac{2mE_X}{\hbar^2} \quad \frac{1}{Y} \frac{d^2 Y}{dy^2} = -\frac{2mE_Y}{\hbar^2}$$

which rearrange into the two ordinary (that is, single variable) differential equations in eqn 9.11.

Fig. 9.7 The wavefunctions for a particle confined to a rectangular surface depicted as contours of equal amplitude. (a) $n_1 = 1$, $n_2 = 1$, the state of lowest energy, (b) $n_1 = 1$, $n_2 = 2$, (c) $n_1 = 2$, $n_2 = 1$, and (d) $n_1 = 2$, $n_2 = 2$.

Exploration Use mathematical software to generate three-dimensional plots of the functions in this illustration. Deduce a rule for the number of nodal lines in a wavefunction as a function of the values of n_x and n_y .

Each of the two ordinary differential equations in eqn 9.11 is the same as the one-dimensional square-well Schrödinger equation. We can therefore adapt the results in eqn 9.4 without further calculation:

$$X_{n_1}(x) = \left(\frac{2}{L_1}\right)^{1/2} \sin \frac{n_1 \pi x}{L_1} \quad Y_{n_2}(y) = \left(\frac{2}{L_2}\right)^{1/2} \sin \frac{n_2 \pi y}{L_2}$$

Then, because $\psi = XY$ and $E = E_X + E_Y$, we obtain

$$\psi_{n_1, n_2}(x, y) = \frac{2}{(L_1 L_2)^{1/2}} \sin \frac{n_1 \pi x}{L_1} \sin \frac{n_2 \pi y}{L_2} \quad 0 \leq x \leq L_1, 0 \leq y \leq L_2$$

$$E_{n_1 n_2} = \left(\frac{n_1^2}{L_1^2} + \frac{n_2^2}{L_2^2} \right) \frac{h^2}{8m} \quad (9.12a)$$

with the quantum numbers taking the values $n_1 = 1, 2, \dots$ and $n_2 = 1, 2, \dots$ independently. Some of these functions are plotted in Fig. 9.7. They are the two-dimensional versions of the wavefunctions shown in Fig. 9.3. Note that two quantum numbers are needed in this two-dimensional problem.

We treat a particle in a three-dimensional box in the same way. The wavefunctions have another factor (for the z -dependence), and the energy has an additional term in n_3^2/L_3^2 . Solution of the Schrödinger equation by the separation of variables technique then gives

$$\psi_{n_1, n_2, n_3}(x, y, z) = \left(\frac{8}{L_1 L_2 L_3} \right)^{1/2} \sin \frac{n_1 \pi x}{L_1} \sin \frac{n_2 \pi y}{L_2} \sin \frac{n_3 \pi z}{L_3}$$

$$0 \leq x \leq L_1, 0 \leq y \leq L_2, 0 \leq z \leq L_3 \quad (9.12b)$$

$$E_{n_1 n_2 n_3} = \left(\frac{n_1^2}{L_1^2} + \frac{n_2^2}{L_2^2} + \frac{n_3^2}{L_3^2} \right) \frac{h^2}{8m}$$

(b) Degeneracy

An interesting feature of the solutions for a particle in a two-dimensional box is obtained when the plane surface is square, with $L_1 = L_2 = L$. Then eqn 9.12a becomes

$$\psi_{n_1, n_2}(x, y) = \frac{2}{L} \sin \frac{n_1 \pi x}{L} \sin \frac{n_2 \pi y}{L} \quad E_{n_1 n_2} = (n_1^2 + n_2^2) \frac{h^2}{8mL^2} \quad (9.13)$$

Fig. 9.8 The wavefunctions for a particle confined to a square surface. Note that one wavefunction can be converted into the other by a rotation of the box by 90°. The two functions correspond to the same energy. Degeneracy and symmetry are closely related.

Fig. 9.9 A particle incident on a barrier from the left has an oscillating wave function, but inside the barrier there are no oscillations (for $E < V$). If the barrier is not too thick, the wavefunction is nonzero at its opposite face, and so oscillates begin again there. (Only the real component of the wavefunction is shown.)

Consider the cases $n_1 = 1, n_2 = 2$ and $n_1 = 2, n_2 = 1$:

$$\psi_{1,2} = \frac{2}{L} \sin \frac{\pi x}{L} \sin \frac{2\pi y}{L} \quad E_{1,2} = \frac{5h^2}{8mL^2}$$

$$\psi_{2,1} = \frac{2}{L} \sin \frac{2\pi x}{L} \sin \frac{\pi y}{L} \quad E_{2,1} = \frac{5h^2}{8mL^2}$$

We see that, although the wavefunctions are different, they are **degenerate**, meaning that they correspond to the same energy. In this case, in which there are two degenerate wavefunctions, we say that the energy level $5(h^2/8mL^2)$ is ‘doubly degenerate’.

The occurrence of degeneracy is related to the symmetry of the system. Figure 9.8 shows contour diagrams of the two degenerate functions $\psi_{1,2}$ and $\psi_{2,1}$. Because the box is square, we can convert one wavefunction into the other simply by rotating the plane by 90°. Interconversion by rotation through 90° is not possible when the plane is not square, and $\psi_{1,2}$ and $\psi_{2,1}$ are then not degenerate. Similar arguments account for the degeneracy of states in a cubic box. We shall see many other examples of degeneracy in the pages that follow (for instance, in the hydrogen atom), and all of them can be traced to the symmetry properties of the system (see Section 12.4b).

9.3 Tunnelling

If the potential energy of a particle does not rise to infinity when it is in the walls of the container, and $E < V$, the wavefunction does not decay abruptly to zero. If the walls are thin (so that the potential energy falls to zero again after a finite distance), then the wavefunction oscillates inside the box, varies smoothly inside the region representing the wall, and oscillates again on the other side of the wall outside the box (Fig. 9.9). Hence the particle might be found on the outside of a container even though according to classical mechanics it has insufficient energy to escape. Such leakage by penetration through a classically forbidden region is called **tunnelling**.

The Schrödinger equation can be used to calculate the probability of tunnelling of a particle of mass m incident on a finite barrier from the left. On the left of the barrier (for $x < 0$) the wavefunctions are those of a particle with $V = 0$, so from eqn 9.2 we can write

$$\psi = Ae^{ikx} + Be^{-ikx} \quad k\hbar = (2mE)^{1/2} \quad (9.14)$$

The Schrödinger equation for the region representing the barrier (for $0 \leq x \leq L$), where the potential energy is the constant V , is

$$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} + V\psi = E\psi \quad (9.15)$$

We shall consider particles that have $E < V$ (so, according to classical physics, the particle has insufficient energy to pass over the barrier), and therefore $V - E$ is positive. The general solutions of this equation are

$$\psi = Ce^{\kappa x} + De^{-\kappa x} \quad \kappa\hbar = \{2m(V - E)\}^{1/2} \quad (9.16)$$

as we can readily verify by differentiating ψ twice with respect to x . The important feature to note is that the two exponentials are now real functions, as distinct from the complex, oscillating functions for the region where $V = 0$ (oscillating functions would be obtained if $E > V$). To the right of the barrier ($x > L$), where $V = 0$ again, the wavefunctions are

$$\psi = A'e^{ikx} + B'e^{-ikx} \quad k\hbar = (2mE)^{1/2} \quad (9.17)$$

The complete wavefunction for a particle incident from the left consists of an incident wave, a wave reflected from the barrier, the exponentially changing amplitudes inside the barrier, and an oscillating wave representing the propagation of the particle to the right after tunnelling through the barrier successfully (Fig. 9.10). The acceptable wavefunctions must obey the conditions set out in Section 8.4b. In particular, they must be continuous at the edges of the barrier (at $x = 0$ and $x = L$, remembering that $e^0 = 1$):

$$A + B = C + D \quad Ce^{\kappa L} + De^{-\kappa L} = A'e^{ikL} + B'e^{-ikL} \quad (9.18)$$

Their slopes (their first derivatives) must also be continuous there (Fig. 9.11):

$$ikA - ikB = \kappa C - \kappa D \quad \kappa Ce^{\kappa L} - \kappa De^{-\kappa L} = ikA'e^{ikL} - ikB'e^{-ikL} \quad (9.19)$$

At this stage, we have four equations for the six unknown coefficients. If the particles are shot towards the barrier from the left, there can be no particles travelling to the left on the right of the barrier. Therefore, we can set $B' = 0$, which removes one more unknown. We cannot set $B = 0$ because some particles may be reflected back from the barrier toward negative x .

The probability that a particle is travelling towards positive x (to the right) on the left of the barrier is proportional to $|A|^2$, and the probability that it is travelling to the right on the right of the barrier is $|A'|^2$. The ratio of these two probabilities is called the **transmission probability**, T . After some algebra (see Problem 9.9) we find

$$T = \left\{ 1 + \frac{(e^{\kappa L} - e^{-\kappa L})^2}{16\varepsilon(1 - \varepsilon)} \right\}^{-1} \quad (9.20a)$$

where $\varepsilon = E/V$. This function is plotted in Fig. 9.12; the transmission coefficient for $E > V$ is shown there too. For high, wide barriers (in the sense that $\kappa L \gg 1$), eqn 9.20a simplifies to

$$T \approx 16\varepsilon(1 - \varepsilon)e^{-2\kappa L} \quad (9.20b)$$

The transmission probability decreases exponentially with the thickness of the barrier and with $m^{1/2}$. It follows that particles of low mass are more able to tunnel through barriers than heavy ones (Fig. 9.13). Tunnelling is very important for electrons and muons, and moderately important for protons; for heavier particles it is less important.

Fig. 9.10 When a particle is incident on a barrier from the left, the wavefunction consists of a wave representing linear momentum to the right, a reflected component representing momentum to the left, a varying but not oscillating component inside the barrier, and a (weak) wave representing motion to the right on the far side of the barrier.

Fig. 9.11 The wavefunction and its slope must be continuous at the edges of the barrier. The conditions for continuity enable us to connect the wavefunctions in the three zones and hence to obtain relations between the coefficients that appear in the solutions of the Schrödinger equation.

Fig. 9.12 The transition probabilities for passage through a barrier. The horizontal axis is the energy of the incident particle expressed as a multiple of the barrier height. The curves are labelled with the value of $L(2mV)^{1/2}/\hbar$. The graph on the left is for $E < V$ and that on the right for $E > V$. Note that $T > 0$ for $E < V$ whereas classically T would be zero. However, $T < 1$ for $E > V$, whereas classically T would be 1.

Exploration Plot T against ε for a hydrogen molecule, a proton and an electron.

Fig. 9.13 The wavefunction of a heavy particle decays more rapidly inside a barrier than that of a light particle. Consequently, a light particle has a greater probability of tunnelling through the barrier.

Fig. 9.14 A potential well with a finite depth.

Fig. 9.15 The lowest two bound-state wavefunctions for a particle in the well shown in Fig. 9.14 and one of the wavefunctions corresponding to an unbound state ($E > V$).

A number of effects in chemistry (for example, the isotope-dependence of some reaction rates) depend on the ability of the proton to tunnel more readily than the deuteron. The very rapid equilibration of proton transfer reactions is also a manifestation of the ability of protons to tunnel through barriers and transfer quickly from an acid to a base. Tunnelling of protons between acidic and basic groups is also an important feature of the mechanism of some enzyme-catalysed reactions. As we shall see in Chapters 24 and 25, electron tunnelling is one of the factors that determine the rates of electron transfer reactions at electrodes and in biological systems.

A problem related to the one just considered is that of a particle in a square-well potential of finite depth (Fig. 9.14). In this kind of potential, the wavefunction penetrates into the walls, where it decays exponentially towards zero, and oscillates within the well. The wavefunctions are found by ensuring, as in the discussion of tunnelling, that they and their slopes are continuous at the edges of the potential. Some of the lowest energy solutions are shown in Fig. 9.15. A further difference from the solutions for an infinitely deep well is that there is only a finite number of bound states. Regardless of the depth and length of the well, there is always at least one bound state. Detailed consideration of the Schrödinger equation for the problem shows that in general the number of levels is equal to N , with

$$N - 1 < \frac{(8mVL)^{1/2}}{h} < N \quad (9.21)$$

where V is the depth of the well and L is its length (for a derivation of this expression, see *Further reading*). We see that the deeper and wider the well, the greater the number of bound states. As the depth becomes infinite, so the number of bound states also becomes infinite, as we have already seen.

IMPACT ON NANOSCIENCE

19.1 Scanning probe microscopy

Nanoscience is the study of atomic and molecular assemblies with dimensions ranging from 1 nm to about 100 nm and *nanotechnology* is concerned with the incorporation of such assemblies into devices. The future economic impact of nanotechnology could be very significant. For example, increased demand for very small digital electronic

devices has driven the design of ever smaller and more powerful microprocessors. However, there is an upper limit on the density of electronic circuits that can be incorporated into silicon-based chips with current fabrication technologies. As the ability to process data increases with the number of circuits in a chip, it follows that soon chips and the devices that use them will have to become bigger if processing power is to increase indefinitely. One way to circumvent this problem is to fabricate devices from nanometre-sized components.

We will explore several concepts of nanoscience throughout the text. We begin with the description of *scanning probe microscopy* (SPM), a collection of techniques that can be used to visualize and manipulate objects as small as atoms on surfaces. Consequently, SPM has far better resolution than electron microscopy (*Impact 18.1*).

One modality of SPM is *scanning tunnelling microscopy* (STM), in which a platinum–rhodium or tungsten needle is scanned across the surface of a conducting solid. When the tip of the needle is brought very close to the surface, electrons tunnel across the intervening space (Fig. 9.16). In the constant-current mode of operation, the stylus moves up and down corresponding to the form of the surface, and the topography of the surface, including any adsorbates, can be mapped on an atomic scale. The vertical motion of the stylus is achieved by fixing it to a piezoelectric cylinder, which contracts or expands according to the potential difference it experiences. In the constant-*z* mode, the vertical position of the stylus is held constant and the current is monitored. Because the tunnelling probability is very sensitive to the size of the gap, the microscope can detect tiny, atom-scale variations in the height of the surface.

Figure 9.17 shows an example of the kind of image obtained with a surface, in this case of gallium arsenide, that has been modified by addition of atoms, in this case caesium atoms. Each ‘bump’ on the surface corresponds to an atom. In a further variation of the STM technique, the tip may be used to nudge single atoms around on the surface, making possible the fabrication of complex and yet very tiny nanometre-sized structures.

In *atomic force microscopy* (AFM) a sharpened stylus attached to a cantilever is scanned across the surface. The force exerted by the surface and any bound species pushes or pulls on the stylus and deflects the cantilever (Fig. 9.18). The deflection is monitored either by interferometry or by using a laser beam. Because no current is needed between the sample and the probe, the technique can be applied to non-conducting surfaces too. A spectacular demonstration of the power of AFM is given in Fig. 9.19, which shows individual DNA molecules on a solid surface.

Fig. 9.16 A scanning tunnelling microscope makes use of the current of electrons that tunnel between the surface and the tip. That current is very sensitive to the distance of the tip above the surface.

Fig. 9.17 An STM image of caesium atoms on a gallium arsenide surface.

Fig. 9.18 In atomic force microscopy, a laser beam is used to monitor the tiny changes in the position of a probe as it is attracted to or repelled from atoms on a surface.

Fig. 9.19 An AFM image of bacterial DNA plasmids on a mica surface. (Courtesy of Veeco Instruments.)

Example 9.2 Exploring the origin of the current in scanning tunnelling microscopy

To get an idea of the distance dependence of the tunnelling current in STM, suppose that the wavefunction of the electron in the gap between sample and needle is given by $\psi = Be^{-\kappa x}$, where $\kappa = \{2m_e(V - E)/\hbar^2\}^{1/2}$; take $V - E = 2.0$ eV. By what factor would the current drop if the needle is moved from $L_1 = 0.50$ nm to $L_2 = 0.60$ nm from the surface?

Method We regard the tunnelling current to be proportional to the transmission probability T , so the ratio of the currents is equal to the ratio of the transmission probabilities. To choose between eqn 9.20a or 9.20b for the calculation of T , first calculate κL for the shortest distance L_1 : if $\kappa L_1 > 1$, then use eqn 9.20b.

Answer When $L = L_1 = 0.50$ nm and $V - E = 2.0$ eV $= 3.20 \times 10^{-19}$ J the value of κL is

$$\begin{aligned}\kappa L_1 &= \left\{ \frac{2m_e(V - E)}{\hbar^2} \right\}^{1/2} L_1 \\ &= \left\{ \frac{2 \times (9.109 \times 10^{-31} \text{ kg}) \times (3.20 \times 10^{-19} \text{ J})}{(1.054 \times 10^{-34} \text{ J s})^2} \right\}^{1/2} \times (5.0 \times 10^{-10} \text{ m}) \\ &= (7.25 \times 10^9 \text{ m}^{-1}) \times (5.0 \times 10^{-10} \text{ m}) = 3.6\end{aligned}$$

Because $\kappa L_1 > 1$, we use eqn 9.20b to calculate the transmission probabilities at the two distances. It follows that

$$\begin{aligned}\frac{\text{current at } L_2}{\text{current at } L_1} &= \frac{T(L_2)}{T(L_1)} = \frac{16\epsilon(1 - \epsilon)e^{-2\kappa L_2}}{16\epsilon(1 - \epsilon)e^{-2\kappa L_1}} = e^{-2\kappa(L_2 - L_1)} \\ &= e^{-2 \times (7.25 \times 10^9 \text{ m}^{-1}) \times (1.0 \times 10^{-10} \text{ m})} = 0.23\end{aligned}$$

We conclude that, at a distance of 0.60 nm between the surface and the needle, the current is 23 per cent of the value measured when the distance is 0.50 nm.

Self-test 9.5 The ability of a proton to tunnel through a barrier contributes to the rapidity of proton transfer reactions in solution and therefore to the properties of acids and bases. Estimate the relative probabilities that a proton and a deuteron can tunnel through the same barrier of height 1.0 eV (1.6×10^{-19} J) and length 100 pm when their energy is 0.9 eV. Any comment?

[$T_H/T_D = 3.7 \times 10^2$; we expect proton transfer reactions to be much faster than deuteron transfer reactions.]

Vibrational motion

A particle undergoes **harmonic motion** if it experiences a restoring force proportional to its displacement:

$$F = -kx \quad (9.22)$$

where k is the **force constant**: the stiffer the ‘spring’, the greater the value of k . Because force is related to potential energy by $F = -dV/dx$ (see *Appendix 3*), the force in eqn 9.22 corresponds to a potential energy

$$V = \frac{1}{2}kx^2 \quad (9.23)$$

This expression, which is the equation of a parabola (Fig. 9.20), is the origin of the term ‘parabolic potential energy’ for the potential energy characteristic of a harmonic oscillator. The Schrödinger equation for the particle is therefore

$$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} + \frac{1}{2}kx^2\psi = E\psi \quad (9.24)$$

9.4 The energy levels

Equation 9.24 is a standard equation in the theory of differential equations and its solutions are well known to mathematicians (for details, see *Further reading*). Quantization of energy levels arises from the boundary conditions: the oscillator will not be found with infinitely large compressions or extensions, so the only allowed solutions are those for which $\psi = 0$ at $x = \pm\infty$. The permitted energy levels are

$$E_v = (v + \frac{1}{2})\hbar\omega \quad \omega = \left(\frac{k}{m}\right)^{1/2} \quad v = 0, 1, 2, \dots \quad (9.25)$$

Note that ω (omega) increases with increasing force constant and decreasing mass. It follows that the separation between adjacent levels is

$$E_{v+1} - E_v = \hbar\omega \quad (9.26)$$

which is the same for all v . Therefore, the energy levels form a uniform ladder of spacing $\hbar\omega$ (Fig. 9.21). The energy separation $\hbar\omega$ is negligibly small for macroscopic objects (with large mass), but is of great importance for objects with mass similar to that of atoms.

Because the smallest permitted value of v is 0, it follows from eqn 9.26 that a harmonic oscillator has a zero-point energy

$$E_0 = \frac{1}{2}\hbar\omega \quad (9.27)$$

The mathematical reason for the zero-point energy is that v cannot take negative values, for if it did the wavefunction would be ill-behaved. The physical reason is the same as for the particle in a square well: the particle is confined, its position is not completely uncertain, and therefore its momentum, and hence its kinetic energy, cannot be exactly zero. We can picture this zero-point state as one in which the particle fluctuates incessantly around its equilibrium position; classical mechanics would allow the particle to be perfectly still.

Fig. 9.20 The parabolic potential energy $V = \frac{1}{2}kx^2$ of a harmonic oscillator, where x is the displacement from equilibrium. The narrowness of the curve depends on the force constant k : the larger the value of k , the narrower the well.

Fig. 9.21 The energy levels of a harmonic oscillator are evenly spaced with separation $\hbar\omega$, with $\omega = (k/m)^{1/2}$. Even in its lowest state, an oscillator has an energy greater than zero.

Illustration 9.3 Calculating a molecular vibrational absorption frequency

Atoms vibrate relative to one another in molecules with the bond acting like a spring. Consider an X—H chemical bond, where a heavy X atom forms a stationary anchor for the very light H atom. That is, only the H atom moves, vibrating as a simple harmonic oscillator. Therefore, eqn 9.25 describes the allowed vibrational energy levels of a X—H bond. The force constant of a typical X—H chemical bond is around 500 N m^{-1} . For example $k = 516.3 \text{ N m}^{-1}$ for the $^1\text{H}^{35}\text{Cl}$ bond. Because the mass of a proton is about $1.7 \times 10^{-27} \text{ kg}$, using $k = 500 \text{ N m}^{-1}$ in eqn 9.25 gives $\omega \approx 5.4 \times 10^{14} \text{ s}^{-1}$ ($5.4 \times 10^2 \text{ THz}$). It follows from eqn 9.26 that the separation of adjacent levels is $\hbar\omega \approx 5.7 \times 10^{-20} \text{ J}$ (57 zJ, about 0.36 eV). This energy separation corresponds to 34 kJ mol^{-1} , which is chemically significant. From eqn 9.27, the zero-point energy of this molecular oscillator is about 3 zJ, which corresponds to 0.2 eV, or 15 kJ mol^{-1} .

Fig. 9.22 The graph of the Gaussian function, $f(x) = e^{-x^2}$.

Comment 9.2

The Hermite polynomials are solutions of the differential equation

$$H_v'' - 2yH_v' + 2vH_v = 0$$

where primes denote differentiation. They satisfy the recursion relation

$$H_{v+1} - 2yH_v + 2vH_{v-1} = 0$$

An important integral is

$$\int_{-\infty}^{\infty} H_v H_v e^{-y^2} dy = \begin{cases} 0 & \text{if } v' \neq v \\ \pi^{1/2} 2^v v! & \text{if } v' = v \end{cases}$$

Hermite polynomials are members of a class of functions called *orthogonal polynomials*. These polynomials have a wide range of important properties that allow a number of quantum mechanical calculations to be done with relative ease. See *Further reading* for a reference to their properties.

The excitation of the vibration of the bond from one level to the level immediately above requires 57 zJ. Therefore, if it is caused by a photon, the excitation requires radiation of frequency $\nu = \Delta E/h = 86$ THz and wavelength $\lambda = c/\nu = 3.5$ μm . It follows that transitions between adjacent vibrational energy levels of molecules are stimulated by or emit infrared radiation. We shall see in Chapter 13 that the concepts just described represent the starting point for the interpretation of vibrational spectroscopy, an important technique for the characterization of small and large molecules in the gas phase or in condensed phases.

9.5 The wavefunctions

It is helpful at the outset to identify the similarities between the harmonic oscillator and the particle in a box, for then we shall be able to anticipate the form of the oscillator wavefunctions without detailed calculation. Like the particle in a box, a particle undergoing harmonic motion is trapped in a symmetrical well in which the potential energy rises to large values (and ultimately to infinity) for sufficiently large displacements (compare Figs. 9.1 and 9.20). However, there are two important differences. First, because the potential energy climbs towards infinity only as x^2 and not abruptly, the wavefunction approaches zero more slowly at large displacements than for the particle in a box. Second, as the kinetic energy of the oscillator depends on the displacement in a more complex way (on account of the variation of the potential energy), the curvature of the wavefunction also varies in a more complex way.

(a) The form of the wavefunctions

The detailed solution of eqn 9.24 shows that the wavefunction for a harmonic oscillator has the form

$$\psi(x) = N \times (\text{polynomial in } x) \times (\text{bell-shaped Gaussian function})$$

where N is a normalization constant. A Gaussian function is a function of the form e^{-x^2} (Fig. 9.22). The precise form of the wavefunctions are

$$\psi_v(x) = N_v H_v(y) e^{-y^2/2} \quad y = \frac{x}{\alpha} \quad \alpha = \left(\frac{\hbar^2}{mk} \right)^{1/4} \quad (9.28)$$

The factor $H_v(y)$ is a **Hermite polynomial** (Table 9.1). For instance, because $H_0(y) = 1$, the wavefunction for the ground state (the lowest energy state, with $v = 0$) of the harmonic oscillator is

$$\psi_0(x) = N_0 e^{-y^2/2} = N_0 e^{-x^2/2\alpha^2} \quad (9.29a)$$

It follows that the probability density is the bell-shaped Gaussian function

$$\psi_0^2(x) = N_0^2 e^{-x^2/\alpha^2} \quad (9.29b)$$

The wavefunction and the probability distribution are shown in Fig. 9.23. Both curves have their largest values at zero displacement (at $x = 0$), so they capture the classical picture of the zero-point energy as arising from the ceaseless fluctuation of the particle about its equilibrium position.

The wavefunction for the first excited state of the oscillator, the state with $v = 1$, is obtained by noting that $H_1(y) = 2y$ (note that some of the Hermite polynomials are very simple functions!):

$$\psi_1(x) = N_1 \times 2ye^{-y^2/2} \quad (9.30)$$

Fig. 9.23 The normalized wavefunction and probability distribution (shown also by shading) for the lowest energy state of a harmonic oscillator.

Fig. 9.24 The normalized wavefunction and probability distribution (shown also by shading) for the first excited state of a harmonic oscillator.

This function has a node at zero displacement ($x=0$), and the probability density has maxima at $x=\pm\alpha$, corresponding to $y=\pm 1$ (Fig. 9.24).

Once again, we should interpret the mathematical expressions we have derived. In the case of the harmonic oscillator wavefunctions in eqn 9.28, we should note the following:

1. The Gaussian function goes very strongly to zero as the displacement increases (in either direction), so all the wavefunctions approach zero at large displacements.
2. The exponent y^2 is proportional to $x^2 \times (mk)^{1/2}$, so the wavefunctions decay more rapidly for large masses and stiff springs.
3. As v increases, the Hermite polynomials become larger at large displacements (as x^v), so the wavefunctions grow large before the Gaussian function damps them down to zero: as a result, the wavefunctions spread over a wider range as v increases.

The shapes of several wavefunctions are shown in Fig. 9.25. The shading in Fig. 9.26 that represents the probability density is based on the squares of these functions. At high quantum numbers, harmonic oscillator wavefunctions have their largest amplitudes near the turning points of the classical motion (the locations at which $V=E$, so

Table 9.1 The Hermite polynomials $H_v(y)$

3	$8y^3 - 12y$
4	$16y^4 - 48y^2 + 12$
5	$32y^5 - 160y^3 + 120y$
6	$64y^6 - 480y^4 + 720y^2 - 120$

Fig. 9.25 The normalized wavefunctions for the first five states of a harmonic oscillator. Note that the number of nodes is equal to v and that alternate wavefunctions are symmetrical or antisymmetrical about $y=0$ (zero displacement).

Fig. 9.26 The probability distributions for the first five states of a harmonic oscillator and the state with $v=20$. Note how the regions of highest probability move towards the turning points of the classical motion as v increases.

Exploration To gain some insight into the origins of the nodes in the harmonic oscillator wavefunctions, plot the Hermite polynomials $H_v(y)$ for $v=0$ through 5.

the kinetic energy is zero). We see classical properties emerging in the correspondence limit of high quantum numbers, for a classical particle is most likely to be found at the turning points (where it travels most slowly) and is least likely to be found at zero displacement (where it travels most rapidly).

Example 9.3 Normalizing a harmonic oscillator wavefunction

Find the normalization constant for the harmonic oscillator wavefunctions.

Method Normalization is always carried out by evaluating the integral of $|\psi|^2$ over all space and then finding the normalization factor from eqn 8.16. The normalized wavefunction is then equal to $N\psi$. In this one-dimensional problem, the volume element is dx and the integration is from $-\infty$ to $+\infty$. The wavefunctions are expressed in terms of the dimensionless variable $y = x/\alpha$, so begin by expressing the integral in terms of y by using $dx = \alpha dy$. The integrals required are given in *Comment 9.2*.

Answer The unnormalized wavefunction is

$$\psi_v(x) = H_v(y) e^{-y^2/2}$$

It follows from the integrals given in *Comment 9.2* that

$$\int_{-\infty}^{\infty} \psi_v^* \psi_v dx = \alpha \int_{-\infty}^{\infty} \psi_v^* \psi_v dy = \alpha \int_{-\infty}^{\infty} H_v^2(y) e^{-y^2} dy = \alpha \pi^{1/2} 2^v v!$$

where $v! = v(v-1)(v-2) \dots 1$. Therefore,

$$N_v = \left(\frac{1}{\alpha \pi^{1/2} 2^v v!} \right)^{1/2}$$

Note that for a harmonic oscillator N_v is different for each value of v .

Self-test 9.6 Confirm, by explicit evaluation of the integral, that ψ_0 and ψ_1 are orthogonal.

[Evaluate the integral $\int_{-\infty}^{\infty} \psi_0^* \psi_1 dx$ by using the information in *Comment 9.2*.]

(b) The properties of oscillators

With the wavefunctions that are available, we can start calculating the properties of a harmonic oscillator. For instance, we can calculate the expectation values of an observable Ω by evaluating integrals of the type

$$\langle \Omega \rangle = \int_{-\infty}^{\infty} \psi_v^* \hat{\Omega} \psi_v dx \quad (9.31)$$

(Here and henceforth, the wavefunctions are all taken to be normalized to 1.) When the explicit wavefunctions are substituted, the integrals look fearsome, but the Hermite polynomials have many simplifying features. For instance, we show in the following example that the mean displacement, $\langle x \rangle$, and the mean square displacement, $\langle x^2 \rangle$, of the oscillator when it is in the state with quantum number v are

$$\langle x \rangle = 0 \quad \langle x^2 \rangle = (v + \frac{1}{2}) \frac{\hbar}{(mk)^{1/2}} \quad (9.32)$$

The result for $\langle x \rangle$ shows that the oscillator is equally likely to be found on either side of $x = 0$ (like a classical oscillator). The result for $\langle x^2 \rangle$ shows that the mean square displacement increases with v . This increase is apparent from the probability densities in Fig. 9.26, and corresponds to the classical amplitude of swing increasing as the oscillator becomes more highly excited.

Example 9.4 Calculating properties of a harmonic oscillator

We can imagine the bending motion of a CO_2 molecule as a harmonic oscillation relative to the linear conformation of the molecule. We may be interested in the extent to which the molecule bends. Calculate the mean displacement of the oscillator when it is in a quantum state v .

Method Normalized wavefunctions must be used to calculate the expectation value. The operator for position along x is multiplication by the value of x (Section 8.5b). The resulting integral can be evaluated either by inspection (the integrand is the product of an odd and an even function), or by explicit evaluation using the formulas in *Comment 9.2*. To give practice in this type of calculation, we illustrate the latter procedure. We shall need the relation $x = \alpha y$, which implies that $dx = \alpha dy$.

Answer The integral we require is

$$\begin{aligned}\langle x \rangle &= \int_{-\infty}^{\infty} \psi_v^* x \psi_v dx = N_v^2 \int_{-\infty}^{\infty} (H_v e^{-y^2/2}) x (H_v e^{-y^2/2}) dx \\ &= \alpha^2 N_v^2 \int_{-\infty}^{\infty} (H_v e^{-y^2/2}) y (H_v e^{-y^2/2}) dy \\ &= \alpha^2 N_v^2 \int_{-\infty}^{\infty} H_v y H_v e^{-y^2} dy\end{aligned}$$

Now use the recursion relation (see *Comment 9.2*) to form

$$yH_v = vH_{v-1} + \frac{1}{2}H_{v+1}$$

which turns the integral into

$$\int_{-\infty}^{\infty} H_v y H_v e^{-y^2} dy = v \int_{-\infty}^{\infty} H_{v-1} H_v e^{-y^2} dy + \frac{1}{2} \int_{-\infty}^{\infty} H_{v+1} H_v e^{-y^2} dy$$

Both integrals are zero, so $\langle x \rangle = 0$. As remarked in the text, the mean displacement is zero because the displacement occurs equally on either side of the equilibrium position. The following Self-test extends this calculation by examining the mean square displacement, which we can expect to be non-zero and to increase with increasing v .

Self-test 9.7 Calculate the mean square displacement $\langle x^2 \rangle$ of the particle from its equilibrium position. (Use the recursion relation twice.) [eqn 9.32]

Comment 9.3

An even function is one for which $f(-x) = f(x)$; an odd function is one for which $f(-x) = -f(x)$. The product of an odd and even function is itself odd, and the integral of an odd function over a symmetrical range about $x = 0$ is zero.

The mean potential energy of an oscillator, the expectation value of $V = \frac{1}{2}kx^2$, can now be calculated very easily:

$$\langle V \rangle = \langle \frac{1}{2}kx^2 \rangle = \frac{1}{2}(v + \frac{1}{2})\hbar \left(\frac{k}{m} \right)^{1/2} = \frac{1}{2}(v + \frac{1}{2})\hbar\omega \quad (9.33)$$

Because the total energy in the state with quantum number v is $(v + \frac{1}{2})\hbar\omega$, it follows that

$$\langle V \rangle = \frac{1}{2}E_v \quad (9.34a)$$

The total energy is the sum of the potential and kinetic energies, so it follows at once that the mean kinetic energy of the oscillator is

$$\langle E_K \rangle = \frac{1}{2}E_v \quad (9.34b)$$

The result that the mean potential and kinetic energies of a harmonic oscillator are equal (and therefore that both are equal to half the total energy) is a special case of the **virial theorem**:

If the potential energy of a particle has the form $V = ax^b$, then its mean potential and kinetic energies are related by

$$2\langle E_K \rangle = b\langle V \rangle \quad (9.35)$$

For a harmonic oscillator $b = 2$, so $\langle E_K \rangle = \langle V \rangle$, as we have found. The virial theorem is a short cut to the establishment of a number of useful results, and we shall use it again.

An oscillator may be found at extensions with $V > E$ that are forbidden by classical physics, for they correspond to negative kinetic energy. For example, it follows from the shape of the wavefunction (see the *Justification* below) that in its lowest energy state there is about an 8 per cent chance of finding an oscillator stretched beyond its classical limit and an 8 per cent chance of finding it with a classically forbidden compression. These tunnelling probabilities are independent of the force constant and mass of the oscillator. The probability of being found in classically forbidden regions decreases quickly with increasing v , and vanishes entirely as v approaches infinity, as we would expect from the correspondence principle. Macroscopic oscillators (such as pendulums) are in states with very high quantum numbers, so the probability that they will be found in a classically forbidden region is wholly negligible. Molecules, however, are normally in their vibrational ground states, and for them the probability is very significant.

Justification 9.4 *Tunnelling in the quantum mechanical harmonic oscillator*

According to classical mechanics, the turning point, x_{tp} , of an oscillator occurs when its kinetic energy is zero, which is when its potential energy $\frac{1}{2}kx^2$ is equal to its total energy E . This equality occurs when

$$x_{tp}^2 = \frac{2E}{k} \quad \text{or, } x_{tp} = \pm \left(\frac{2E}{k} \right)^{1/2}$$

with E given by eqn 9.25. The probability of finding the oscillator stretched beyond a displacement x_{tp} is the sum of the probabilities $\psi^2 dx$ of finding it in any of the intervals dx lying between x_{tp} and infinity:

$$P = \int_{x_{tp}}^{\infty} \psi_v^2 dx$$

The variable of integration is best expressed in terms of $y = x/\alpha$ with $\alpha = (\hbar^2/mk)^{1/2}$, and then the turning point on the right lies at

$$y_{tp} = \frac{x_{tp}}{\alpha} = \left\{ \frac{2(v + \frac{1}{2})\hbar\omega}{\alpha^2 k} \right\}^{1/2} = (2v + 1)^{1/2}$$

For the state of lowest energy ($v = 0$), $y_{tp} = 1$ and the probability is

$$P = \int_{x_{\text{tp}}}^{\infty} \psi_0^2 dx = \alpha N_0^2 \int_1^{\infty} e^{-y^2} dy$$

The integral is a special case of the *error function*, $\text{erf } z$, which is defined as follows:

$$\text{erf } z = 1 - \frac{2}{\pi^{1/2}} \int_z^{\infty} e^{-y^2} dy$$

The values of this function are tabulated and available in mathematical software packages, and a small selection of values is given in Table 9.2. In the present case

$$P = \frac{1}{2}(1 - \text{erf } 1) = \frac{1}{2}(1 - 0.843) = 0.079$$

It follows that, in 7.9 per cent of a large number of observations, any oscillator in the state $v = 0$ will be found stretched to a classically forbidden extent. There is the same probability of finding the oscillator with a classically forbidden compression. The total probability of finding the oscillator tunnelled into a classically forbidden region (stretched or compressed) is about 16 per cent. A similar calculation for the state with $v = 6$ shows that the probability of finding the oscillator outside the classical turning points has fallen to about 7 per cent.

Table 9.2 The error function

z	$\text{erf } z$
0	0
0.01	0.0113
0.05	0.0564
0.10	0.1125
0.50	0.5205
1.00	0.8427
1.50	0.9661
2.00	0.9953

Rotational motion

The treatment of rotational motion can be broken down into two parts. The first deals with motion in two dimensions and the second with rotation in three dimensions. It may be helpful to review the classical description of rotational motion given in *Appendix 3*, particularly the concepts of moment of inertia and angular momentum.

9.6 Rotation in two dimensions: a particle on a ring

We consider a particle of mass m constrained to move in a circular path of radius r in the xy -plane (Fig. 9.27). The total energy is equal to the kinetic energy, because $V = 0$ everywhere. We can therefore write $E = p^2/2m$. According to classical mechanics, the **angular momentum**, J_z , around the z -axis (which lies perpendicular to the xy -plane) is $J_z = \pm pr$, so the energy can be expressed as $J_z^2/2mr^2$. Because mr^2 is the **moment of inertia**, I , of the mass on its path, it follows that

$$E = \frac{J_z^2}{2I} \quad (9.36)$$

We shall now see that not all the values of the angular momentum are permitted in quantum mechanics, and therefore that both angular momentum and rotational energy are quantized.

(a) The qualitative origin of quantized rotation

Because $J_z = \pm pr$, and, from the de Broglie relation, $p = h/\lambda$, the angular momentum about the z -axis is

$$J_z = \pm \frac{hr}{\lambda}$$

Opposite signs correspond to opposite directions of travel. This equation shows that the shorter the wavelength of the particle on a circular path of given radius, the greater the angular momentum of the particle. It follows that, if we can see why the

Fig. 9.27 The angular momentum of a particle of mass m on a circular path of radius r in the xy -plane is represented by a vector J with the single non-zero component J_z of magnitude pr perpendicular to the plane.

Fig. 9.28 Two solutions of the Schrödinger equation for a particle on a ring. The circumference has been opened out into a straight line; the points at $\phi = 0$ and 2π are identical. The solution in (a) is unacceptable because it is not single-valued. Moreover, on successive circuits it interferes destructively with itself, and does not survive. The solution in (b) is acceptable: it is single-valued, and on successive circuits it reproduces itself.

Fig. 9.29 The angular momentum of a particle confined to a plane can be represented by a vector of length $|m_l|$ units along the z -axis and with an orientation that indicates the direction of motion of the particle. The direction is given by the right-hand screw rule.

wavelength is restricted to discrete values, then we shall understand why the angular momentum is quantized.

Suppose for the moment that λ can take an arbitrary value. In that case, the wavefunction depends on the azimuthal angle ϕ as shown in Fig. 9.28a. When ϕ increases beyond 2π , the wavefunction continues to change, but for an arbitrary wavelength it gives rise to a different value at each point, which is unacceptable (Section 8.4b). An acceptable solution is obtained only if the wavefunction reproduces itself on successive circuits, as in Fig. 9.28b. Because only some wavefunctions have this property, it follows that only some angular momenta are acceptable, and therefore that only certain rotational energies exist. Hence, the energy of the particle is quantized. Specifically, the only allowed wavelengths are

$$\lambda = \frac{2\pi r}{m_l}$$

with m_l the conventional notation for this quantum number, taking integral values including 0. The value $m_l = 0$ corresponds to $\lambda = \infty$; a 'wave' of infinite wavelength has a constant height at all values of ϕ . The angular momentum is therefore limited to the values

$$J_z = \pm \frac{hr}{\lambda} = \pm \frac{m_l hr}{2\pi r} = \pm \frac{m_l h}{2\pi}$$

where we have allowed m_l to have positive or negative values. That is,

$$J_z = m_l \hbar \quad m_l = 0, \pm 1, \pm 2, \dots \quad (9.37)$$

Positive values of m_l correspond to rotation in a clockwise sense around the z -axis (as viewed in the direction of z , Fig. 9.29) and negative values of m_l correspond to counter-clockwise rotation around z . It then follows from eqn 9.36 that the energy is limited to the values

$$E = \frac{J_z^2}{2I} = \frac{m_l^2 \hbar^2}{2I} \quad (9.38a)$$

We shall see shortly that the corresponding normalized wavefunctions are

$$\psi_{m_l}(\phi) = \frac{e^{im_l\phi}}{(2\pi)^{1/2}} \quad (9.38b)$$

The wavefunction with $m_l = 0$ is $\psi_0(\phi) = 1/(2\pi)^{1/2}$, and has the same value at all points on the circle.

We have arrived at a number of conclusions about rotational motion by combining some classical notions with the de Broglie relation. Such a procedure can be very useful for establishing the general form (and, as in this case, the exact energies) for a quantum mechanical system. However, to be sure that the correct solutions have been obtained, and to obtain practice for more complex problems where this less formal approach is inadequate, we need to solve the Schrödinger equation explicitly. The formal solution is described in the *Justification* that follows.

Justification 9.5 The energies and wavefunctions of a particle on a ring

The hamiltonian for a particle of mass m in a plane (with $V = 0$) is the same as that given in eqn 9.10:

$$\hat{H} = -\frac{\hbar^2}{2m} \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \right)$$

and the Schrödinger equation is $H\psi = E\psi$, with the wavefunction a function of the angle ϕ . It is always a good idea to use coordinates that reflect the full symmetry of the system, so we introduce the coordinates r and ϕ (Fig. 9.30), where $x = r \cos \phi$ and $y = r \sin \phi$. By standard manipulations (see *Further reading*) we can write

$$\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} = \frac{\partial^2}{\partial r^2} + \frac{1}{r} \frac{\partial}{\partial r} + \frac{1}{r^2} \frac{\partial^2}{\partial \phi^2} \quad (9.39)$$

However, because the radius of the path is fixed, the derivatives with respect to r can be discarded. The hamiltonian then becomes

$$\hat{H} = -\frac{\hbar^2}{2mr^2} \frac{d^2}{d\phi^2}$$

The moment of inertia $I = mr^2$ has appeared automatically, so H may be written

$$\hat{H} = -\frac{\hbar^2}{2I} \frac{d^2}{d\phi^2} \quad (9.40)$$

and the Schrödinger equation is

$$\frac{d^2\psi}{d\phi^2} = -\frac{2IE}{\hbar^2} \psi \quad (9.41)$$

The normalized general solutions of the equation are

$$\psi_{m_l}(\phi) = \frac{e^{im_l\phi}}{(2\pi)^{1/2}} \quad m_l = \pm \frac{(2IE)^{1/2}}{\hbar} \quad (9.42)$$

The quantity m_l is just a dimensionless number at this stage.

We now select the acceptable solutions from among these general solutions by imposing the condition that the wavefunction should be single-valued. That is, the wavefunction ψ must satisfy a **cyclic boundary condition**, and match at points separated by a complete revolution: $\psi(\phi + 2\pi) = \psi(\phi)$. On substituting the general wavefunction into this condition, we find

$$\psi_{m_l}(\phi + 2\pi) = \frac{e^{im_l(\phi+2\pi)}}{(2\pi)^{1/2}} = \frac{e^{im_l\phi} e^{2\pi i m_l}}{(2\pi)^{1/2}} = \psi_{m_l}(\phi) e^{2\pi i m_l}$$

As $e^{i\pi} = -1$, this relation is equivalent to

$$\psi_{m_l}(\phi + 2\pi) = (-1)^{2m_l} \psi_{m_l}(\phi) \quad (9.43)$$

Because we require $(-1)^{2m_l} = 1$, $2m_l$ must be a positive or a negative even integer (including 0), and therefore m_l must be an integer: $m_l = 0, \pm 1, \pm 2, \dots$

(b) Quantization of rotation

We can summarize the conclusions so far as follows. The energy is quantized and restricted to the values given in eqn 9.38a ($E = m_l^2 \hbar^2 / 2I$). The occurrence of m_l as its square means that the energy of rotation is independent of the sense of rotation (the sign of m_l), as we expect physically. In other words, states with a given value of $|m_l|$ are doubly degenerate, except for $m_l = 0$, which is non-degenerate. Although the result has been derived for the rotation of a single mass point, it also applies to any body of moment of inertia I constrained to rotate about one axis.

We have also seen that the angular momentum is quantized and confined to the values given in eqn 9.37 ($J_z = m_l \hbar$). The increasing angular momentum is associated with the increasing number of nodes in the real and imaginary parts of the wavefunction: the wavelength decreases stepwise as $|m_l|$ increases, so the momentum with which the particle travels round the ring increases (Fig. 9.31). As shown in the following

Fig. 9.30 The cylindrical coordinates z , r , and ϕ for discussing systems with axial (cylindrical) symmetry. For a particle confined to the xy -plane, only r and ϕ can change.

Fig. 9.31 The real parts of the wavefunctions of a particle on a ring. As shorter wavelengths are achieved, the magnitude of the angular momentum around the z -axis grows in steps of $\hbar$.

Comment 9.4

The complex function $e^{im_l\phi}$ does not have nodes; however, it may be written as $\cos m_l\phi + i \sin m_l\phi$, and the real ($\cos m_l\phi$) and imaginary ($\sin m_l\phi$) components do have nodes.

Comment 9.5

The angular momentum in three dimensions is defined as

$$\begin{aligned} \mathbf{l} = \mathbf{r} \times \mathbf{p} &= \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ x & y & z \\ p_x & p_y & p_z \end{vmatrix} \\ &= (yp_z - zp_y)\mathbf{i} - (xp_z - zp_x)\mathbf{j} \\ &\quad + (xp_y - yp_x)\mathbf{k} \end{aligned}$$

where $\mathbf{i}$, $\mathbf{j}$, and $\mathbf{k}$ are unit vectors pointing along the positive directions on the x -, y -, and z -axes. It follows that the z -component of the angular momentum has a magnitude given by eqn 9.44. For more information on vectors, see Appendix 2.

Fig. 9.32 The basic ideas of the vector representation of angular momentum: the magnitude of the angular momentum is represented by the length of the vector, and the orientation of the motion in space by the orientation of the vector (using the right-hand screw rule).

Justification, we can come to the same conclusion more formally by using the argument about the relation between eigenvalues and the values of observables established in Section 8.5.

Justification 9.6 *The quantization of angular momentum*

In the discussion of translational motion in one dimension, we saw that the opposite signs in the wavefunctions e^{ikx} and e^{-ikx} correspond to opposite directions of travel, and that the linear momentum is given by the eigenvalue of the linear momentum operator. The same conclusions can be drawn here, but now we need the eigenvalues of the angular momentum operator. In classical mechanics the orbital angular momentum l_z about the z -axis is defined as

$$l_z = xp_y - yp_x \quad [9.44]$$

where p_x is the component of linear motion parallel to the x -axis and p_y is the component parallel to the y -axis. The operators for the two linear momentum components are given in eqn 8.26, so the operator for angular momentum about the z -axis, which we denote $\hat{l}_z$, is

$$\hat{l}_z = \frac{\hbar}{i} \left(x \frac{\partial}{\partial y} - y \frac{\partial}{\partial x} \right) \quad (9.45)$$

When expressed in terms of the coordinates r and ϕ , by standard manipulations this equation becomes

$$\hat{l}_z = \frac{\hbar}{i} \frac{\partial}{\partial \phi} \quad (9.46)$$

With the angular momentum operator available, we can test the wavefunction in eqn 9.38b. Disregarding the normalization constant, we find

$$\hat{l}_z \psi_{m_l} = \frac{\hbar}{i} \frac{d\psi_{m_l}}{d\phi} = im_l \frac{\hbar}{i} e^{im_l\phi} = m_l \hbar \psi_{m_l} \quad (9.47)$$

That is, ψ_{m_l} is an eigenfunction of $\hat{l}_z$, and corresponds to an angular momentum $m_l \hbar$. When m_l is positive, the angular momentum is positive (clockwise when seen from below); when m_l is negative, the angular momentum is negative (counterclockwise when seen from below). These features are the origin of the vector representation of angular momentum, in which the magnitude is represented by the length of a vector and the direction of motion by its orientation (Fig. 9.32).

To locate the particle given its wavefunction in eqn 9.38b, we form the probability density:

$$\psi_{m_l}^* \psi_{m_l} = \left(\frac{e^{im_l\phi}}{(2\pi)^{1/2}} \right)^* \left(\frac{e^{im_l\phi}}{(2\pi)^{1/2}} \right) = \left(\frac{e^{-im_l\phi}}{(2\pi)^{1/2}} \right) \left(\frac{e^{im_l\phi}}{(2\pi)^{1/2}} \right) = \frac{1}{2\pi}$$

Because this probability density is independent of ϕ , the probability of locating the particle somewhere on the ring is also independent of ϕ (Fig. 9.33). Hence the location of the particle is completely indefinite, and knowing the angular momentum precisely eliminates the possibility of specifying the particle's location. Angular momentum and angle are a pair of complementary observables (in the sense defined in Section 8.6), and the inability to specify them simultaneously with arbitrary precision is another example of the uncertainty principle.

9.7 Rotation in three dimensions: the particle on a sphere

We now consider a particle of mass m that is free to move anywhere on the surface of a sphere of radius r . We shall need the results of this calculation when we come to describe rotating molecules and the states of electrons in atoms and in small clusters of atoms. The requirement that the wavefunction should match as a path is traced over the poles as well as round the equator of the sphere surrounding the central point introduces a second cyclic boundary condition and therefore a second quantum number (Fig. 9.34).

(a) The Schrödinger equation

The hamiltonian for motion in three dimensions (Table 8.1) is

$$\hat{H} = -\frac{\hbar^2}{2m} \nabla^2 + V \quad \nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \quad (9.48)$$

The symbol ∇^2 is a convenient abbreviation for the sum of the three second derivatives; it is called the **laplacian**, and read either ‘del squared’ or ‘nabla squared’. For the particle confined to a spherical surface, $V = 0$ wherever it is free to travel, and the radius r is a constant. The wavefunction is therefore a function of the **colatitude**, θ , and the **azimuth**, ϕ (Fig. 9.35), and we write it $\psi(\theta, \phi)$. The Schrödinger equation is

$$-\frac{\hbar^2}{2m} \nabla^2 \psi = E \psi \quad (9.49)$$

As shown in the following *Justification*, this partial differential equation can be simplified by the separation of variables procedure by expressing the wavefunction (for constant r) as the product

$$\psi(\theta, \phi) = \Theta(\theta) \Phi(\phi) \quad (9.50)$$

where Θ is a function only of θ and Φ is a function only of ϕ .

Justification 9.7 The separation of variables technique applied to the particle on a sphere

The laplacian in spherical polar coordinates is (see *Further reading*)

$$\nabla^2 = \frac{\partial^2}{\partial r^2} + \frac{2}{r} \frac{\partial}{\partial r} + \frac{1}{r^2} \Lambda^2 \quad (9.51a)$$

where the **legendrian**, Λ^2 , is

$$\Lambda^2 = \frac{1}{\sin^2 \theta} \frac{\partial^2}{\partial \phi^2} + \frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \sin \theta \frac{\partial}{\partial \theta} \quad (9.51b)$$

Because r is constant, we can discard the part of the laplacian that involves differentiation with respect to r , and so write the Schrödinger equation as

$$\frac{1}{r^2} \Lambda^2 \psi = -\frac{2mE}{\hbar^2} \psi$$

or, because $I = mr^2$, as

$$\Lambda^2 \psi = -\epsilon \psi \quad \epsilon = \frac{2IE}{\hbar^2}$$

Fig. 9.33 The probability density for a particle in a definite state of angular momentum is uniform, so there is an equal probability of finding the particle anywhere on the ring.

Fig. 9.34 The wavefunction of a particle on the surface of a sphere must satisfy two cyclic boundary conditions; this requirement leads to two quantum numbers for its state of angular momentum.

Fig. 9.35 Spherical polar coordinates. For a particle confined to the surface of a sphere, only the colatitude, θ , and the azimuth, ϕ , can change.

Table 9.3 The spherical harmonics

l	m_l	$Y_{l,m_l}(\theta, \phi)$
0	0	$\left(\frac{1}{4\pi}\right)^{1/2}$
1	0	$\left(\frac{3}{4\pi}\right)^{1/2} \cos \theta$
	± 1	$\mp \left(\frac{3}{8\pi}\right)^{1/2} \sin \theta e^{\pm i\phi}$
2	0	$\left(\frac{5}{16\pi}\right)^{1/2} (3 \cos^2 \theta - 1)$
	± 1	$\mp \left(\frac{15}{8\pi}\right)^{1/2} \cos \theta \sin \theta e^{\pm i\phi}$
	± 2	$\left(\frac{15}{32\pi}\right)^{1/2} \sin^2 \theta e^{\pm 2i\phi}$
3	0	$\left(\frac{7}{16\pi}\right)^{1/2} (5 \cos^3 \theta - 3 \cos \theta)$
	± 1	$\mp \left(\frac{21}{64\pi}\right)^{1/2} (5 \cos^2 \theta - 1) \sin \theta e^{\pm i\phi}$
	± 2	$\left(\frac{105}{32\pi}\right)^{1/2} \sin^2 \theta \cos \theta e^{\pm 2i\phi}$
	± 3	$\mp \left(\frac{35}{64\pi}\right)^{1/2} \sin^3 \theta e^{\pm 3i\phi}$

Comment 9.6

The spherical harmonics are orthogonal and normalized in the following sense:

$$\int_0^\pi \int_0^{2\pi} Y_{l',m_l'}(\theta, \phi) Y_{l,m_l}(\theta, \phi) \sin \theta d\theta d\phi = \delta_{l'l} \delta_{m_l'm_l}$$

An important ‘triple integral’ is

$$\int_0^\pi \int_0^{2\pi} Y_{l',m_l'}(\theta, \phi) Y_{l',m_l'}(\theta, \phi) Y_{l,m_l}(\theta, \phi) \sin \theta d\theta d\phi = 0$$

unless $m_l'' = m_l' + m_l$ and we can form a triangle with sides of lengths l'', l' , and l (such as 1, 2, and 3 or 1, 1, and 1, but not 1, 2, and 4).

Comment 9.7

The real and imaginary components of the Φ component of the wavefunctions, $e^{im_l\phi} = \cos m_l\phi + i \sin m_l\phi$, each have $|m_l|$ angular nodes, but these nodes are not seen when we plot the probability density, because $|e^{im_l\phi}|^2 = 1$.

To verify that this expression is separable, we substitute $\psi = \Theta\Phi$:

$$\frac{1}{\sin^2 \theta} \frac{\partial^2(\Theta\Phi)}{\partial \phi^2} + \frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \sin \theta \frac{\partial(\Theta\Phi)}{\partial \theta} = -\epsilon \Theta\Phi$$

We now use the fact that Θ and Φ are each functions of one variable, so the partial derivatives become complete derivatives:

$$\frac{\Theta}{\sin^2 \theta} \frac{d^2 \Phi}{d\phi^2} + \frac{\Phi}{\sin \theta} \frac{d}{d\theta} \sin \theta \frac{d\Theta}{d\theta} = -\epsilon \Theta\Phi$$

Division through by $\Theta\Phi$, multiplication by $\sin^2 \theta$, and minor rearrangement gives

$$\Phi \frac{d^2 \Phi}{d\phi^2} + \frac{\sin \theta}{\Theta} \frac{d}{d\theta} \sin \theta \frac{d\Theta}{d\theta} + \epsilon \sin^2 \theta = 0$$

The first term on the left depends only on ϕ and the remaining two terms depend only on θ . We met a similar situation when discussing a particle on a rectangular surface (*Justification 9.3*), and by the same argument, the complete equation can be separated. Thus, if we set the first term equal to the numerical constant $-m_l^2$ (using a notation chosen with an eye to the future), the separated equations are

$$\frac{1}{\Phi} \frac{d^2 \Phi}{d\phi^2} = -m_l^2 \quad \frac{\sin \theta}{\Theta} \frac{d}{d\theta} \sin \theta \frac{d\Theta}{d\theta} + \epsilon \sin^2 \theta = m_l^2$$

The first of these two equations is the same as that in *Justification 9.5*, so it has the same solutions (eqn 9.38b). The second is much more complicated to solve, but the solutions are tabulated as the *associated Legendre functions*. The cyclic boundary conditions on Θ result in the introduction of a second quantum number, l , which identifies the acceptable solutions. The presence of the quantum number m_l in the second equation implies, as we see below, that the range of acceptable values of m_l is restricted by the value of l .

As indicated in *Justification 9.7*, solution of the Schrödinger equation shows that the acceptable wavefunctions are specified by two quantum numbers l and m_l that are restricted to the values

$$l = 0, 1, 2, \dots \quad m_l = l, l-1, \dots, -l \quad (9.52)$$

Note that the **orbital angular momentum quantum number** l is non-negative and that, for a given value of l , there are $2l+1$ permitted values of the **magnetic quantum number**, m_l . The normalized wavefunctions are usually denoted $Y_{l,m_l}(\theta, \phi)$ and are called the **spherical harmonics** (Table 9.3).

Figure 9.36 is a representation of the spherical harmonics for $l=0$ to 4 and $m_l=0$ which emphasizes how the number of angular nodes (the positions at which the wavefunction passes through zero) increases as the value of l increases. There are no angular nodes around the z -axis for functions with $m_l=0$, which corresponds to there being no component of orbital angular momentum about that axis. Figure 9.37 shows the distribution of the particle of a given angular momentum in more detail. In this representation, the value of $|Y_{l,m_l}|^2$ at each value of θ and ϕ is proportional to the distance of the surface from the origin. Note how, for a given value of l , the most probable location of the particle migrates towards the xy -plane as the value of $|m_l|$ increases.

It also follows from the solution of the Schrödinger equation that the energy E of the particle is restricted to the values

$$E = l(l+1) \frac{\hbar^2}{2I} \quad l = 0, 1, 2, \dots \quad (9.53)$$

Fig. 9.36 A representation of the wavefunctions of a particle on the surface of a sphere which emphasizes the location of angular nodes: dark and light shading correspond to different signs of the wavefunction. Note that the number of nodes increases as the value of l increases. All these wavefunctions correspond to $m_l = 0$; a path round the vertical z -axis of the sphere does not cut through any nodes.

Fig. 9.37 A more complete representation of the wavefunctions for $l = 0, 1, 2$, and 3 . The distance of a point on the surface from the origin is proportional to the square modulus of the amplitude of the wavefunction at that point.

Exploration Plot the variation with the radius r of the first ten energy levels of a particle on a sphere. Which of the following statements are true: (a) for a given value of r , the energy separation between adjacent levels decreases with increasing l , (b) increasing r leads to an decrease in the value of the energy for each level, (c) the energy difference between adjacent levels increases as r increases.

We see that the energy is quantized, and that it is independent of m_l . Because there are $2l + 1$ different wavefunctions (one for each value of m_l) that correspond to the same energy, it follows that a level with quantum number l is $(2l + 1)$ -fold degenerate.

(b) Angular momentum

The energy of a rotating particle is related classically to its angular momentum J by $E = J^2/2I$ (see *Appendix 3*). Therefore, by comparing this equation with eqn 9.53, we can deduce that, because the energy is quantized, then so too is the magnitude of the angular momentum, and confined to the values

$$\text{Magnitude of angular momentum} = \{l(l+1)\}^{1/2}\hbar \quad l = 0, 1, 2, \dots \quad (9.54a)$$

We have already seen (in the context of rotation in a plane) that the angular momentum about the z -axis is quantized, and that it has the values

$$z\text{-Component of angular momentum} = m_l\hbar \quad m_l = l, l-1, \dots, -l \quad (9.54b)$$

The fact that the number of nodes in $\psi_{l,m_l}(\theta, \phi)$ increases with l reflects the fact that higher angular momentum implies higher kinetic energy, and therefore a more sharply buckled wavefunction. We can also see that the states corresponding to high angular momentum around the z -axis are those in which most nodal lines cut the equator: a high kinetic energy now arises from motion parallel to the equator because the curvature is greatest in that direction.

Illustration 9.4 Calculating the frequency of a molecular rotational transition

Under certain circumstances, the particle on a sphere is a reasonable model for the description of the rotation of diatomic molecules. Consider, for example, the rotation of a $^1\text{H}^{127}\text{I}$ molecule: because of the large difference in atomic masses, it is appropriate to picture the ^1H atom as orbiting a stationary ^{127}I atom at a distance $r = 160$ pm, the equilibrium bond distance. The moment of inertia of $^1\text{H}^{127}\text{I}$ is then $I = m_{\text{H}}r^2 = 4.288 \times 10^{-47} \text{ kg m}^2$. It follows that

$$\frac{\hbar^2}{2I} = \frac{(1.054\,57 \times 10^{-34} \text{ J s})^2}{2 \times (4.288 \times 10^{-47} \text{ kg m}^2)} = 1.297 \times 10^{-22} \text{ J}$$

or 0.1297 zJ . This energy corresponds to 78.09 J mol^{-1} . From eqn 9.53, the first few rotational energy levels are therefore 0 ($l=0$), 0.2594 zJ ($l=1$), 0.7782 zJ ($l=2$), and 1.556 zJ ($l=3$). The degeneracies of these levels are $1, 3, 5$, and 7 , respectively (from $2l+1$), and the magnitudes of the angular momentum of the molecule are $0, 2^{1/2}\hbar, 6^{1/2}\hbar$, and $(12)^{1/2}\hbar$ (from eqn 9.54a). It follows from our calculations that the $l=0$ and $l=1$ levels are separated by $\Delta E = 0.2594 \text{ zJ}$. A transition between these two rotational levels of the molecule can be brought about by the emission or absorption of a photon with a frequency given by the Bohr frequency condition (eqn 8.10):

$$\nu = \frac{\Delta E}{h} = \frac{2.594 \times 10^{-22} \text{ J}}{6.626 \times 10^{-34} \text{ J s}} = 3.915 \times 10^{11} \text{ Hz} = 391.5 \text{ GHz}$$

Radiation with this frequency belongs to the microwave region of the electromagnetic spectrum, so microwave spectroscopy is a convenient method for the study of molecular rotations. Because the transition energies depend on the moment of inertia, microwave spectroscopy is a very accurate technique for the determination of bond lengths. We discuss rotational spectra further in Chapter 13.

Self-test 9.8 Repeat the calculation for a $^2\text{H}^{127}\text{I}$ molecule (same bond length as $^1\text{H}^{127}\text{I}$).

[Energies are smaller by a factor of two; same angular momenta and numbers of components]

Fig. 9.38 The permitted orientations of angular momentum when $l = 2$. We shall see soon that this representation is too specific because the azimuthal orientation of the vector (its angle around z) is indeterminate.

(c) Space quantization

The result that m_l is confined to the values $l, l-1, \dots, -l$ for a given value of l means that the component of angular momentum about the z -axis may take only $2l + 1$ values. If the angular momentum is represented by a vector of length proportional to its magnitude (that is, of length $\{l(l+1)\}^{1/2}$ units), then to represent correctly the value of the component of angular momentum, the vector must be oriented so that its projection on the z -axis is of length m_l units. In classical terms, this restriction means that the plane of rotation of the particle can take only a discrete range of orientations (Fig. 9.38). The remarkable implication is that *the orientation of a rotating body is quantized*.

The quantum mechanical result that a rotating body may not take up an arbitrary orientation with respect to some specified axis (for example, an axis defined by the direction of an externally applied electric or magnetic field) is called **space quantization**. It was confirmed by an experiment first performed by Otto Stern and Walther Gerlach in 1921, who shot a beam of silver atoms through an inhomogeneous magnetic field (Fig. 9.39). The idea behind the experiment was that a rotating, charged body behaves like a magnet and interacts with the applied field. According to classical mechanics, because the orientation of the angular momentum can take any value, the associated magnet can take any orientation. Because the direction in which the magnet is driven by the inhomogeneous field depends on the magnet's orientation, it follows that a broad band of atoms is expected to emerge from the region where the magnetic field acts. According to quantum mechanics, however, because the angular momentum is quantized, the associated magnet lies in a number of discrete orientations, so several sharp bands of atoms are expected.

In their first experiment, Stern and Gerlach appeared to confirm the classical prediction. However, the experiment is difficult because collisions between the atoms in the beam blur the bands. When the experiment was repeated with a beam of very low intensity (so that collisions were less frequent) they observed discrete bands, and so confirmed the quantum prediction.

(d) The vector model

Throughout the preceding discussion, we have referred to the z -component of angular momentum (the component about an arbitrary axis, which is conventionally denoted z), and have made no reference to the x - and y -components (the components

Fig. 9.39 (a) The experimental arrangement for the Stern–Gerlach experiment: the magnet provides an inhomogeneous field. (b) The classically expected result. (c) The observed outcome using silver atoms.

Fig. 9.40 (a) A summary of Fig. 9.38. However, because the azimuthal angle of the vector around the z -axis is indeterminate, a better representation is as in (b), where each vector lies at an unspecified azimuthal angle on its cone.

about the two axes perpendicular to z). The reason for this omission is found by examining the operators for the three components, each one being given by a term like that in eqn 9.45:

$$\hat{l}_x = \frac{\hbar}{i} \left(y \frac{\partial}{\partial z} - z \frac{\partial}{\partial y} \right) \quad \hat{l}_y = \frac{\hbar}{i} \left(z \frac{\partial}{\partial x} - x \frac{\partial}{\partial z} \right) \quad \hat{l}_z = \frac{\hbar}{i} \left(x \frac{\partial}{\partial y} - y \frac{\partial}{\partial x} \right) \quad (9.55)$$

As you are invited to show in Problem 9.27, these three operators do not commute with one another:

$$[\hat{l}_x, \hat{l}_y] = i\hbar \hat{l}_z \quad [\hat{l}_y, \hat{l}_z] = i\hbar \hat{l}_x \quad [\hat{l}_z, \hat{l}_x] = i\hbar \hat{l}_y \quad (9.56a)$$

Therefore, we cannot specify more than one component (unless $l=0$). In other words, l_x , l_y , and l_z are complementary observables. On the other hand, the operator for the square of the magnitude of the angular momentum is

$$\hat{l}^2 = \hat{l}_x^2 + \hat{l}_y^2 + \hat{l}_z^2 = \hbar^2 \Lambda^2 \quad (9.56b)$$

where Λ^2 is the legendrian in eqn 9.51b. This operator does commute with all three components:

$$[\hat{l}^2, \hat{l}_q] = 0 \quad q = x, y, \text{ and } z \quad (9.56c)$$

(See Problem 9.29.) Therefore, although we may specify the magnitude of the angular momentum and any of its components, if l_z is known, then it is impossible to ascribe values to the other two components. It follows that the illustration in Fig. 9.38, which is summarized in Fig. 9.40a, gives a false impression of the state of the system, because it suggests definite values for the x - and y -components. A better picture must reflect the impossibility of specifying l_x and l_y if l_z is known.

The **vector model** of angular momentum uses pictures like that in Fig. 9.40b. The cones are drawn with side $\{l(l+1)\}^{1/2}$ units, and represent the magnitude of the angular momentum. Each cone has a definite projection (of m_l units) on the z -axis, representing the system's precise value of l_z . The l_x and l_y projections, however, are indefinite. The vector representing the state of angular momentum can be thought of as lying with its tip on any point on the mouth of the cone. At this stage it should not be thought of as sweeping round the cone; that aspect of the model will be added later when we allow the picture to convey more information.

IMPACT ON NANOSCIENCE I9.2 Quantum dots

In *Impact I9.1* we outlined some advantages of working in the nanometre regime. Another is the possibility of using quantum mechanical effects that render the properties of an assembly dependent on its size. Here we focus on the origins and consequences of these quantum mechanical effects.

Consider a sample of a metal, such as copper or gold. It carries an electrical current because the electrons are delocalized over all the atomic nuclei. That is, we may treat the movement of electrons in metals with a particle in a box model, though it is necessary to imagine that the electrons move independently of each other. Immediately, we predict from eqn 9.6 that the energy levels of the electrons in a large box, such as a copper wire commonly used to make electrical connections, form a continuum so we are justified in neglecting quantum mechanical effects on the properties of the material. However, consider a *nanocrystal*, a small cluster of atoms with dimensions in the nanometre scale. Again using eqn 9.6, we predict that the electronic energies are quantized and that the separation between energy levels decreases with increasing size of the cluster. This quantum mechanical effect can be observed in 'boxes' of any

shape. For example, you are invited to show in Problem 9.39 that the energy levels of an electron *in* a sphere of radius R are given by

$$E_n = \frac{n^2 h^2}{8m_e R^2} \quad (9.57)$$

The quantization of energy in nanocrystals has important technological implications when the material is a semiconductor, in which the electrical conductivity increases with increasing temperature or upon excitation by light (see Chapter 20 for a more detailed discussion). Transfer of energy to a semiconductor increases the mobility of electrons in the material. However, for every electron that moves to a different site in the sample, a unit of positive charge, called a *hole*, is left behind. The holes are also mobile, so to describe electrical conductivity in semiconductors we need to consider the movement of electron–hole pairs, also called **excitons**, in the material.

The electrons and holes may be regarded as particles trapped in a box, so eqn 9.6 can give us qualitative insight into the origins of conductivity in semiconductors. We conclude as before that only in nanocrystals are the energies of the charge carriers quantized. Now we explore the impact of energy quantization on the optical and electronic properties of semiconducting nanocrystals.

Three-dimensional nanocrystals of semiconducting materials containing 10^3 to 10^5 atoms are called **quantum dots**. They can be made in solution or by depositing atoms on a surface, with the size of the nanocrystal being determined by the details of the synthesis (see, for example, *Impact I20.2*). A quantitative but approximate treatment that leads to the energy of the exciton begins with the following hamiltonian for a spherical quantum dot of radius R :

$$\hat{H} = -\frac{\hbar^2}{2m_e} \nabla_e^2 - \frac{\hbar^2}{2m_h} \nabla_h^2 + V(\mathbf{r}_e, \mathbf{r}_h) \quad (9.58)$$

where the first two terms are the kinetic energy operators for the electron and hole (with masses m_e and m_h , respectively), and the third term is the potential energy of interaction between electron and hole, which are located at positions $\mathbf{r}_e$ and $\mathbf{r}_h$ from the centre of the sphere. Taking into account only the Coulomb attraction between the hole, with charge $+e$, and the electron, with charge $-e$, we write (see Chapter 9 and *Appendix 3* for details):

$$V(\mathbf{r}_e, \mathbf{r}_h) = -\frac{e^2}{4\pi\epsilon |\mathbf{r}_e - \mathbf{r}_h|} \quad (9.59)$$

where $|\mathbf{r}_e - \mathbf{r}_h|$ is the distance between the electron and hole and ϵ is the permittivity of the medium (we are ignoring the effect of polarization of the medium due to the presence of charges). Solving the Schrödinger equation in this case is not a trivial task, but the final expression for the energy of the exciton, E_{ex} , is relatively simple (see *Further reading* for details):

$$E_{\text{ex}} = \frac{h^2}{8R^2} \left(\frac{1}{m_e} + \frac{1}{m_h} \right) - \frac{1.8e^2}{4\pi\epsilon R} \quad (9.60)$$

As expected, we see that the energy of the exciton decreases with increasing radius of the quantum dot. Moreover, for small R , the second term on the right of the preceding equation is smaller than the first term and the energy of the exciton is largely kinetic, with the resulting expression resembling the case for a particle in a sphere.

The expression for E_{ex} has important consequences for the optical properties of quantum dots. First, we see that the energy required to create mobile charge carriers and to induce electrical conductivity depends on the size of the quantum dot. The

electrical properties of large, macroscopic samples of semiconductors cannot be tuned in this way. Second, in many quantum dots, such as the nearly spherical nanocrystals of cadmium selenide (CdSe), the exciton can be generated by absorption of visible light. Therefore, we predict that, as the radius of the quantum dot decreases, the excitation wavelength increases. That is, as the size of the quantum dot varies, so does the colour of the material. This phenomenon is indeed observed in suspensions of CdSe quantum dots of different sizes.

Because quantum dots are semiconductors with tunable electrical properties, it is easy to imagine uses for these materials in the manufacture of transistors. But the special optical properties of quantum dots can also be exploited. Just as the generation of an electron–hole pair requires absorption of light of a specific wavelength, so does recombination of the pair result in the emission of light of a specific wavelength. This property forms the basis for the use of quantum dots in the visualization of biological cells at work. For example, a CdSe quantum dot can be modified by covalent attachment of an organic spacer to its surface. When the other end of the spacer reacts specifically with a cellular component, such as a protein, nucleic acid, or membrane, the cell becomes labelled with a light-emitting quantum dot. The spatial distribution of emission intensity and, consequently, of the labelled molecule can then be measured with a microscope. Though this technique has been used extensively with organic molecules as labels, quantum dots are more stable and are stronger light emitters.

9.8 Spin

Stern and Gerlach observed *two* bands of Ag atoms in their experiment. This observation seems to conflict with one of the predictions of quantum mechanics, because an angular momentum l gives rise to $2l + 1$ orientations, which is equal to 2 only if $l = \frac{1}{2}$, contrary to the conclusion that l must be an integer. The conflict was resolved by the suggestion that the angular momentum they were observing was not due to orbital angular momentum (the motion of an electron around the atomic nucleus) but arose instead from the motion of the electron about its own axis. This intrinsic angular momentum of the electron is called its **spin**. The explanation of the existence of spin emerged when Dirac combined quantum mechanics with special relativity and established the theory of relativistic quantum mechanics.

The spin of an electron about its own axis does not have to satisfy the same boundary conditions as those for a particle circulating around a central point, so the quantum number for spin angular momentum is subject to different restrictions. To distinguish this spin angular momentum from orbital angular momentum we use the **spin quantum number** s (in place of l ; like l , s is a non-negative number) and m_s , the **spin magnetic quantum number**, for the projection on the z -axis. The magnitude of the spin angular momentum is $\{s(s + 1)\}^{1/2}\hbar$ and the component $m_s\hbar$ is restricted to the $2s + 1$ values

$$m_s = s, s - 1, \dots, -s \quad (9.61)$$

Fig. 9.41 An electron spin ($s = \frac{1}{2}$) can take only two orientations with respect to a specified axis. An α electron (top) is an electron with $m_s = +\frac{1}{2}$; a β electron (bottom) is an electron with $m_s = -\frac{1}{2}$. The vector representing the spin angular momentum lies at an angle of 55° to the z -axis (more precisely, the half-angle of the cones is $\arccos(1/3^{1/2})$).

The detailed analysis of the spin of a particle is sophisticated and shows that the property should not be taken to be an actual spinning motion. It is better to regard ‘spin’ as an intrinsic property like mass and charge. However, the picture of an actual spinning motion can be very useful when used with care. For an electron it turns out that only one value of s is allowed, namely $s = \frac{1}{2}$, corresponding to an angular momentum of magnitude $(\frac{3}{4})^{1/2}\hbar = 0.866\hbar$. This spin angular momentum is an intrinsic property of the electron, like its rest mass and its charge, and every electron has exactly the same value: the magnitude of the spin angular momentum of an electron cannot be changed. The spin may lie in $2s + 1 = 2$ different orientations (Fig. 9.41).

One orientation corresponds to $m_s = +\frac{1}{2}$ (this state is often denoted α or $\uparrow$); the other orientation corresponds to $m_s = -\frac{1}{2}$ (this state is denoted β or $\downarrow$).

The outcome of the Stern–Gerlach experiment can now be explained if we suppose that each Ag atom possesses an angular momentum due to the spin of a single electron, because the two bands of atoms then correspond to the two spin orientations. Why the atoms behave like this is explained in Chapter 10 (but it is already probably familiar from introductory chemistry that the ground-state configuration of a silver atom is $[\text{Kr}]4d^{10}5s^1$, a single unpaired electron outside a closed shell).

Like the electron, other elementary particles have characteristic spin. For example, protons and neutrons are spin- $\frac{1}{2}$ particles (that is, $s = \frac{1}{2}$) and invariably spin with angular momentum $(\frac{3}{4})^{1/2}\hbar = 0.866\hbar$. Because the masses of a proton and a neutron are so much greater than the mass of an electron, yet they all have the same spin angular momentum, the classical picture would be of these two particles spinning much more slowly than an electron. Some elementary particles have $s = 1$, and so have an intrinsic angular momentum of magnitude $2^{1/2}\hbar$. Some mesons are spin-1 particles (as are some atomic nuclei), but for our purposes the most important spin-1 particle is the photon. From the discussion in this chapter, we see that the photon has zero rest mass, zero charge, an energy $h\nu$, a linear momentum h/λ or $h\nu/c$, an intrinsic angular momentum of $2^{1/2}\hbar$, and travels at the speed c . We shall see the importance of photon spin in the next chapter.

Particles with half-integral spin are called **fermions** and those with integral spin (including 0) are called **bosons**. Thus, electrons and protons are fermions and photons are bosons. It is a very deep feature of nature that all the elementary particles that constitute matter are fermions whereas the elementary particles that are responsible for the forces that bind fermions together are all bosons. Photons, for example, transmit the electromagnetic force that binds together electrically charged particles. Matter, therefore, is an assembly of fermions held together by forces conveyed by bosons.

The properties of angular momentum that we have developed are set out in Table 9.4. As mentioned there, when we use the quantum numbers l and m_l we shall mean orbital angular momentum (circulation in space). When we use s and m_s we shall mean spin angular momentum (intrinsic angular momentum). When we use j and m_j we shall mean either (or, in some contexts to be described in Chapter 10, a combination of orbital and spin momenta).

Table 9.4 Properties of angular momentum

Quantum number	Symbol	Values*	Specifies
Orbital angular momentum	l	0, 1, 2, ...	Magnitude, $\{l(l+1)\}^{1/2}\hbar$
Magnetic	m_l	$l, l-1, \dots, -l$	Component on z-axis, $m_l\hbar$
Spin	s	$\frac{1}{2}$	Magnitude, $\{s(s+1)\}^{1/2}\hbar$
Spin magnetic	m_s	$\pm\frac{1}{2}$	Component on z-axis, $m_s\hbar$
Total	j	$l+s, l+s-1, \dots, l-s $	Magnitude, $\{j(j+1)\}^{1/2}\hbar$
Total magnetic	m_j	$j, j-1, \dots, -j$	Component on z-axis, $m_j\hbar$

To combine two angular momenta, use the Clebsch–Gordan series:

$$j = j_1 + j_2, j_1 + j_2 - 1, \dots, |j_1 - j_2|$$

For many-electron systems, the quantum numbers are designated by uppercase letters (L, M_L, S, M_S , etc.).

*Note that the quantum numbers for magnitude (l, s, j , etc.) are never negative.

Techniques of approximation

All the applications treated so far have had exact solutions. However, many problems—and almost all the problems of interest in chemistry—do not have exact solutions. To make progress with these problems we need to develop techniques of approximation. There are two major approaches, *variation theory* and *perturbation theory*. Variation theory is most commonly encountered in the context of molecular orbital theory, and we consider it there (Chapter 11). Here, we concentrate on perturbation theory.

9.9 Time-independent perturbation theory

In **perturbation theory**, we suppose that the hamiltonian for the problem we are trying to solve, $\hat{H}$, can be expressed as the sum of a simple hamiltonian, $\hat{H}^{(0)}$, which has known eigenvalues and eigenfunctions, and a contribution, $\hat{H}^{(1)}$, which represents the extent to which the true hamiltonian differs from the ‘model’ hamiltonian:

$$\hat{H} = \hat{H}^{(0)} + \hat{H}^{(1)} \quad (9.62)$$

In **time-independent perturbation theory**, the perturbation is always present and unvarying. For example, it might represent a dip in the potential energy of a particle in a box in some region along the length of the box.

In time-independent perturbation theory, we suppose that the true energy of the system differs from the energy of the simple system, and that we can write

$$E = E^{(0)} + E^{(1)} + E^{(2)} + \dots \quad (9.63)$$

where $E^{(1)}$ is the ‘first-order correction’ to the energy, a contribution proportional to $\hat{H}^{(1)}$, and $E^{(2)}$ is the ‘second-order correction’ to the energy, a contribution proportional to $\hat{H}^{(1)2}$, and so on. The true wavefunction also differs from the ‘simple’ wavefunction, and we write

$$\psi = \psi^{(0)} + \psi^{(1)} + \psi^{(2)} + \dots \quad (9.64)$$

In practice, we need to consider only the ‘first-order correction’ to the wavefunction, $\psi^{(1)}$. As we show in *Further information 9.2*, the first- and second-order corrections to the energy of the ground state (with the wavefunction ψ_0 and energy E_0), are

$$E_0^{(1)} = \int \psi_0^{(0)*} \hat{H}^{(1)} \psi_0^{(0)} d\tau = H_{00}^{(1)} \quad (9.65a)$$

and

$$E_0^{(2)} = \sum_{n \neq 0} \frac{\left| \int \psi_0^{(0)*} \hat{H}^{(1)} \psi_n^{(0)} d\tau \right|^2}{E_0^{(0)} - E_n^{(0)}} = \sum_{n \neq 0} \frac{|H_{n0}^{(1)}|^2}{E_0^{(0)} - E_n^{(0)}} \quad (9.65b)$$

where we have introduced the **matrix element**

$$\Omega_{nm} = \int \psi_n^* \hat{\Omega} \psi_m d\tau \quad [9.65c]$$

in a convenient compact notation for integrals that we shall use frequently.

As usual, it is important to be able to interpret these equations physically. We can interpret $E^{(1)}$ as the average value of the perturbation, calculated by using the unperturbed wavefunction. An analogy is the shift in energy of vibration of a violin string

when small weights are hung along its length. The weights hanging close to the nodes have little effect on its energy of vibration. Those hanging at the antinodes, however, have a pronounced effect (Fig. 9.42a). The second-order energy represents a similar average of the perturbation, but now the average is taken over the *perturbed* wavefunctions. In terms of the violin analogy, the average is now taken over the distorted waveform of the vibrating string, in which the nodes and antinodes are slightly shifted (Fig. 9.42b).

We should note the following three features of eqn 9.65b:

1. Because $E_n(0) > E_0(0)$, all the terms in the denominator are negative and, because the numerators are all positive, the second-order correction is negative, which represents a *lowering* of the energy of the ground state.
2. The perturbation appears (as its square) in the numerator; so the stronger the perturbation, the greater the lowering of the ground-state energy.
3. If the energy levels of the system are widely spaced, all the denominators are large, so the sum is likely to be small; in which case the perturbation has little effect on the energy of the system: the system is 'stiff', and unresponsive to perturbations. The opposite is true when the energy levels lie close together.

Fig. 9.42 (a) The first-order energy is an average of the perturbation (represented by the hanging weights) over the unperturbed wavefunction. (b) The second-order energy is a similar average, but over the distortion induced by the perturbation.

Example 9.5 Using perturbation theory

Find the first-order correction to the ground-state energy for a particle in a well with a variation in the potential of the form $V = -\epsilon \sin(\pi x/L)$, as in Fig. 9.43.

Method Identify the first-order perturbation hamiltonian and evaluate $E_0^{(1)}$ from eqn 9.65a. We can expect a small lowering of the energy because the average potential energy of the particle is lower in the distorted box.

Answer The perturbation hamiltonian is

$$\hat{H}^{(1)} = -\epsilon \sin(\pi x/L)$$

Therefore, the first-order correction to the energy is

$$E_0^{(1)} = \int_0^L \psi_1 \hat{H}^{(1)} \psi_1 dx = -\frac{2\epsilon}{L} \int_0^L \sin^3 \frac{\pi x}{L} dx = -\frac{8\epsilon}{3\pi}$$

Note that the energy is lowered by the perturbation, as would be expected for the shape shown in Fig. 9.43.

Self-test 9.9 Suppose that only ψ_3 contributes to the distortion of the wavefunction: calculate the coefficient c_3 and the second-order correction to the energy by using eqn 9.65b and eqn 9.76 in *Further information 9.2*.

$$[c_3 = -8\epsilon mL^2/15\pi h^2, E_0^{(2)} = -64\epsilon^2 mL^2/225\pi^2 h^2]$$

Fig. 9.43 The potential energy for a particle in a box with a potential that varies as $-\epsilon \sin(\pi x/L)$ across the floor of the box. We can expect the particle to accumulate more in the centre of the box (in the ground state at least) than in the unperturbed box.

9.10 Time-dependent perturbation theory

In **time-dependent perturbation theory**, the perturbation is either switched on and allowed to rise to its final value or is varying in time. Many of the perturbations encountered in chemistry are time-dependent. The most important is the effect of an oscillating electromagnetic field, which is responsible for spectroscopic transitions between quantized energy levels in atoms and molecules.

Classically, for a molecule to be able to interact with the electromagnetic field and absorb or emit a photon of frequency ν , it must possess, at least transiently, a dipole oscillating at that frequency. In this section, we develop the quantum mechanical view and begin by writing the hamiltonian for the system as

$$\hat{H} = \hat{H}^{(0)} + \hat{H}^{(1)}(t) \quad (9.66)$$

where $\hat{H}^{(1)}(t)$ is the time-dependent perturbation. Because the perturbation arises from the effect of an oscillating electric field with the electric dipole moment, we write

$$\hat{H}^{(1)}(t) = -\mu_z \mathcal{E} \cos \omega t \quad (9.67)$$

where ω is the frequency of the field and $\mathcal{E}$ is its amplitude. We suppose that the perturbation is absent until $t = 0$, and then it is turned on.

We show in *Further information 9.2* that the rate of change of population of the state ψ_f due to transitions from state ψ_i , $w_{f \leftarrow i}$, is proportional to the square modulus of the matrix element of the perturbation between the two states:

$$w_{f \leftarrow i} \propto |H_{fi}^{(1)}|^2 \quad (9.68)$$

Because in our case the perturbation is that of the interaction of the electromagnetic field with a molecule (eqn 9.67), we conclude that

$$w_{f \leftarrow i} \propto |\mu_{z,fi}|^2 \mathcal{E}^2 \quad (9.69)$$

Therefore, the rate of transition, and hence the intensity of absorption of the incident radiation, is proportional to the square of the **transition dipole moment**:

$$\mu_{z,fi} = \int \psi_f^* \mu_z \psi_i d\tau \quad [9.70]$$

The size of the transition dipole can be regarded as a measure of the charge redistribution that accompanies a transition.

The rate of transition is also proportional to $\mathcal{E}^2$, and therefore the intensity of the incident radiation (because the intensity is proportional to $\mathcal{E}^2$; see *Appendix 3*). This result will be the basis of most of our subsequent discussion of spectroscopy in Chapters 10 and 13–15 and of the kinetics of electron transfer in Chapter 24.

Comment 9.8

An electric dipole consists of two electric charges $+q$ and $-q$ separated by a distance R . The electric dipole moment vector μ has a magnitude $\mu = qR$.

Checklist of key ideas

☐ 1. The wavefunction of a free particle is $\psi_k = Ae^{ikx} + Be^{-ikx}$, $E_k = k^2 \hbar^2 / 2m$. ☐ 2. The wavefunctions and energies of a particle in a one-dimensional box of length L are, respectively, $\psi_n(x) = (2/L)^{1/2} \sin(n\pi x/L)$ and $E_n = n^2 \hbar^2 / 8mL^2$, $n = 1, 2, \dots$. The zero-point energy, the lowest possible energy is $E_1 = \hbar^2 / 8mL^2$. ☐ 3. The correspondence principle states that classical mechanics emerges from quantum mechanics as high quantum numbers are reached. ☐ 4. The functions ψ_n and $\psi_{n'}$ are orthogonal if $\int \psi_n^* \psi_{n'} d\tau = 0$; all wavefunctions corresponding to different energies of a system are orthogonal. Orthonormal functions are sets of functions that are normalized and mutually orthogonal. ☐ 5. The wavefunctions and energies of a particle in a two-dimensional box are given by eqn 9.12a.	☐ 6. Degenerate wavefunctions are different wavefunctions corresponding to the same energy. ☐ 7. Tunnelling is the penetration into or through classically forbidden regions. The transmission probability is given by eqn 9.20a. ☐ 8. Harmonic motion is the motion in the presence of a restoring force proportional to the displacement, $F = -kx$, where k is the force constant. As a consequence, $V = \frac{1}{2} kx^2$. ☐ 9. The wavefunctions and energy levels of a quantum mechanical harmonic oscillator are given by eqns 9.28 and 9.25, respectively. ☐ 10. The virial theorem states that, if the potential energy of a particle has the form $V = ax^b$, then its mean potential and kinetic energies are related by $2\langle E_K \rangle = b\langle V \rangle$. ☐ 11. Angular momentum is the moment of linear momentum around a point.

- 12. The wavefunctions and energies of a particle on a ring are, respectively, $\psi_{m_l}(\phi) = (1/2\pi)^{1/2} e^{im_l\phi}$ and $E = m_l^2 \hbar^2 / 2I$, with $I = mr^2$ and $m_l = 0, \pm 1, \pm 2, \dots$
- 13. The wavefunctions of a particle on a sphere are the spherical harmonics, the functions $Y_{l,m_l}(\theta, \phi)$ (Table 9.3). The energies are $E = l(l+1)\hbar^2/2I$, $l = 0, 1, 2, \dots$
- 14. For a particle on a sphere, the magnitude of the angular momentum is $\{l(l+1)\}^{1/2}\hbar$ and the z-component of the angular momentum is $m_l\hbar$, $m_l = l, l-1, \dots, -l$.
- 15. Space quantization is the restriction of the component of angular momentum around an axis to discrete values.
- 16. Spin is an intrinsic angular momentum of a fundamental particle. A fermion is a particle with a half-integral spin quantum number; a boson is a particle with an integral spin quantum number.
- 17. For an electron, the spin quantum number is $s = \frac{1}{2}$.
- 18. The spin magnetic quantum number is $m_s = s, s-1, \dots, -s$; for an electron, $m_s = +\frac{1}{2}, -\frac{1}{2}$.
- 19. Perturbation theory is a technique that supplies approximate solutions to the Schrödinger equation and in which the hamiltonian for the problem is expressed as a sum of simpler hamiltonians.
- 20. In time-independent perturbation theory, the perturbation is always present and unvarying. The first- and second-order corrections to the energy are given by eqns 9.65a and 9.65b, respectively. In time-dependent perturbation theory, the perturbation is either switched on and allowed to rise to its final value or is varying in time.
- 21. The rate of change of population of the state ψ_f due to transitions from state ψ_i is $w_{f \leftarrow i} \propto |\mu_{z,fi}|^2 \mathcal{E}^2$, where $\mu_{z,fi} = \int \psi_f^* \mu_z \psi_i d\tau$ is the transition dipole moment.

Further information

Further information 9.1 Dirac notation

The integral in eqn 9.9 is often written

$$\langle n | n' \rangle = 0 \quad (n' \neq n)$$

This **Dirac bracket notation** is much more succinct than writing out the integral in full. It also introduces the words ‘bra’ and ‘ket’ into the language of quantum mechanics. Thus, the **bra** $\langle n |$ corresponds to ψ_n^* and the **ket** $| n' \rangle$ corresponds to the wavefunction $\psi_{n'}$. When the bra and ket are put together as in this expression, the integration over all space is understood. Similarly, the normalization condition in eqn 8.17c becomes simply

$$\langle n | n \rangle = 1$$

in bracket notation. These two expressions can be combined into one:

$$\langle n | n' \rangle = \delta_{nn'} \quad (9.71)$$

Here $\delta_{nn'}$, which is called the **Kronecker delta**, is 1 when $n' = n$ and 0 when $n' \neq n$.

Integrals of the form $\int \psi_n^* \hat{Q} \psi_m d\tau$, which we first encounter in connection with perturbation theory (Section 9.9) and which are

commonly called ‘matrix elements’, are incorporated into the bracket notation by writing

$$\langle n | \hat{Q} | m \rangle = \int \psi_n^* \hat{Q} \psi_m d\tau \quad (9.72)$$

Note how the operator stands between the bra and the ket (which may denote different states), in the place of the c in $\langle \text{bra} | c | \text{ket} \rangle$. An integration is implied whenever a complete bracket is written. In this notation, an expectation value is

$$\langle \hat{Q} \rangle = \langle n | \hat{Q} | n \rangle \quad (9.73)$$

with the bra and the ket corresponding to the same state (with quantum number n and wavefunction ψ_n). In this notation, an operator is hermitian (eqn 8.30) if

$$\langle n | \hat{Q} | m \rangle = \langle m | \hat{Q} | n \rangle^* \quad (9.74)$$

Further information 9.2 Perturbation theory

Here we treat perturbation theory in detail. Our first task is to develop the results of time-independent perturbation theory, in which a system is subjected to a perturbation that does not vary with

time. Then, we go on to discuss time-dependent perturbation theory, in which a perturbation is turned on at a specific time and the system is allowed to evolve.

1 Time-independent perturbation theory

To develop expressions for the corrections to the wavefunction and energy of a system subjected to a time-independent perturbation, we write

$$\psi = \psi^{(0)} + \lambda \psi^{(1)} + \lambda^2 \psi^{(2)} + \dots$$

where the power of λ indicates the order of the correction. Likewise, we write

$$\hat{H} = \hat{H}^{(0)} + \lambda \hat{H}^{(1)}$$

and

$$E = E^{(0)} + \lambda E^{(1)} + \lambda^2 E^{(2)} + \dots$$

When these expressions are inserted into the Schrödinger equation, $\hat{H}\psi = E\psi$, we obtain

$$\begin{aligned} & (\hat{H}^{(0)} + \lambda \hat{H}^{(1)})(\psi^{(0)} + \lambda \psi^{(1)} + \lambda^2 \psi^{(2)} + \dots) \\ &= (E^{(0)} + \lambda E^{(1)} + \lambda^2 E^{(2)} + \dots)(\psi^{(0)} + \lambda \psi^{(1)} + \lambda^2 \psi^{(2)} + \dots) \end{aligned}$$

which we can rewrite as

$$\begin{aligned} & \hat{H}^{(0)}\psi^{(0)} + \lambda(\hat{H}^{(1)}\psi^{(0)} + \hat{H}^{(0)}\psi^{(1)}) + \lambda^2(\hat{H}^{(0)}\psi^{(2)} + \hat{H}^{(1)}\psi^{(1)}) + \dots \\ &= E^{(0)}\psi^{(0)} + \lambda(E^{(0)}\psi^{(1)} + E^{(1)}\psi^{(0)}) + \lambda^2(E^{(0)}\psi^{(2)} + E^{(1)}\psi^{(1)} \\ & \quad + E^{(2)}\psi^{(0)}) + \dots \end{aligned}$$

By comparing powers of λ , we find

$$\text{Terms in } \lambda^0: \quad \hat{H}^{(0)}\psi^{(0)} = E^{(0)}\psi^{(0)}$$

$$\text{Terms in } \lambda: \quad \hat{H}^{(1)}\psi^{(0)} + \hat{H}^{(0)}\psi^{(1)} = E^{(0)}\psi^{(1)} + E^{(1)}\psi^{(0)}$$

$$\text{Terms in } \lambda^2: \quad \hat{H}^{(0)}\psi^{(2)} + \hat{H}^{(1)}\psi^{(1)} = E^{(2)}\psi^{(0)} + E^{(1)}\psi^{(1)} + E^{(0)}\psi^{(2)}$$

and so on.

The equations we have derived are applicable to any state of the system. From now on we shall consider only the ground state ψ_0 with energy E_0 . The first equation, which we now write

$$\hat{H}^{(0)}\psi_0^{(0)} = E_0^{(0)}\psi_0^{(0)}$$

is the Schrödinger equation for the ground state of the unperturbed system, which we assume we can solve (for instance, it might be the equation for the ground state of the particle in a box, with the solutions given in eqn 9.7). To solve the next equation, which is now written

$$\hat{H}^{(1)}\psi_0^{(0)} + \hat{H}^{(0)}\psi_0^{(1)} = E_0^{(0)}\psi_0^{(1)} + E_0^{(1)}\psi_0^{(0)}$$

we suppose that the first-order correction to the wavefunction can be expressed as a linear combination of the wavefunctions of the unperturbed system, and write

$$\psi_0^{(1)} = \sum_n c_n \psi_n^{(0)} \quad (9.75)$$

Substitution of this expression gives

$$\hat{H}^{(1)}\psi_0^{(0)} + \sum_n c_n \hat{H}^{(0)}\psi_n^{(0)} = \sum_n c_n E_0^{(0)}\psi_n^{(0)} + E_0^{(1)}\psi_0^{(0)}$$

We can isolate the term in $E_0^{(1)}$ by making use of the fact that the $\psi_n^{(0)}$ form a complete orthogonal and normalized set in the sense that

$$\int \psi_0^{(0)*} \psi_n^{(0)} d\tau = 0 \quad \text{if } n \neq 0, \quad \text{but } 1 \text{ if } n = 0$$

Therefore, when we multiply through by $\psi_0^{(0)*}$ and integrate over all space, we get

$$\begin{aligned} & \int \psi_0^{(0)*} \hat{H}^{(1)} \psi_0^{(0)} d\tau + \sum_n c_n \int \psi_0^{(0)*} \hat{H}^{(0)} \psi_n^{(0)} d\tau \\ &= \sum_n c_n E_0^{(0)} \int \psi_0^{(0)*} \psi_n^{(0)} d\tau + E_0^{(1)} \int \psi_0^{(0)*} \psi_0^{(0)} d\tau \end{aligned}$$

That is,

$$\int \psi_0^{(0)*} \hat{H}^{(1)} \psi_0^{(0)} d\tau = E_0^{(1)}$$

which is eqn 9.65a.

To find the coefficients c_n , we multiply the same expression through by $\psi_k^{(0)*}$, where now $k \neq 0$, which gives

$$\begin{aligned} & \int \psi_k^{(0)*} \hat{H}^{(1)} \psi_0^{(0)} d\tau + \sum_n c_n \int \psi_k^{(0)*} \hat{H}^{(0)} \psi_n^{(0)} d\tau \\ &= \sum_n c_n E_0^{(0)} \int \psi_k^{(0)*} \psi_n^{(0)} d\tau + E_0^{(1)} \int \psi_k^{(0)*} \psi_0^{(0)} d\tau \end{aligned}$$

That is,

$$\int \psi_k^{(0)*} \hat{H}^{(1)} \psi_0^{(0)} d\tau + c_k E_0^{(0)} = c_k E_0^{(0)}$$

which we can rearrange into

$$c_k = - \frac{\int \psi_k^{(0)*} \hat{H}^{(1)} \psi_0^{(0)} d\tau}{E_k^{(0)} - E_0^{(0)}} \quad (9.76)$$

The second-order energy is obtained starting from the second-order expression, which for the ground state is

$$\hat{H}^{(0)}\psi_0^{(2)} + \hat{H}^{(1)}\psi_0^{(1)} = E_0^{(2)}\psi_0^{(0)} + E_0^{(1)}\psi_0^{(1)} + E_0^{(0)}\psi_0^{(2)}$$

To isolate the term $E_0^{(2)}$ we multiply both sides by $\psi_0^{(0)*}$, integrate over all space, and obtain

$$\begin{aligned} & \int \psi_0^{(0)*} \hat{H}^{(0)} \psi_0^{(2)} d\tau + \int \psi_0^{(0)*} \hat{H}^{(1)} \psi_0^{(1)} d\tau \\ &= E_0^{(2)} \int \psi_0^{(0)*} \psi_0^{(0)} d\tau + E_0^{(1)} \int \psi_0^{(0)*} \psi_0^{(1)} d\tau + E_0^{(0)} \int \psi_0^{(0)*} \psi_0^{(2)} d\tau \end{aligned}$$

The first and last terms cancel, and we are left with

$$E_0^{(2)} = \int \psi_0^{(0)*} \hat{H}^{(1)} \psi_0^{(1)} d\tau - E_0^{(1)} \int \psi_0^{(0)*} \psi_0^{(1)} d\tau$$

We have already found the first-order corrections to the energy and the wavefunction, so this expression could be regarded as an explicit expression for the second-order energy. However, we can go one step further by substituting eqn 9.75:

$$\begin{aligned} E_0^{(2)} &= \sum_n c_n \int \overbrace{\psi_0^{(0)*} \hat{H}^{(1)} \psi_n^{(0)} d\tau}^{H_{0n}^{(1)}} - \sum_n c_n E_0^{(1)} \int \overbrace{\psi_0^{(0)*} \psi_n^{(0)} d\tau}^{\delta_{0n}} \\ &= \sum_n c_n H_{0n}^{(1)} - c_0 E_0^{(1)} \end{aligned}$$

The final term cancels the term $c_0 H_{00}^{(1)}$ in the sum, and we are left with

$$E_0^{(2)} = \sum_{n \neq 0} c_n H_{0n}^{(1)}$$

Substitution of the expression for c_n in eqn 9.76 now produces the final result, eqn 9.65b.

2 Time-dependent perturbation theory

To cope with a perturbed wavefunction that evolves with time, we need to solve the time-dependent Schrödinger equation,

$$\hat{H}\Psi = i\hbar \frac{\partial \Psi}{\partial t} \quad (9.77)$$

We confirm below, that if we write the first-order correction to the wavefunction as

$$\Psi_0^{(1)}(t) = \sum_n c_n(t) \Psi_n^{(0)} = \sum_n c_n(t) \psi_n^{(0)} e^{-iE_n^{(0)}t/\hbar} \quad (9.78a)$$

then the coefficients in this expansion are given by

$$c_n(t) = \frac{1}{i\hbar} \int_0^t H_{n0}^{(1)}(t) e^{i\omega_{n0}t} dt \quad (9.78b)$$

The formal demonstration of eqn 9.78 is quite lengthy (see *Further reading*). Here we shall show that, given eqn 9.78b, a perturbation that is switched on very slowly to a constant value gives the same expression for the coefficients as we obtained for time-independent perturbation theory. For such a perturbation, we write

$$\hat{H}^{(1)}(t) = \hat{H}^{(1)}(1 - e^{-t/\tau})$$

and take the time constant τ to be very long (Fig. 9.44). Substitution of this expression into eqn 9.78b gives

$$\begin{aligned} c_n(t) &= \frac{1}{i\hbar} H_{n0}^{(1)} \int_0^t (1 - e^{-t'/\tau}) e^{i\omega_{n0}t'} dt' \\ &= \frac{1}{i\hbar} H_{n0}^{(1)} \left\{ \frac{e^{i\omega_{n0}t} - 1}{i\omega_{n0}} - \frac{e^{(i\omega_{n0} - 1/\tau)t} - 1}{i\omega_{n0} - 1/\tau} \right\} \end{aligned}$$

Fig. 9.44 The time-dependence of a slowly switched perturbation. A large value of τ corresponds to very slow switching.

At this point we suppose that the perturbation is switched slowly, in the sense that $\tau \gg 1/\omega_{n0}$ (so that the $1/\tau$ in the second denominator can be ignored). We also suppose that we are interested in the coefficients long after the perturbation has settled down into its final value, when $t \gg \tau$ (so that the exponential in the second numerator is close to zero and can be ignored). Under these conditions,

$$c_n(t) = -\frac{H_{n0}^{(0)}}{\hbar\omega_{n0}} e^{i\omega_{n0}t}$$

Now we recognize that $\hbar\omega_{n0} = E_n^{(0)} - E_0^{(0)}$, which gives

$$c_n(t) = -\frac{H_{n0}^{(0)}}{E_n^{(0)} - E_0^{(0)}} e^{iE_n^{(0)}t} e^{-iE_0^{(0)}t}$$

When this expression is substituted into eqn 9.78a, we obtain the time-independent expression, eqn 9.76 (apart from an irrelevant overall phase factor).

In accord with the general rules for the interpretation of wavefunctions, the probability that the system will be found in the state n is proportional to the square modulus of the coefficient of the state, $|c_n(t)|^2$. Therefore, the rate of change of population of a final state ψ_f due to transitions from an initial state ψ_i is

$$w_{f \leftarrow i} = \frac{d|c_f|^2}{dt} = \frac{dc_f^* c_f}{dt} = c_f \frac{dc_f^*}{dt} + c_f^* \frac{dc_f}{dt}$$

Because the coefficients are proportional to the matrix elements of the perturbation, $w_{f \leftarrow i}$ is proportional to the square modulus of the matrix element of the perturbation between the two states:

$$w_{f \leftarrow i} \propto |H_{fi}^{(1)}|^2$$

which is eqn 9.68.

Discussion questions

- 9.1** Discuss the physical origin of quantization energy for a particle confined to moving inside a one-dimensional box or on a ring.
- 9.2** Discuss the correspondence principle and provide two examples.
- 9.3** Define, justify, and provide examples of zero-point energy.
- 9.4** Discuss the physical origins of quantum mechanical tunnelling. Why is tunnelling more likely to contribute to the mechanisms of electron transfer

and proton transfer processes than to mechanisms of group transfer reactions, such as $AB + C \rightarrow A + BC$ (where A, B, and C are large molecular groups)?

- 9.5** Distinguish between a fermion and a boson. Provide examples of each type of particle.
- 9.6** Describe the features that stem from nanometre-scale dimensions that are not found in macroscopic objects.

Exercises

9.1a Calculate the energy separations in joules, kilojoules per mole, electronvolts, and reciprocal centimetres between the levels (a) $n = 2$ and $n = 1$, (b) $n = 6$ and $n = 5$ of an electron in a box of length 1.0 nm.

9.1b Calculate the energy separations in joules, kilojoules per mole, electronvolts, and reciprocal centimetres between the levels (a) $n = 3$ and $n = 1$, (b) $n = 7$ and $n = 6$ of an electron in a box of length 1.50 nm.

9.2a Calculate the probability that a particle will be found between $0.49L$ and $0.51L$ in a box of length L when it has (a) $n = 1$, (b) $n = 2$. Take the wavefunction to be a constant in this range.

9.2b Calculate the probability that a particle will be found between $0.65L$ and $0.67L$ in a box of length L when it has (a) $n = 1$, (b) $n = 2$. Take the wavefunction to be a constant in this range.

9.3a Calculate the expectation values of p and p^2 for a particle in the state $n = 1$ in a square-well potential.

9.3b Calculate the expectation values of p and p^2 for a particle in the state $n = 2$ in a square-well potential.

9.4a An electron is confined to a square well of length L . What would be the length of the box such that the zero-point energy of the electron is equal to its rest mass energy, $m_e c^2$? Express your answer in terms of the parameter $\lambda_C = h/m_e c$, the ‘Compton wavelength’ of the electron.

9.4b Repeat Exercise 9.4a for a general particle of mass m in a cubic box.

9.5a What are the most likely locations of a particle in a box of length L in the state $n = 3$?

9.5b What are the most likely locations of a particle in a box of length L in the state $n = 5$?

9.6a Consider a particle in a cubic box. What is the degeneracy of the level that has an energy three times that of the lowest level?

9.6b Consider a particle in a cubic box. What is the degeneracy of the level that has an energy $\frac{14}{3}$ times that of the lowest level?

9.7a Calculate the percentage change in a given energy level of a particle in a cubic box when the length of the edge of the cube is decreased by 10 per cent in each direction.

9.7b A nitrogen molecule is confined in a cubic box of volume 1.00 m^3 . Assuming that the molecule has an energy equal to $\frac{3}{2}kT$ at $T = 300 \text{ K}$, what is the value of $n = (n_x^2 + n_y^2 + n_z^2)^{1/2}$ for this molecule? What is the energy separation between the levels n and $n + 1$? What is its de Broglie wavelength? Would it be appropriate to describe this particle as behaving classically?

9.8a Calculate the zero-point energy of a harmonic oscillator consisting of a particle of mass $2.33 \times 10^{-26} \text{ kg}$ and force constant 155 N m^{-1} .

9.8b Calculate the zero-point energy of a harmonic oscillator consisting of a particle of mass $5.16 \times 10^{-26} \text{ kg}$ and force constant 285 N m^{-1} .

9.9a For a harmonic oscillator of effective mass $1.33 \times 10^{-25} \text{ kg}$, the difference in adjacent energy levels is 4.82 zJ . Calculate the force constant of the oscillator.

9.9b For a harmonic oscillator of effective mass $2.88 \times 10^{-25} \text{ kg}$, the difference in adjacent energy levels is 3.17 zJ . Calculate the force constant of the oscillator.

9.10a Calculate the wavelength of a photon needed to excite a transition between neighbouring energy levels of a harmonic oscillator of effective mass equal to that of a proton (1.0078 u) and force constant 855 N m^{-1} .

9.10b Calculate the wavelength of a photon needed to excite a transition between neighbouring energy levels of a harmonic oscillator of effective mass equal to that of an oxygen atom (15.9949 u) and force constant 544 N m^{-1} .

9.11a Refer to Exercise 9.10a and calculate the wavelength that would result from doubling the effective mass of the oscillator.

9.11b Refer to Exercise 9.10b and calculate the wavelength that would result from doubling the effective mass of the oscillator.

9.12a Calculate the minimum excitation energies of (a) a pendulum of length 1.0 m on the surface of the Earth, (b) the balance-wheel of a clockwork watch ($\nu = 5 \text{ Hz}$).

9.12b Calculate the minimum excitation energies of (a) the 33 kHz quartz crystal of a watch, (b) the bond between two O atoms in O_2 , for which $k = 1177 \text{ N m}^{-1}$.

9.13a Confirm that the wavefunction for the ground state of a one-dimensional linear harmonic oscillator given in Table 9.1 is a solution of the Schrödinger equation for the oscillator and that its energy is $\frac{1}{2}\hbar\omega$.

9.13b Confirm that the wavefunction for the first excited state of a one-dimensional linear harmonic oscillator given in Table 9.1 is a solution of the Schrödinger equation for the oscillator and that its energy is $\frac{3}{2}\hbar\omega$.

9.14a Locate the nodes of the harmonic oscillator wavefunction with $\nu = 4$.

9.14b Locate the nodes of the harmonic oscillator wavefunction with $\nu = 5$.

9.15a Assuming that the vibrations of a $^{35}\text{Cl}_2$ molecule are equivalent to those of a harmonic oscillator with a force constant $k = 329 \text{ N m}^{-1}$, what is the zero-point energy of vibration of this molecule? The mass of a ^{35}Cl atom is 34.9688 u .

9.15b Assuming that the vibrations of a $^{14}\text{N}_2$ molecule are equivalent to those of a harmonic oscillator with a force constant $k = 2293.8 \text{ N m}^{-1}$, what is the zero-point energy of vibration of this molecule? The mass of a ^{14}N atom is 14.0031 u .

9.16a The wavefunction, $\psi(\phi)$, for the motion of a particle in a ring is of the form $\psi = Ne^{im_l\phi}$. Determine the normalization constant, N .

9.16b Confirm that wavefunctions for a particle in a ring with different values of the quantum number m_l are mutually orthogonal.

9.17a A point mass rotates in a circle with $l = 1$. Calculate the magnitude of its angular momentum and the possible projections of the angular momentum on an arbitrary axis.

9.17b A point mass rotates in a circle with $l = 2$. Calculate the magnitude of its angular momentum and the possible projections of the angular momentum on an arbitrary axis.

9.18a Draw scale vector diagrams to represent the states (a) $s = \frac{1}{2}$, $m_s = +\frac{1}{2}$, (b) $l = 1$, $m_l = +1$, (c) $l = 2$, $m_l = 0$.

9.18b Draw the vector diagram for all the permitted states of a particle with $l = 6$.

Problems*

Numerical problems

9.1 Calculate the separation between the two lowest levels for an O_2 molecule in a one-dimensional container of length 5.0 cm. At what value of n does the energy of the molecule reach $\frac{1}{2}kT$ at 300 K, and what is the separation of this level from the one immediately below?

9.2 The mass to use in the expression for the vibrational frequency of a diatomic molecule is the effective mass $\mu = m_A m_B / (m_A + m_B)$, where m_A and m_B are the masses of the individual atoms. The following data on the infrared absorption wavenumbers (in cm^{-1}) of molecules are taken from *Spectra of diatomic molecules*, G. Herzberg, van Nostrand (1950):

H^{35}Cl	H^{81}Br	HI	CO	NO
2990	2650	2310	2170	1904

Calculate the force constants of the bonds and arrange them in order of increasing stiffness.

9.3 The rotation of an $^1\text{H}^{127}\text{I}$ molecule can be pictured as the orbital motion of an H atom at a distance 160 pm from a stationary I atom. (This picture is quite good; to be precise, both atoms rotate around their common centre of mass, which is very close to the I nucleus.) Suppose that the molecule rotates only in a plane. Calculate the energy needed to excite the molecule into rotation. What, apart from 0, is the minimum angular momentum of the molecule?

9.4 Calculate the energies of the first four rotational levels of $^1\text{H}^{127}\text{I}$ free to rotate in three dimensions, using for its moment of inertia $I = \mu R^2$, with $\mu = m_{\text{H}} m_{\text{I}} / (m_{\text{H}} + m_{\text{I}})$ and $R = 160$ pm.

9.5 A small step in the potential energy is introduced into the one-dimensional square-well problem as in Fig. 9.45. (a) Write a general

Fig. 9.45

expression for the first-order correction to the ground-state energy, $E_0^{(1)}$. (b) Evaluate the energy correction for $a = L/10$ (so the blip in the potential occupies the central 10 per cent of the well), with $n = 1$.

9.6 We normally think of the one-dimensional well as being horizontal. Suppose it is vertical; then the potential energy of the particle depends on x because of the presence of the gravitational field. Calculate the first-order correction to the zero-point energy, and evaluate it for an electron in a box on the surface of the Earth. Account for the result. *Hint.* The energy of the particle depends on its height as mgh , where $g = 9.81 \text{ m s}^{-2}$. Because g is so small, the energy correction is small; but it would be significant if the box were near a very massive star.

9.7 Calculate the second-order correction to the energy for the system described in Problem 9.6 and calculate the ground-state wavefunction. Account for the shape of the distortion caused by the perturbation. *Hint.* The following integrals are useful

$$\int x \sin ax \sin bx \, dx = -\frac{d}{da} \int \cos ax \sin bx \, dx$$

$$\int \cos ax \sin bx \, dx = \frac{\cos(a-b)x}{2(a-b)} - \frac{\cos(a+b)x}{2(a+b)} + \text{constant}$$

Theoretical problems

9.8 Suppose that 1.0 mol perfect gas molecules all occupy the lowest energy level of a cubic box. How much work must be done to change the volume of the box by ΔV ? Would the work be different if the molecules all occupied a state $n \neq 1$? What is the relevance of this discussion to the expression for the expansion work discussed in Chapter 2? Can you identify a distinction between adiabatic and isothermal expansion?

9.9 Derive eqn 9.20a, the expression for the transmission probability.

9.10† Consider the one-dimensional space in which a particle can experience one of three potentials depending upon its position. They are: $V = 0$ for $-\infty < x \leq 0$, $0, V = V_2$ for $0 \leq x \leq L$, and $V = V_3$ for $L \leq x < \infty$. The particle wavefunction is to have both a component e^{ik_1x} that is incident upon the barrier V_2 and a reflected component e^{-ik_1x} in region 1 ($-\infty < x \leq 0$). In region 3 the wavefunction has only a forward component, e^{ik_3x} , which represents a particle that has traversed the barrier. The energy of the particle, E , is somewhere in the range of the $V_2 > E > V_3$. The transmission probability, T , is the ratio of the square modulus of the region 3 amplitude to the square modulus of the incident amplitude. (a) Base your calculation on the continuity of the amplitudes and the slope of the wavefunction at the locations of the zone boundaries and derive a general equation for T . (b) Show that the general equation for T reduces to eqn 9.20b in the high, wide barrier limit when

* Problems denoted with the symbol † were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

$V_1 = V_3 = 0$. (c) Draw a graph of the probability of proton tunnelling when $V_3 = 0$, $L = 50$ pm, and $E = 10$ kJ mol⁻¹ in the barrier range $E < V_2 < 2E$.

9.11 The wavefunction inside a long barrier of height V is $\psi = Ne^{-\kappa x}$. Calculate (a) the probability that the particle is inside the barrier and (b) the average penetration depth of the particle into the barrier.

9.12 Confirm that a function of the form e^{-gx^2} is a solution of the Schrödinger equation for the ground state of a harmonic oscillator and find an expression for g in terms of the mass and force constant of the oscillator.

9.13 Calculate the mean kinetic energy of a harmonic oscillator by using the relations in Table 9.1.

9.14 Calculate the values of $\langle x^3 \rangle$ and $\langle x^4 \rangle$ for a harmonic oscillator by using the relations in Table 9.1.

9.15 Determine the values of $\delta x = (\langle x^2 \rangle - \langle x \rangle^2)^{1/2}$ and $\delta p = (\langle p^2 \rangle - \langle p \rangle^2)^{1/2}$ for (a) a particle in a box of length L and (b) a harmonic oscillator. Discuss these quantities with reference to the uncertainty principle.

9.16 We shall see in Chapter 13 that the intensities of spectroscopic transitions between the vibrational states of a molecule are proportional to the square of the integral $\int \psi_f^* x \psi_i dx$ over all space. Use the relations between Hermite polynomials given in Table 9.1 to show that the only permitted transitions are those for which $v' = v \pm 1$ and evaluate the integral in these cases.

9.17 The potential energy of the rotation of one CH₃ group relative to its neighbour in ethane can be expressed as $V(\phi) = V_0 \cos 3\phi$. Show that for small displacements the motion of the group is harmonic and calculate the energy of excitation from $v = 0$ to $v = 1$. What do you expect to happen to the energy levels and wavefunctions as the excitation increases?

9.18 Show that, whatever superposition of harmonic oscillator states is used to construct a wavepacket, it is localized at the same place at the times $0, T, 2T, \dots$, where T is the classical period of the oscillator.

9.19 Use the virial theorem to obtain an expression for the relation between the mean kinetic and potential energies of an electron in a hydrogen atom.

9.20 Evaluate the z -component of the angular momentum and the kinetic energy of a particle on a ring that is described by the (unnormalized) wavefunctions (a) $e^{i\phi}$, (b) $e^{-2i\phi}$, (c) $\cos \phi$, and (d) $(\cos \chi)e^{i\phi} + (\sin \chi)e^{-i\phi}$.

9.21 Is the Schrödinger equation for a particle on an elliptical ring of semimajor axes a and b separable? *Hint.* Although r varies with angle ϕ , the two are related by $r^2 = a^2 \sin^2 \phi + b^2 \cos^2 \phi$.

9.22 Use mathematical software to construct a wavepacket of the form

$$\Psi(\phi, t) = \sum_{m_l=0}^{m_{\text{max}}} c_{m_l} e^{i(m_l \phi - E_{m_l} t/\hbar)} \quad E_{m_l} = m_l^2 \hbar^2 / 2I$$

with coefficients c of your choice (for example, all equal). Explore how the wavepacket migrates on the ring but spreads with time.

9.23 Confirm that the spherical harmonics (a) $Y_{0,0}$, (b) $Y_{2,-1}$, and (c) $Y_{3,+3}$ satisfy the Schrödinger equation for a particle free to rotate in three dimensions, and find its energy and angular momentum in each case.

9.24 Confirm that $Y_{3,+3}$ is normalized to 1. (The integration required is over the surface of a sphere.)

9.25 Derive an expression in terms of l and m_l for the half-angle of the apex of the cone used to represent an angular momentum according to the vector model. Evaluate the expression for an α spin. Show that the minimum possible angle approaches 0 as $l \rightarrow \infty$.

9.26 Show that the function $f = \cos ax \cos cy \cos cz$ is an eigenfunction of ∇^2 , and determine its eigenvalue.

9.27 Derive (in Cartesian coordinates) the quantum mechanical operators for the three components of angular momentum starting from the classical definition of angular momentum, $\mathbf{l} = \mathbf{r} \times \mathbf{p}$. Show that any two of the components do not mutually commute, and find their commutator.

9.28 Starting from the operator $l_z = xp_y - yp_x$, prove that in spherical polar coordinates $l_z = -i\hbar \partial/\partial \phi$.

9.29 Show that the commutator $[l^2, l_z] = 0$, and then, without further calculation, justify the remark that $[l^2, l_q] = 0$ for all $q = x, y$, and z .

9.30† A particle is confined to move in a one-dimensional box of length L . (a) If the particle is classical, show that the average value of x is $\frac{1}{2}L$ and that the root-mean square value is $L/3^{1/2}$. (b) Show that for large values of n , a quantum particle approaches the classical values. This result is an example of the correspondence principle, which states that, for very large values of the quantum numbers, the predictions of quantum mechanics approach those of classical mechanics.

Applications: to biology and nanotechnology

9.31 When β -carotene is oxidized *in vivo*, it breaks in half and forms two molecules of retinal (vitamin A), which is a precursor to the pigment in the retina responsible for vision (*Impact 114.1*). The conjugated system of retinal consists of 11 C atoms and one O atom. In the ground state of retinal, each level up to $n = 6$ is occupied by two electrons. Assuming an average internuclear distance of 140 pm, calculate (a) the separation in energy between the ground state and the first excited state in which one electron occupies the state with $n = 7$, and (b) the frequency of the radiation required to produce a transition between these two states. (c) Using your results and *Illustration 9.1*, choose among the words in parentheses to generate a rule for the prediction of frequency shifts in the absorption spectra of linear polyenes:

The absorption spectrum of a linear polyene shifts to (higher/lower) frequency as the number of conjugated atoms (increases/decreases).

9.32 Many biological electron transfer reactions, such as those associated with biological energy conversion, may be visualized as arising from electron tunnelling between protein-bound co-factors, such as cytochromes, quinones, flavins, and chlorophylls. This tunnelling occurs over distances that are often greater than 1.0 nm, with sections of protein separating electron donor from acceptor. For a specific combination of donor and acceptor, the rate of electron tunnelling is proportional to the transmission probability, with $\kappa \approx 7$ nm⁻¹ (eqn 9.20). By what factor does the rate of electron tunnelling between two co-factors increase as the distance between them changes from 2.0 nm to 1.0 nm?

9.33 Carbon monoxide binds strongly to the Fe²⁺ ion of the haem group of the protein myoglobin. Estimate the vibrational frequency of CO bound to myoglobin by using the data in Problem 9.2 and by making the following assumptions: the atom that binds to the haem group is immobilized, the protein is infinitely more massive than either the C or O atom, the C atom binds to the Fe²⁺ ion, and binding of CO to the protein does not alter the force constant of the C≡O bond.

9.34 Of the four assumptions made in Problem 9.33, the last two are questionable. Suppose that the first two assumptions are still reasonable and that you have at your disposal a supply of myoglobin, a suitable buffer in which to suspend the protein, ¹²C¹⁶O, ¹³C¹⁶O, ¹²C¹⁸O, ¹³C¹⁸O, and an infrared spectrometer. Assuming that isotopic substitution does not affect the force constant of the C≡O bond, describe a set of experiments that: (a) proves which atom, C or O, binds to the haem group of myoglobin, and (b) allows for the determination of the force constant of the C≡O bond for myoglobin-bound carbon monoxide.

9.35 The particle on a ring is a useful model for the motion of electrons around the porphine ring (2), the conjugated macrocycle that forms the

2 Porphine (free base form)

structural basis of the haem group and the chlorophylls. We may treat the group as a circular ring of radius 440 pm, with 22 electrons in the conjugated system moving along the perimeter of the ring. As in *Illustration 9.1*, we assume that in the ground state of the molecule quantized each state is occupied by two electrons. (a) Calculate the energy and angular momentum of an electron in the highest occupied level. (b) Calculate the frequency of radiation that can induce a transition between the highest occupied and lowest unoccupied levels.

9.36 When in Chapter 19 we come to study macromolecules, such as synthetic polymers, proteins, and nucleic acids, we shall see that one conformation is that of a random coil. For a one-dimensional random coil of N units, the restoring force at small displacements and at a temperature T is

$$F = -\frac{kT}{2l} \ln \left(\frac{N+n}{N-n} \right)$$

where l is the length of each monomer unit and nl is the distance between the ends of the chain (see Section 19.8). Show that for small extensions ($n \ll N$) the restoring force is proportional to n and therefore the coil undergoes harmonic oscillation with force constant kT/Nl^2 . Suppose that the mass to use for the vibrating chain is its total mass Nm , where m is the mass of one monomer unit, and deduce the root mean square separation of the ends of the chain due to quantum fluctuations in its vibrational ground state.

9.37 The forces measured by AFM arise primarily from interactions between electrons of the stylus and on the surface. To get an idea of the magnitudes of these forces, calculate the force acting between two electrons separated by 2.0 nm. *Hints.* The Coulombic potential energy of a charge q_1 at a distance r from another charge q_2 is

$$V = \frac{q_1 q_2}{4\pi\epsilon_0 r}$$

where $\epsilon_0 = 8.854 \times 10^{-12} \text{ C}^2 \text{ J}^{-1} \text{ m}^{-1}$ is the vacuum permittivity. To calculate the force between the electrons, note that $F = -dV/dr$.

9.38 Here we explore further the idea introduced in *Impact 19.2* that quantum mechanical effects need to be invoked in the description of the electronic properties of metallic nanocrystals, here modelled as three-dimensional boxes. (a) Set up the Schrödinger equation for a particle of mass m in a three-dimensional rectangular box with sides L_1 , L_2 , and L_3 . Show that the Schrödinger equation is separable. (b) Show that the wavefunction and the energy are defined by three quantum numbers. (c) Specialize the result from part (b) to an electron moving in a cubic box of side $L = 5 \text{ nm}$ and draw an energy diagram resembling Fig. 9.2 and showing the first 15 energy levels. Note that each energy level may consist of degenerate energy states. (d) Compare the energy level diagram from part (c) with the energy level diagram for an electron in a one-dimensional box of length $L = 5 \text{ nm}$. Are the energy levels become more or less sparsely distributed in the cubic box than in the one-dimensional box?

9.39 We remarked in *Impact 19.2* that the particle in a sphere is a reasonable starting point for the discussion of the electronic properties of spherical metal nanoparticles. Here, we justify eqn 9.54, which shows that the energy of an electron in a sphere is quantized. (a) The Hamiltonian for a particle free to move inside a sphere of radius R is

$$\hat{H} = -\frac{\hbar^2}{2m} \nabla^2$$

Show that the Schrödinger equation is separable into radial and angular components. That is, begin by writing $\psi(r, \theta, \phi) = X(r)Y(\theta, \phi)$, where $X(r)$ depends only on the distance of the particle away from the centre of the sphere, and $Y(\theta, \phi)$ is a spherical harmonic. Then show that the Schrödinger equation can be separated into two equations, one for X , the radial equation, and the other for Y , the angular equation:

$$-\frac{\hbar^2}{2m} \left(\frac{d^2 X(r)}{dr^2} + \frac{2}{r} \frac{dX(r)}{dr} \right) + \frac{l(l+1)\hbar^2}{2mr^2} X(r) = EX(r)$$

$$\Lambda^2 Y = -l(l+1)Y$$

You may wish to consult *Further information 10.1* for additional help.

(c) Consider the case $l = 0$. Show by differentiation that the solution of the radial equation has the form

$$X(r) = (2\pi R)^{-1/2} \frac{\sin(n\pi r/R)}{r}$$

(e) Now go on to show that the allowed energies are given by:

$$E_n = \frac{n^2 \hbar^2}{8mR^2}$$

This result for the energy (which is eqn 9.54 after substituting m_e for m) also applies when $l \neq 0$.

Problems

We now use the principles of quantum mechanics introduced in the preceding two chapters to describe the internal structures of atoms. We see what experimental information is available from a study of the spectrum of atomic hydrogen. Then we set up the Schrödinger equation for an electron in an atom and separate it into angular and radial parts. The wavefunctions obtained are the ‘atomic orbitals’ of hydrogenic atoms. Next, we use these hydrogenic atomic orbitals to describe the structures of many-electron atoms. In conjunction with the Pauli exclusion principle, we account for the periodicity of atomic properties. The spectra of many-electron atoms are more complicated than those of hydrogen, but the same principles apply. We see in the closing sections of the chapter how such spectra are described by using term symbols, and the origin of the finer details of their appearance.

In this chapter we see how to use quantum mechanics to describe the **electronic structure** of an atom, the arrangement of electrons around a nucleus. The concepts we meet are of central importance for understanding the structures and reactions of atoms and molecules, and hence have extensive chemical applications. We need to distinguish between two types of atoms. A **hydrogenic atom** is a one-electron atom or ion of general atomic number Z ; examples of hydrogenic atoms are H , He^+ , Li^{2+} , O^{7+} , and even U^{91+} . A **many-electron atom** (or *polyelectronic atom*) is an atom or ion with more than one electron; examples include all neutral atoms other than H . So even He , with only two electrons, is a many-electron atom. Hydrogenic atoms are important because their Schrödinger equations can be solved exactly. They also provide a set of concepts that are used to describe the structures of many-electron atoms and, as we shall see in the next chapter, the structures of molecules too.

The structure and spectra of hydrogenic atoms

When an electric discharge is passed through gaseous hydrogen, the H_2 molecules are dissociated and the energetically excited H atoms that are produced emit light of discrete frequencies, producing a spectrum of a series of ‘lines’ (Fig. 10.1). The Swedish spectroscopist Johannes Rydberg noted (in 1890) that all of them are described by the expression

$$\tilde{\nu} = R_{\text{H}} \left(\frac{1}{n_1^2} - \frac{1}{n_2^2} \right) \quad R_{\text{H}} = 109\,677 \text{ cm}^{-1} \quad (10.1)$$

with $n_1 = 1$ (the *Lyman series*), 2 (the *Balmer series*), and 3 (the *Paschen series*), and that in each case $n_2 = n_1 + 1, n_1 + 2, \dots$. The constant R_{H} is now called the **Rydberg constant** for the hydrogen atom.

Fig. 10.1 The spectrum of atomic hydrogen. Both the observed spectrum and its resolution into overlapping series are shown. Note that the Balmer series lies in the visible region.

Self-test 10.1 Calculate the shortest wavelength line in the Paschen series.
[821 nm]

The form of eqn 10.1 strongly suggests that the wavenumber of each spectral line can be written as the difference of two **terms**, each of the form

$$T_n = \frac{R_H}{n^2} \quad (10.2)$$

The **Ritz combination principle** states that *the wavenumber of any spectral line is the difference between two terms*. We say that two terms T_1 and T_2 ‘combine’ to produce a spectral line of wavenumber

$$\tilde{\nu} = T_1 - T_2 \quad (10.3)$$

Thus, if each spectroscopic term represents an energy hcT , the difference in energy when the atom undergoes a transition between two terms is $\Delta E = hcT_1 - hcT_2$ and, according to the Bohr frequency conditions (Section 8.1d), the frequency of the radiation emitted is given by $\nu = cT_1 - cT_2$. This expression rearranges into the Ritz formula when expressed in terms of wavenumbers (on division by c). The Ritz combination principle applies to all types of atoms and molecules, but only for hydrogenic atoms do the terms have the simple form $(\text{constant})/n^2$.

Because spectroscopic observations show that electromagnetic radiation is absorbed and emitted by atoms only at certain wavenumbers, it follows that only certain energy states of atoms are permitted. Our tasks in the first part of this chapter are to determine the origin of this energy quantization, to find the permitted energy levels, and to account for the value of R_H .

10.1 The structure of hydrogenic atoms

The Coulomb potential energy of an electron in a hydrogenic atom of atomic number Z (and nuclear charge Ze) is

$$V = -\frac{Ze^2}{4\pi\epsilon_0 r} \quad (10.4)$$

where r is the distance of the electron from the nucleus and ϵ_0 is the vacuum permittivity. The hamiltonian for the electron and a nucleus of mass m_N is therefore

$$\begin{aligned}\hat{H} &= \hat{E}_{\text{K,electron}} + \hat{E}_{\text{K,nucleus}} + \hat{V} \\ &= -\frac{\hbar^2}{2m_e} \nabla_e^2 - \frac{\hbar^2}{2m_N} \nabla_N^2 - \frac{Ze^2}{4\pi\epsilon_0 r}\end{aligned}\quad (10.5)$$

The subscripts on ∇^2 indicate differentiation with respect to the electron or nuclear coordinates.

(a) The separation of variables

Physical intuition suggests that the full Schrödinger equation ought to separate into two equations, one for the motion of the atom as a whole through space and the other for the motion of the electron relative to the nucleus. We show in *Further information 10.1* how this separation is achieved, and that the Schrödinger equation for the internal motion of the electron relative to the nucleus is

$$-\frac{\hbar^2}{2\mu} \nabla^2 \psi - \frac{Ze^2}{4\pi\epsilon_0 r} \psi = E\psi \quad \frac{1}{\mu} = \frac{1}{m_e} + \frac{1}{m_N} \quad (10.6)$$

where differentiation is now with respect to the coordinates of the electron relative to the nucleus. The quantity μ is called the **reduced mass**. The reduced mass is very similar to the electron mass because m_N , the mass of the nucleus, is much larger than the mass of an electron, so $1/\mu \approx 1/m_e$. In all except the most precise work, the reduced mass can be replaced by m_e .

Because the potential energy is centrosymmetric (independent of angle), we can suspect that the equation is separable into radial and angular components. Therefore, we write

$$\psi(r, \theta, \phi) = R(r)Y(\theta, \phi) \quad (10.7)$$

and examine whether the Schrödinger equation can be separated into two equations, one for R and the other for Y . As shown in *Further information 10.1*, the equation does separate, and the equations we have to solve are

$$\Lambda^2 Y = -l(l+1)Y \quad (10.8)$$

$$-\frac{\hbar^2}{2\mu} \frac{d^2 u}{dr^2} + V_{\text{eff}} u = Eu \quad u = rR \quad (10.9)$$

where

$$V_{\text{eff}} = -\frac{Ze^2}{4\pi\epsilon_0 r} + \frac{l(l+1)\hbar^2}{2\mu r^2} \quad (10.10)$$

Equation 10.8 is the same as the Schrödinger equation for a particle free to move round a central point, and we considered it in Section 9.7. The solutions are the spherical harmonics (Table 9.3), and are specified by the quantum numbers l and m_l . We consider them in more detail shortly. Equation 10.9 is called the **radial wave equation**. The radial wave equation is the description of the motion of a particle of mass μ in a one-dimensional region $0 \leq r < \infty$ where the potential energy is V_{eff} .

(b) The radial solutions

We can anticipate some features of the shapes of the radial wavefunctions by analysing the form of V_{eff} . The first term in eqn 10.10 is the Coulomb potential energy of the

electron in the field of the nucleus. The second term stems from what in classical physics would be called the centrifugal force that arises from the angular momentum of the electron around the nucleus. When $l = 0$, the electron has no angular momentum, and the effective potential energy is purely Coulombic and attractive at all radii (Fig. 10.2). When $l \neq 0$, the centrifugal term gives a positive (repulsive) contribution to the effective potential energy. When the electron is close to the nucleus ($r \approx 0$), this repulsive term, which is proportional to $1/r^2$, dominates the attractive Coulombic component, which is proportional to $1/r$, and the net effect is an effective repulsion of the electron from the nucleus. The two effective potential energies, the one for $l = 0$ and the one for $l \neq 0$, are qualitatively very different close to the nucleus. However, they are similar at large distances because the centrifugal contribution tends to zero more rapidly (as $1/r^2$) than the Coulombic contribution (as $1/r$). Therefore, we can expect the solutions with $l = 0$ and $l \neq 0$ to be quite different near the nucleus but similar far away from it. We show in the *Justification* below that close to the nucleus the radial wavefunction is proportional to r^l , and the higher the orbital angular momentum, the less likely the electron is to be found (Fig. 10.3). We also show that far from the nucleus all wavefunctions approach zero exponentially.

Justification 10.1 The shape of the radial wavefunction

When r is very small (close to the nucleus), $u \approx 0$, so the right-hand side of eqn 10.9 is zero; we can also ignore all but the largest terms (those depending on $1/r^2$) in eqn 10.9 and write

$$-\frac{d^2u}{dr^2} + \frac{l(l+1)}{r^2}u \approx 0$$

The solution of this equation (for $r \approx 0$) is

$$u \approx Ar^{l+1} + \frac{B}{r^l}$$

Because $R = u/r$, and R cannot be infinite at $r = 0$, we must set $B = 0$, and hence obtain $R \approx Ar^l$.

Far from the nucleus, when r is very large, we can ignore all terms in $1/r$ and eqn 10.9 becomes

$$-\frac{\hbar^2}{2\mu} \frac{d^2u}{dr^2} \approx Eu$$

where $\approx$ means ‘asymptotically equal to’. Because

$$\frac{d^2u}{dr^2} = \frac{d^2(rR)}{dr^2} = r \frac{d^2R}{dr^2} + 2 \frac{dR}{dr} \approx r \frac{d^2R}{dr^2}$$

this equation has the form

$$-\frac{\hbar^2}{2\mu} \frac{d^2R}{dr^2} \approx ER$$

The acceptable (finite) solution of this equation (for r large) is

$$R \approx e^{-(2\mu|E|/\hbar^2)r}$$

and the wavefunction decays exponentially towards zero as r increases.

We shall not go through the technical steps of solving the radial equation for the full range of radii, and see how the form r^l close to the nucleus blends into the exponentially

Fig. 10.2 The effective potential energy of an electron in the hydrogen atom. When the electron has zero orbital angular momentum, the effective potential energy is the Coulombic potential energy. When the electron has nonzero orbital angular momentum, the centrifugal effect gives rise to a positive contribution that is very large close to the nucleus. We can expect the $l = 0$ and $l \neq 0$ wavefunctions to be very different near the nucleus.

Exploration Plot the effective potential energy against r for several nonzero values of the orbital angular momentum l . How does the location of the minimum in the effective potential energy vary with l ?

Fig. 10.3 Close to the nucleus, orbitals with $l = 1$ are proportional to r , orbitals with $l = 2$ are proportional to r^2 , and orbitals with $l = 3$ are proportional to r^3 . Electrons are progressively excluded from the neighbourhood of the nucleus as l increases. An orbital with $l = 0$ has a finite, nonzero value at the nucleus.

decaying form at great distances (see *Further reading*). It is sufficient to know that the two limits can be matched only for integral values of a quantum number n , and that the allowed energies corresponding to the allowed solutions are

$$E_n = -\frac{Z^2 \mu e^4}{32\pi^2 \epsilon_0^2 \hbar^2 n^2} \quad (10.11)$$

with $n = 1, 2, \dots$. Likewise, the radial wavefunctions depend on the values of both n and l (but not on m_l), and all of them have the form

$$R(r) = (\text{polynomial in } r) \times (\text{decaying exponential in } r) \quad (10.12)$$

These functions are most simply written in terms of the dimensionless quantity ρ (rho), where

$$\rho = \frac{2Zr}{na_0} \quad a_0 = \frac{4\pi\epsilon_0 \hbar^2}{m_e e^2} \quad (10.13)$$

The **Bohr radius**, a_0 , has the value 52.9 pm; it is so called because the same quantity appeared in Bohr's early model of the hydrogen atom as the radius of the electron orbit of lowest energy. Specifically, the radial wavefunctions for an electron with quantum numbers n and l are the (real) functions

$$R_{n,l}(r) = N_{n,l} \rho^l L_{n+1}^{2l+1}(\rho) e^{-\rho/2} \quad (10.14)$$

where L is a polynomial in ρ called an *associated Laguerre polynomial*: it links the $r \approx 0$ solutions on its left (corresponding to $R \propto \rho^l$) to the exponentially decaying function on its right. The notation might look fearsome, but the polynomials have quite simple forms, such as 1, ρ , and $2 - \rho$ (they can be picked out in Table 10.1). Specifically, we can interpret the components of this expression as follows:

1 The exponential factor ensures that the wavefunction approaches zero far from the nucleus.

Table 10.1 Hydrogenic radial wavefunctions

Orbital	n	l	$R_{n,l}$
1s	1	0	$2 \left(\frac{Z}{a} \right)^{3/2} e^{-\rho/2}$
2s	2	0	$\frac{1}{8^{1/2}} \left(\frac{Z}{a} \right)^{3/2} (2 - \rho) e^{-\rho/2}$
2p	2	1	$\frac{1}{24^{1/2}} \left(\frac{Z}{a} \right)^{3/2} \rho e^{-\rho/2}$
3s	3	0	$\frac{1}{243^{1/2}} \left(\frac{Z}{a} \right)^{3/2} (6 - 6\rho + \rho^2) e^{-\rho/2}$
3p	3	1	$\frac{1}{486^{1/2}} \left(\frac{Z}{a} \right)^{3/2} (4 - \rho) \rho e^{-\rho/2}$
3d	3	2	$\frac{1}{2430^{1/2}} \left(\frac{Z}{a} \right)^{3/2} \rho^2 e^{-\rho/2}$

$\rho = (2Z/na)r$ with $a = 4\pi\epsilon_0 \hbar^2 / \mu e^2$. For an infinitely heavy nucleus (or one that may be assumed to be so), $\mu = m_e$ and $a = a_0$, the Bohr radius. The full wavefunction is obtained by multiplying R by the appropriate Y given in Table 9.3.

Fig. 10.4 The radial wavefunctions of the first few states of hydrogenic atoms of atomic number Z . Note that the orbitals with $l = 0$ have a nonzero and finite value at the nucleus. The horizontal scales are different in each case: orbitals with high principal quantum numbers are relatively distant from the nucleus.

Exploration Use mathematical software to find the locations of the radial nodes in hydrogenic wavefunctions with n up to 3.

2 The factor ρ^l ensures that (provided $l > 0$) the wavefunction vanishes at the nucleus.

3 The associated Laguerre polynomial is a function that oscillates from positive to negative values and accounts for the presence of radial nodes.

Expressions for some radial wavefunctions are given in Table 10.1 and illustrated in Fig. 10.4.

Comment 10.1

The zero at $r = 0$ is not a radial node because the radial wavefunction does not pass through zero at that point (because r cannot be negative). Nodes at the nucleus are all angular nodes.

Illustration 10.1 Calculating a probability density

To calculate the probability density at the nucleus for an electron with $n = 1$, $l = 0$, and $m_l = 0$, we evaluate ψ at $r = 0$:

$$\psi_{1,0,0}(0, \theta, \phi) = R_{1,0}(0) Y_{0,0}(\theta, \phi) = 2 \left(\frac{Z}{a_0} \right)^{3/2} \left(\frac{1}{4\pi} \right)^{1/2}$$

The probability density is therefore

$$\psi_{1,0,0}(0,\theta,\phi)^2 = \frac{Z^3}{\pi a_0^3}$$

which evaluates to $2.15 \times 10^{-6} \text{ pm}^{-3}$ when $Z = 1$.

Self-test 10.2 Evaluate the probability density at the nucleus of the electron for an electron with $n = 2$, $l = 0$, $m_l = 0$. $[(Z/a_0)^3/8\pi]$

10.2 Atomic orbitals and their energies

An **atomic orbital** is a one-electron wavefunction for an electron in an atom. Each hydrogenic atomic orbital is defined by three quantum numbers, designated n , l , and m_l . When an electron is described by one of these wavefunctions, we say that it ‘occupies’ that orbital. We could go on to say that the electron is in the state $|n, l, m_l\rangle$. For instance, an electron described by the wavefunction $\psi_{1,0,0}$ and in the state $|1, 0, 0\rangle$ is said to occupy the orbital with $n = 1$, $l = 0$, and $m_l = 0$.

The quantum number n is called the **principal quantum number**; it can take the values $n = 1, 2, 3, \dots$ and determines the energy of the electron:

An electron in an orbital with quantum number n has an energy given by eqn 10.11.

The two other quantum numbers, l and m_l , come from the angular solutions, and specify the angular momentum of the electron around the nucleus:

An electron in an orbital with quantum number l has an angular momentum of magnitude $\{l(l+1)\}^{1/2}\hbar$, with $l = 0, 1, 2, \dots, n-1$.

An electron in an orbital with quantum number m_l has a z -component of angular momentum $m_l\hbar$, with $m_l = 0, \pm 1, \pm 2, \dots, \pm l$.

Note how the value of the principal quantum number, n , controls the maximum value of l and l controls the range of values of m_l .

To define the state of an electron in a hydrogenic atom fully we need to specify not only the orbital it occupies but also its spin state. We saw in Section 9.8 that an electron possesses an intrinsic angular momentum that is described by the two quantum numbers s and m_s (the analogues of l and m_l). The value of s is fixed at $\frac{1}{2}$ for an electron, so we do not need to consider it further at this stage. However, m_s may be either $+\frac{1}{2}$ or $-\frac{1}{2}$, and to specify the electron’s state in a hydrogenic atom we need to specify which of these values describes it. It follows that, to specify the state of an electron in a hydrogenic atom, we need to give the values of four quantum numbers, namely n , l , m_l , and m_s .

(a) The energy levels

The energy levels predicted by eqn 10.11 are depicted in Fig. 10.5. The energies, and also the separation of neighbouring levels, are proportional to Z^2 , so the levels are four times as wide apart (and the ground state four times deeper in energy) in He^+ ($Z = 2$) than in H ($Z = 1$). All the energies given by eqn 10.11 are negative. They refer to the **bound states** of the atom, in which the energy of the atom is lower than that of the infinitely separated, stationary electron and nucleus (which corresponds to the zero of energy). There are also solutions of the Schrödinger equation with positive energies. These solutions correspond to **unbound states** of the electron, the states to which an electron is raised when it is ejected from the atom by a high-energy collision or photon. The energies of the unbound electron are not quantized and form the continuum states of the atom.

Fig. 10.5 The energy levels of a hydrogen atom. The values are relative to an infinitely separated, stationary electron and a proton.

Equation 10.11 is consistent with the spectroscopic result summarized by eqn 10.1, and we can identify the Rydberg constant for hydrogen ($Z = 1$) as

$$hcR_H = \frac{\mu_H e^4}{32\pi^2 \epsilon_0^2 \hbar^2} \quad [10.15]$$

where μ_H is the reduced mass for hydrogen. The **Rydberg constant** itself, R , is defined by the same expression except for the replacement of μ_H by the mass of an electron, m_e , corresponding to a nucleus of infinite mass:

$$R_H = \frac{\mu_H}{m_e} R \quad R = \frac{m_e e^4}{8\epsilon_0^2 h^3 c} \quad [10.16]$$

Insertion of the values of the fundamental constants into the expression for R_H gives almost exact agreement with the experimental value. The only discrepancies arise from the neglect of relativistic corrections (in simple terms, the increase of mass with speed), which the non-relativistic Schrödinger equation ignores.

(b) Ionization energies

The **ionization energy**, I , of an element is the minimum energy required to remove an electron from the ground state, the state of lowest energy, of one of its atoms. Because the ground state of hydrogen is the state with $n = 1$, with energy $E_1 = -hcR_H$ and the atom is ionized when the electron has been excited to the level corresponding to $n = \infty$ (see Fig. 10.5), the energy that must be supplied is

$$I = hcR_H \quad (10.17)$$

The value of I is 2.179 aJ (a, for atto, is the prefix that denotes 10^{-18}), which corresponds to 13.60 eV.

Comment 10.2

The particle in a finite well, discussed in Section 9.3, is a primitive but useful model that gives insight into the bound and unbound states of the electron in a hydrogenic atom. Figure 9.15 shows that the energies of a particle (for example, an electron in a hydrogenic atom) are quantized when its total energy, E , is lower than its potential energy, V (the Coulomb interaction energy between the electron and the nucleus). When $E > V$, the particle can escape from the well (the atom is ionized) and its energies are no longer quantized, forming a continuum.

Example 10.1 Measuring an ionization energy spectroscopically

The emission spectrum of atomic hydrogen shows lines at 82 259, 97 492, 102 824, 105 292, 106 632, and 107 440 cm^{-1} , which correspond to transitions to the same lower state. Determine (a) the ionization energy of the lower state, (b) the value of the Rydberg constant.

Method The spectroscopic determination of ionization energies depends on the determination of the series limit, the wavenumber at which the series terminates and becomes a continuum. If the upper state lies at an energy $-hcR_H/n^2$, then, when the atom makes a transition to E_{lower} , a photon of wavenumber

$$\tilde{\nu} = -\frac{R_H}{n^2} - \frac{E_{\text{lower}}}{hc}$$

is emitted. However, because $I = -E_{\text{lower}}$, it follows that

$$\tilde{\nu} = \frac{I}{hc} - \frac{R_H}{n^2}$$

A plot of the wavenumbers against $1/n^2$ should give a straight line of slope $-R_H$ and intercept I/hc . Use a computer to make a least-squares fit of the data to get a result that reflects the precision of the data.

Answer The wavenumbers are plotted against $1/n^2$ in Fig. 10.6. The (least-squares) intercept lies at 109 679 cm^{-1} , so the ionization energy is 2.1788 aJ (1312.1 kJ mol^{-1}).

Fig. 10.6 The plot of the data in Example 10.1 used to determine the ionization energy of an atom (in this case, of H).

Exploration The initial value of n was not specified in Example 10.1. Show that the correct value can be determined by making several choices and selecting the one that leads to a straight line.

The slope is, in this instance, numerically the same, so $R_H = 109\,679\text{ cm}^{-1}$. A similar extrapolation procedure can be used for many-electron atoms (see Section 10.5).

Self-test 10.3 The emission spectrum of atomic deuterium shows lines at $15\,238$, $20\,571$, $23\,039$, and $24\,380\text{ cm}^{-1}$, which correspond to transitions to the same lower state. Determine (a) the ionization energy of the lower state, (b) the ionization energy of the ground state, (c) the mass of the deuteron (by expressing the Rydberg constant in terms of the reduced mass of the electron and the deuteron, and solving for the mass of the deuteron).

[(a) 328.1 kJ mol^{-1} , (b) $1312.4\text{ kJ mol}^{-1}$, (c) $2.8 \times 10^{-27}\text{ kg}$, a result very sensitive to R_D]

(c) Shells and subshells

All the orbitals of a given value of n are said to form a single **shell** of the atom. In a hydrogenic atom, all orbitals of given n , and therefore belonging to the same shell, have the same energy. It is common to refer to successive shells by letters:

$$\begin{array}{ccccccc} n = & 1 & 2 & 3 & 4 & \dots \\ & K & L & M & N & \dots \end{array}$$

Thus, all the orbitals of the shell with $n = 2$ form the L shell of the atom, and so on.

The orbitals with the same value of n but different values of l are said to form a **subshell** of a given shell. These subshells are generally referred to by letters:

$$\begin{array}{ccccccccccc} l = & 0 & 1 & 2 & 3 & 4 & 5 & 6 & \dots \\ & s & p & d & f & g & h & i & \dots \end{array}$$

The letters then run alphabetically (j is not used). Figure 10.7 is a version of Fig. 10.5 which shows the subshells explicitly. Because l can range from 0 to $n - 1$, giving n values in all, it follows that there are n subshells of a shell with principal quantum number n . Thus, when $n = 1$, there is only one subshell, the one with $l = 0$. When $n = 2$, there are two subshells, the $2s$ subshell (with $l = 0$) and the $2p$ subshell (with $l = 1$).

When $n = 1$ there is only one subshell, that with $l = 0$, and that subshell contains only one orbital, with $m_l = 0$ (the only value of m_l permitted). When $n = 2$, there are four orbitals, one in the s subshell with $l = 0$ and $m_l = 0$, and three in the $l = 1$ subshell with $m_l = +1, 0, -1$. When $n = 3$ there are nine orbitals (one with $l = 0$, three with $l = 1$, and five with $l = 2$). The organization of orbitals in the shells is summarized in Fig. 10.8. In general, the number of orbitals in a shell of principal quantum number n is n^2 , so in a hydrogenic atom each energy level is n^2 -fold degenerate.

(d) Atomic orbitals

The orbital occupied in the ground state is the one with $n = 1$ (and therefore with $l = 0$ and $m_l = 0$, the only possible values of these quantum numbers when $n = 1$). From Table 10.1 we can write (for $Z = 1$):

$$\psi = \frac{1}{(\pi a_0^3)^{1/2}} e^{-r/a_0} \quad (10.18)$$

This wavefunction is independent of angle and has the same value at all points of constant radius; that is, the $1s$ orbital is *spherically symmetrical*. The wavefunction decays exponentially from a maximum value of $1/(\pi a_0^3)^{1/2}$ at the nucleus (at $r = 0$). It follows that the most probable point at which the electron will be found is at the nucleus itself.

Fig. 10.7 The energy levels of the hydrogen atom showing the subshells and (in square brackets) the numbers of orbitals in each subshell. In hydrogenic atoms, all orbitals of a given shell have the same energy.

Fig. 10.8 The organization of orbitals (white squares) into subshells (characterized by l) and shells (characterized by n).

Fig. 10.9 The balance of kinetic and potential energies that accounts for the structure of the ground state of hydrogen (and similar atoms). (a) The sharply curved but localized orbital has high mean kinetic energy, but low mean potential energy; (b) the mean kinetic energy is low, but the potential energy is not very favourable; (c) the compromise of moderate kinetic energy and moderately favourable potential energy.

We can understand the general form of the ground-state wavefunction by considering the contributions of the potential and kinetic energies to the total energy of the atom. The closer the electron is to the nucleus on average, the lower its average potential energy. This dependence suggests that the lowest potential energy should be obtained with a sharply peaked wavefunction that has a large amplitude at the nucleus and is zero everywhere else (Fig. 10.9). However, this shape implies a high kinetic energy, because such a wavefunction has a very high average curvature. The electron would have very low kinetic energy if its wavefunction had only a very low average curvature. However, such a wavefunction spreads to great distances from the nucleus and the average potential energy of the electron will be correspondingly high. The actual ground-state wavefunction is a compromise between these two extremes: the wavefunction spreads away from the nucleus (so the expectation value of the potential energy is not as low as in the first example, but nor is it very high) and has a reasonably low average curvature (so the expectation of the kinetic energy is not very low, but nor is it as high as in the first example).

The energies of ns orbitals increase (become less negative; the electron becomes less tightly bound) as n increases because the average distance of the electron from the nucleus increases. By the virial theorem with $b = -1$ (eqn 9.35), $\langle E_K \rangle = -\frac{1}{2}\langle V \rangle$ so, even though the average kinetic energy decreases as n increases, the total energy is equal to $\frac{1}{2}\langle V \rangle$, which becomes less negative as n increases.

One way of depicting the probability density of the electron is to represent $|\psi|^2$ by the density of shading (Fig. 10.10). A simpler procedure is to show only the **boundary surface**, the surface that captures a high proportion (typically about 90 per cent) of the electron probability. For the $1s$ orbital, the boundary surface is a sphere centred on the nucleus (Fig. 10.11).

Fig. 10.10 Representations of the $1s$ and $2s$ hydrogenic atomic orbitals in terms of their electron densities (as represented by the density of shading)

Fig. 10.11 The boundary surface of an s orbital, within which there is a 90 per cent probability of finding the electron.

Fig. 10.12 The variation of the mean radius of a hydrogenic atom with the principal and orbital angular momentum quantum numbers. Note that the mean radius lies in the order $d < p < s$ for a given value of n .

The general expression for the mean radius of an orbital with quantum numbers l and n is

$$r_{n,l} = n^2 \left\{ 1 + \frac{1}{2} \left(1 - \frac{l(l+1)}{n^2} \right) \right\} \frac{a_0}{Z} \quad (10.19)$$

The variation with n and l is shown in Fig. 10.12. Note that, for a given principal quantum number, the mean radius decreases as l increases, so the average distance of an electron from the nucleus is less when it is in a $2p$ orbital, for instance, than when it is in a $2s$ orbital.

Example 10.2 Calculating the mean radius of an orbital

Use hydrogenic orbitals to calculate the mean radius of a $1s$ orbital.

Method The mean radius is the expectation value

$$\langle r \rangle = \int \psi^* r \psi d\tau = \int r |\psi|^2 d\tau$$

We therefore need to evaluate the integral using the wavefunctions given in Table 10.1 and $d\tau = r^2 dr \sin \theta d\theta d\phi$. The angular parts of the wavefunction are normalized in the sense that

$$\int_0^\pi \int_0^{2\pi} |Y_{l,m_l}|^2 \sin \theta d\theta d\phi = 1$$

The integral over r required is given in Example 8.7.

Answer With the wavefunction written in the form $\psi = RY$, the integration is

$$\langle r \rangle = \int_0^\infty \int_0^\pi \int_0^{2\pi} r R_{n,l}^2 |Y_{l,m_l}|^2 r^2 dr \sin \theta d\theta d\phi = \int_0^\infty r^3 R_{n,l}^2 dr$$

For a $1s$ orbital,

$$R_{1,0} = 2 \left(\frac{Z}{a_0} \right)^{1/2} e^{-Zr/a_0}$$

Hence

$$\langle r \rangle = \frac{4Z}{a_0^3} \int_0^\infty r^3 e^{-2Zr/a_0} dr = \frac{3a_0}{2Z}$$

Self-test 10.4 Evaluate the mean radius (a) of a $3s$ orbital by integration, and (b) of a $3p$ orbital by using the general formula, eqn 10.19. [(a) $27a_0/2Z$; (b) $25a_0/2Z$]

All s -orbitals are spherically symmetric, but differ in the number of radial nodes. For example, the $1s$, $2s$, and $3s$ orbitals have 0, 1, and 2 radial nodes, respectively. In general, an ns orbital has $n - 1$ radial nodes.

Self-test 10.5 (a) Use the fact that a $2s$ orbital has radial nodes where the polynomial factor (Table 10.1) is equal to zero, and locate the radial node at $2a_0/Z$ (see Fig. 10.4). (b) Similarly, locate the two nodes of a $3s$ orbital.

[(a) $2a_0/Z$; (b) $1.90a_0/Z$ and $7.10a_0/Z$]

(e) Radial distribution functions

The wavefunction tells us, through the value of $|\psi|^2$, the probability of finding an electron in any region. We can imagine a probe with a volume $d\tau$ and sensitive to electrons, and which we can move around near the nucleus of a hydrogen atom. Because the probability density in the ground state of the atom is $|\psi|^2 \propto e^{-2Zr/a_0}$, the reading from the detector decreases exponentially as the probe is moved out along any radius but is constant if the probe is moved on a circle of constant radius (Fig. 10.13).

Now consider the probability of finding the electron *anywhere* between the two walls of a spherical shell of thickness dr at a radius r . The sensitive volume of the probe is now the volume of the shell (Fig. 10.14), which is $4\pi r^2 dr$ (the product of its surface area, $4\pi r^2$, and its thickness, dr). The probability that the electron will be found between the inner and outer surfaces of this shell is the probability density at the radius r multiplied by the volume of the probe, or $|\psi|^2 \times 4\pi r^2 dr$. This expression has the form $P(r)dr$, where

$$P(r) = 4\pi r^2 \psi^2 \quad (10.20)$$

The more general expression, which also applies to orbitals that are not spherically symmetrical, is

$$P(r) = r^2 R(r)^2 \quad (10.21)$$

where $R(r)$ is the radial wavefunction for the orbital in question.

Justification 10.2 The general form of the radial distribution function

The probability of finding an electron in a volume element $d\tau$ when its wavefunction is $\psi = RY$ is $|RY|^2 d\tau$ with $d\tau = r^2 dr \sin\theta d\theta d\phi$. The total probability of finding the electron at any angle at a constant radius is the integral of this probability over the surface of a sphere of radius r , and is written $P(r)dr$; so

$$\begin{aligned} P(r)dr &= \int_0^\pi \int_0^{2\pi} \overbrace{R(r)^2 |Y(\theta, \phi)|^2}^{\psi^2} \overbrace{r^2 dr \sin\theta d\theta d\phi}^{d\tau} \\ &= r^2 R(r)^2 dr \int_0^\pi \int_0^{2\pi} \overbrace{|Y(\theta, \phi)|^2 \sin\theta d\theta d\phi}^1 = r^2 R(r)^2 dr \end{aligned}$$

The last equality follows from the fact that the spherical harmonics are normalized to 1 (see Example 10.2). It follows that $P(r) = r^2 R(r)^2$, as stated in the text.

The **radial distribution function**, $P(r)$, is a probability density in the sense that, when it is multiplied by dr , it gives the probability of finding the electron anywhere between the two walls of a spherical shell of thickness dr at the radius r . For a 1s orbital,

$$P(r) = \frac{4Z^3}{a_0^3} r^2 e^{-2Zr/a_0} \quad (10.22)$$

Let's interpret this expression:

- 1 Because $r^2 = 0$ at the nucleus, at the nucleus $P(0) = 0$.
- 2 As $r \rightarrow \infty$, $P(r) \rightarrow 0$ on account of the exponential term.
- 3 The increase in r^2 and the decrease in the exponential factor means that P passes through a maximum at an intermediate radius (see Fig. 10.14).

Fig. 10.13 A constant-volume electron-sensitive detector (the small cube) gives its greatest reading at the nucleus, and a smaller reading elsewhere. The same reading is obtained anywhere on a circle of given radius: the s orbital is spherically symmetrical.

Fig. 10.14 The radial distribution function P gives the probability that the electron will be found anywhere in a shell of radius r . For a 1s electron in hydrogen, P is a maximum when r is equal to the Bohr radius a_0 . The value of P is equivalent to the reading that a detector shaped like a spherical shell would give as its radius is varied.

The maximum of $P(r)$, which can be found by differentiation, marks the most probable radius at which the electron will be found, and for a $1s$ orbital in hydrogen occurs at $r = a_0$, the Bohr radius. When we carry through the same calculation for the radial distribution function of the $2s$ orbital in hydrogen, we find that the most probable radius is $5.2a_0 = 275$ pm. This larger value reflects the expansion of the atom as its energy increases.

Example 10.3 Calculating the most probable radius

Calculate the most probable radius, r^* , at which an electron will be found when it occupies a $1s$ orbital of a hydrogenic atom of atomic number Z , and tabulate the values for the one-electron species from H to Ne^{9+} .

Method We find the radius at which the radial distribution function of the hydrogenic $1s$ orbital has a maximum value by solving $dP/dr = 0$. If there are several maxima, then we choose the one corresponding to the greatest amplitude (the outermost one).

Answer The radial distribution function is given in eqn 10.22. It follows that

$$\frac{dP}{dr} = \frac{4Z^3}{a_0^3} \left(2r - \frac{2Zr^2}{a_0} \right) e^{-2Zr/a_0}$$

This function is zero where the term in parentheses is zero, which is at

$$r^* = \frac{a_0}{Z}$$

Then, with $a_0 = 52.9$ pm, the radial node lies at

	H	He ⁺	Li ²⁺	Be ³⁺	B ⁴⁺	C ⁵⁺	N ⁶⁺	O ⁷⁺	F ⁸⁺	Ne ⁹⁺
r^*/pm	52.9	26.5	17.6	13.2	10.6	8.82	7.56	6.61	5.88	5.29

Notice how the $1s$ orbital is drawn towards the nucleus as the nuclear charge increases. At uranium the most probable radius is only 0.58 pm, almost 100 times closer than for hydrogen. (On a scale where $r^* = 10$ cm for H, $r^* = 1$ mm for U.) The electron then experiences strong accelerations and relativistic effects are important.

Self-test 10.6 Find the most probable distance of a $2s$ electron from the nucleus in a hydrogenic atom. $[(3 + 5^{1/2})a_0/Z]$

(f) p Orbitals

The three $2p$ orbitals are distinguished by the three different values that m_l can take when $l = 1$. Because the quantum number m_l tells us the orbital angular momentum around an axis, these different values of m_l denote orbitals in which the electron has different orbital angular momenta around an arbitrary z -axis but the same magnitude of that momentum (because l is the same for all three). The orbital with $m_l = 0$, for instance, has zero angular momentum around the z -axis. Its angular variation is proportional to $\cos \theta$, so the probability density, which is proportional to $\cos^2 \theta$, has its maximum value on either side of the nucleus along the z -axis (at $\theta = 0$ and 180°). The wavefunction of a $2p$ -orbital with $m_l = 0$ is

Fig. 10.15 The boundary surfaces of p orbitals. A nodal plane passes through the nucleus and separates the two lobes of each orbital. The dark and light areas denote regions of opposite sign of the wavefunction.

Exploration Use mathematical software to plot the boundary surfaces of the real parts of the spherical harmonics $Y_{1,m_l}(\theta, \phi)$. The resulting plots are not strictly the p orbital boundary surfaces, but sufficiently close to be reasonable representations of the shapes of hydrogenic orbitals.

$$\begin{aligned}\psi_{p_0} &= R_{2,1}(r)Y_{1,0}(\theta, \phi) = \frac{1}{4(2\pi)^{1/2}} \left(\frac{Z}{a_0} \right)^{5/2} r \cos \theta e^{-Zr/2a_0} \\ &= r \cos \theta f(r)\end{aligned}$$

where $f(r)$ is a function only of r . Because in spherical polar coordinates $z = r \cos \theta$, this wavefunction may also be written

$$\psi_{p_z} = z f(r) \quad (10.23)$$

All p orbitals with $m_l = 0$ have wavefunctions of this form regardless of the value of n . This way of writing the orbital is the origin of the name ' p_z orbital': its boundary surface is shown in Fig. 10.15. The wavefunction is zero everywhere in the xy -plane, where $z = 0$, so the xy -plane is a **nodal plane** of the orbital: the wavefunction changes sign on going from one side of the plane to the other.

The wavefunctions of $2p$ orbitals with $m_l = \pm 1$ have the following form:

$$\begin{aligned}\psi_{p_{\pm 1}} &= R_{2,1}(r)Y_{1,\pm 1}(\theta, \phi) = \mp \frac{1}{8\pi^{1/2}} \left(\frac{Z}{a_0} \right)^{5/2} r e^{-Zr/2a_0} \sin \theta e^{\pm i\phi} \\ &= \mp \frac{1}{2^{1/2}} r \sin \theta e^{\pm i\phi} f(r)\end{aligned}$$

We saw in Chapter 8 that a moving particle can be described by a complex wavefunction. In the present case, the functions correspond to non-zero angular momentum about the z -axis: $e^{+i\phi}$ corresponds to clockwise rotation when viewed from below, and $e^{-i\phi}$ corresponds to counter-clockwise rotation (from the same viewpoint). They have zero amplitude where $\theta = 0$ and 180° (along the z -axis) and maximum amplitude at 90° , which is in the xy -plane. To draw the functions it is usual to represent them as standing waves. To do so, we take the real linear combinations

$$\begin{aligned}\psi_{p_x} &= -\frac{1}{2^{1/2}}(p_{+1} - p_{-1}) = r \sin \theta \cos \phi f(r) = x f(r) \\ \psi_{p_y} &= \frac{i}{2^{1/2}}(p_{+1} + p_{-1}) = r \sin \theta \sin \phi f(r) = y f(r)\end{aligned} \quad (10.24)$$

These linear combinations are indeed standing waves with no net orbital angular momentum around the z -axis, as they are superpositions of states with equal and opposite values of m_l . The p_x orbital has the same shape as a p_z orbital, but it is directed

along the x -axis (see Fig. 10.15); the p_y orbital is similarly directed along the y -axis. The wavefunction of any p orbital of a given shell can be written as a product of x , y , or z and the same radial function (which depends on the value of n).

Justification 10.3 *The linear combination of degenerate wavefunctions*

We justify here the step of taking linear combinations of degenerate orbitals when we want to indicate a particular point. The freedom to do so rests on the fact that, whenever two or more wavefunctions correspond to the same energy, any linear combination of them is an equally valid solution of the Schrödinger equation.

Suppose ψ_1 and ψ_2 are both solutions of the Schrödinger equation with energy E ; then we know that

$$H\psi_1 = E\psi_1 \quad H\psi_2 = E\psi_2$$

Now consider the linear combination

$$\psi = c_1\psi_1 + c_2\psi_2$$

where c_1 and c_2 are arbitrary coefficients. Then it follows that

$$H\psi = H(c_1\psi_1 + c_2\psi_2) = c_1H\psi_1 + c_2H\psi_2 = c_1E\psi_1 + c_2E\psi_2 = E\psi$$

Hence, the linear combination is also a solution corresponding to the same energy E .

(g) d Orbitals

When $n = 3$, l can be 0, 1, or 2. As a result, this shell consists of one $3s$ orbital, three $3p$ orbitals, and five $3d$ orbitals. The five d orbitals have $m_l = +2, +1, 0, -1, -2$ and correspond to five different angular momenta around the z -axis (but the same *magnitude* of angular momentum, because $l = 2$ in each case). As for the p orbitals, d orbitals with opposite values of m_l (and hence opposite senses of motion around the z -axis) may be combined in pairs to give real standing waves, and the boundary surfaces of the resulting shapes are shown in Fig. 10.16. The real combinations have the following forms:

$$\begin{aligned} d_{xy} &= xyf(r) & d_{yz} &= yzf(r) & d_{zx} &= zxf(r) \\ d_{x^2-y^2} &= \frac{1}{2}(x^2 - y^2)f(r) & d_{z^2} &= \left(\frac{1}{2}\sqrt{3}\right)(3z^2 - r^2)f(r) \end{aligned} \quad (10.25)$$

Fig. 10.16 The boundary surfaces of d orbitals. Two nodal planes in each orbital intersect at the nucleus and separate the lobes of each orbital. The dark and light areas denote regions of opposite sign of the wavefunction.

Exploration To gain insight into the shapes of the f orbitals, use mathematical software to plot the boundary surfaces of the spherical harmonics $Y_{3,m_l}(\theta, \phi)$.

10.3 Spectroscopic transitions and selection rules

The energies of the hydrogenic atoms are given by eqn 10.11. When the electron undergoes a **transition**, a change of state, from an orbital with quantum numbers n_1, l_1, m_{l1} to another (lower energy) orbital with quantum numbers n_2, l_2, m_{l2} , it undergoes a change of energy ΔE and discards the excess energy as a photon of electromagnetic radiation with a frequency ν given by the Bohr frequency condition (eqn 8.10).

It is tempting to think that all possible transitions are permissible, and that a spectrum arises from the transition of an electron from any initial orbital to any other orbital. However, this is not so, because a photon has an intrinsic spin angular momentum corresponding to $s = 1$ (Section 9.8). The change in angular momentum of the electron must compensate for the angular momentum carried away by the photon. Thus, an electron in a d orbital ($l = 2$) cannot make a transition into an s orbital ($l = 0$) because the photon cannot carry away enough angular momentum. Similarly, an s electron cannot make a transition to another s orbital, because there would then be no change in the electron's angular momentum to make up for the angular momentum carried away by the photon. It follows that some spectroscopic transitions are **allowed**, meaning that they can occur, whereas others are **forbidden**, meaning that they cannot occur.

A **selection rule** is a statement about which transitions are allowed. They are derived (for atoms) by identifying the transitions that conserve angular momentum when a photon is emitted or absorbed. The selection rules for hydrogenic atoms are

$$\Delta l = \pm 1 \quad \Delta m_l = 0, \pm 1 \quad (10.26)$$

The principal quantum number n can change by any amount consistent with the Δl for the transition, because it does not relate directly to the angular momentum.

Justification 10.4 The identification of selection rules

We saw in Section 9.10 that the rate of transition between two states is proportional to the square of the transition dipole moment, μ_{fi} , between the initial and final states, where (using the notation introduced in *Further information 9.1*)

$$\mu_{fi} = \langle f | \mu | i \rangle \quad [10.27]$$

and μ is the electric dipole moment operator. For a one-electron atom μ is multiplication by $-e\mathbf{r}$ with components $\mu_x = -ex$, $\mu_y = -ey$, and $\mu_z = -ez$. If the transition dipole moment is zero, the transition is forbidden; the transition is allowed if the transition moment is non-zero. Physically, the transition dipole moment is a measure of the dipolar 'kick' that the electron gives to or receives from the electromagnetic field.

To evaluate a transition dipole moment, we consider each component in turn. For example, for the z -component,

$$\mu_{z,fi} = -e \langle f | z | i \rangle = -e \int \psi_f^* z \psi_i d\tau \quad (10.28)$$

To evaluate the integral, we note from Table 9.3 that $z = (4\pi/3)^{1/2} r Y_{1,0}$, so

$$\int \psi_f^* z \psi_i d\tau = \int_0^\infty \int_0^\pi \int_0^{2\pi} \overbrace{R_{n_f, l_f}^* Y_{l_f, m_{l_f}}^*}^{\psi_f^*} \overbrace{\left(\frac{4\pi}{3} \right)^{1/2} r Y_{1,0}}^z \overbrace{R_{n_i, l_i} Y_{l_i, m_{l_i}} \sin \theta d\theta d\phi}^{\psi_i d\tau}$$

This multiple integral is the product of three factors, an integral over r and two integrals over the angles, so the factors on the right can be grouped as follows:

$$\int \psi_f^* z \psi_i d\tau = \left(\frac{4\pi}{3} \right)^{1/2} \int_0^\infty R_{n_f, l_f}^* r R_{n_i, l_i} r^2 dr \int_0^\pi \int_0^{2\pi} Y_{l_f, m_{l_f}}^* Y_{1,0} Y_{l_i, m_{l_i}} \sin \theta d\theta d\phi$$

Fig. 10.17 A Grotrian diagram that summarizes the appearance and analysis of the spectrum of atomic hydrogen. The thicker the line, the more intense the transition.

It follows from the properties of the spherical harmonics (Comment 9.6) that the integral

$$\int_0^\pi \int_0^{2\pi} Y_{l_f, m_f}^* Y_{l_i, m_i} Y_{1, m} \sin \theta d\theta d\phi$$

is zero unless $l_f = l_i \pm 1$ and $m_{l_f} = m_{l_i} + m$. Because $m = 0$ in the present case, the angular integral, and hence the z -component of the transition dipole moment, is zero unless $\Delta l = \pm 1$ and $\Delta m_l = 0$, which is a part of the set of selection rules. The same procedure, but considering the x - and y -components, results in the complete set of rules.

Illustration 10.2 Applying selection rules

To identify the orbitals to which a $4d$ electron may make radiative transitions, we first identify the value of l and then apply the selection rule for this quantum number. Because $l = 2$, the final orbital must have $l = 1$ or 3 . Thus, an electron may make a transition from a $4d$ orbital to any np orbital (subject to $\Delta m_l = 0, \pm 1$) and to any nf orbital (subject to the same rule). However, it cannot undergo a transition to any other orbital, so a transition to any ns orbital or to another nd orbital is forbidden.

Self-test 10.7 To what orbitals may a $4s$ electron make electric-dipole allowed radiative transitions? [to np orbitals only]

The selection rules and the atomic energy levels jointly account for the structure of a **Grotrian diagram** (Fig. 10.17), which summarizes the energies of the states and the transitions between them. The thicknesses of the transition lines in the diagram denote their relative intensities in the spectrum; we see how to determine transition intensities in Section 13.2.

The structures of many-electron atoms

The Schrödinger equation for a many-electron atom is highly complicated because all the electrons interact with one another. Even for a helium atom, with its two electrons, no analytical expression for the orbitals and energies can be given, and we are forced to make approximations. We shall adopt a simple approach based on what we already know about the structure of hydrogenic atoms. Later we shall see the kind of numerical computations that are currently used to obtain accurate wavefunctions and energies.

10.4 The orbital approximation

The wavefunction of a many-electron atom is a very complicated function of the coordinates of all the electrons, and we should write it $\psi(\mathbf{r}_1, \mathbf{r}_2, \dots)$, where $\mathbf{r}_i$ is the vector from the nucleus to electron i . However, in the **orbital approximation** we suppose that a reasonable first approximation to this exact wavefunction is obtained by thinking of each electron as occupying its ‘own’ orbital, and write

$$\psi(\mathbf{r}_1, \mathbf{r}_2, \dots) = \psi(\mathbf{r}_1)\psi(\mathbf{r}_2) \dots \quad (10.29)$$

We can think of the individual orbitals as resembling the hydrogenic orbitals, but corresponding to nuclear charges modified by the presence of all the other electrons in the atom. This description is only approximate, but it is a useful model for discussing the chemical properties of atoms, and is the starting point for more sophisticated descriptions of atomic structure.

Justification 10.5 *The orbital approximation*

The orbital approximation would be exact if there were no interactions between electrons. To demonstrate the validity of this remark, we need to consider a system in which the hamiltonian for the energy is the sum of two contributions, one for electron 1 and the other for electron 2:

$$\hat{H} = \hat{H}_1 + \hat{H}_2$$

In an actual atom (such as helium atom), there is an additional term corresponding to the interaction of the two electrons, but we are ignoring that term. We shall now show that if $\psi(r_1)$ is an eigenfunction of $\hat{H}_1$ with energy E_1 , and $\psi(r_2)$ is an eigenfunction of $\hat{H}_2$ with energy E_2 , then the product $\psi(r_1, r_2) = \psi(r_1)\psi(r_2)$ is an eigenfunction of the combined hamiltonian $\hat{H}$. To do so we write

$$\begin{aligned}\hat{H}\psi(r_1, r_2) &= (\hat{H}_1 + \hat{H}_2)\psi(r_1)\psi(r_2) = \hat{H}_1\psi(r_1)\psi(r_2) + \psi(r_1)\hat{H}_2\psi(r_2) \\ &= E_1\psi(r_1)\psi(r_2) + \psi(r_1)E_2\psi(r_2) = (E_1 + E_2)\psi(r_1)\psi(r_2) \\ &= E\psi(r_1, r_2)\end{aligned}$$

where $E = E_1 + E_2$. This is the result we need to prove. However, if the electrons interact (as they do in fact), then the proof fails.

(a) The helium atom

The orbital approximation allows us to express the electronic structure of an atom by reporting its **configuration**, the list of occupied orbitals (usually, but not necessarily, in its ground state). Thus, as the ground state of a hydrogenic atom consists of the single electron in a $1s$ orbital, we report its configuration as $1s^1$.

The He atom has two electrons. We can imagine forming the atom by adding the electrons in succession to the orbitals of the bare nucleus (of charge $2e$). The first electron occupies a $1s$ hydrogenic orbital, but because $Z = 2$ that orbital is more compact than in H itself. The second electron joins the first in the $1s$ orbital, so the electron configuration of the ground state of He is $1s^2$.

(b) The Pauli principle

Lithium, with $Z = 3$, has three electrons. The first two occupy a $1s$ orbital drawn even more closely than in He around the more highly charged nucleus. The third electron, however, does not join the first two in the $1s$ orbital because that configuration is forbidden by the **Pauli exclusion principle**:

No more than two electrons may occupy any given orbital, and if two do occupy one orbital, then their spins must be paired.

Electrons with paired spins, denoted $\uparrow\downarrow$, have zero net spin angular momentum because the spin of one electron is cancelled by the spin of the other. Specifically, one electron has $m_s = +\frac{1}{2}$, the other has $m_s = -\frac{1}{2}$ and they are orientated on their respective cones so that the resultant spin is zero (Fig. 10.18). The exclusion principle is the key to the structure of complex atoms, to chemical periodicity, and to molecular structure. It was proposed by Wolfgang Pauli in 1924 when he was trying to account for the

Fig. 10.18 Electrons with paired spins have zero resultant spin angular momentum. They can be represented by two vectors that lie at an indeterminate position on the cones shown here, but wherever one lies on its cone, the other points in the opposite direction; their resultant is zero.

absence of some lines in the spectrum of helium. Later he was able to derive a very general form of the principle from theoretical considerations.

The Pauli exclusion principle in fact applies to any pair of identical fermions (particles with half integral spin). Thus it applies to protons, neutrons, and ^{13}C nuclei (all of which have spin $\frac{1}{2}$) and to ^{35}Cl nuclei (which have spin $\frac{3}{2}$). It does not apply to identical bosons (particles with integral spin), which include photons (spin 1), ^{12}C nuclei (spin 0). Any number of identical bosons may occupy the same state (that is, be described by the same wavefunction).

The Pauli exclusion principle is a special case of a general statement called the **Pauli principle**:

When the labels of any two identical fermions are exchanged, the total wavefunction changes sign; when the labels of any two identical bosons are exchanged, the total wavefunction retains the same sign.

By ‘total wavefunction’ is meant the entire wavefunction, including the spin of the particles. To see that the Pauli principle implies the Pauli exclusion principle, we consider the wavefunction for two electrons $\psi(1,2)$. The Pauli principle implies that it is a fact of nature (which has its roots in the theory of relativity) that the wavefunction must change sign if we interchange the labels 1 and 2 wherever they occur in the function:

$$\psi(2,1) = -\psi(1,2) \quad (10.30)$$

Suppose the two electrons in an atom occupy an orbital ψ , then in the orbital approximation the overall wavefunction is $\psi(1)\psi(2)$. To apply the Pauli principle, we must deal with the total wavefunction, the wavefunction including spin. There are several possibilities for two spins: both α , denoted $\alpha(1)\alpha(2)$, both β , denoted $\beta(1)\beta(2)$, and one α the other β , denoted either $\alpha(1)\beta(2)$ or $\alpha(2)\beta(1)$. Because we cannot tell which electron is α and which is β , in the last case it is appropriate to express the spin states as the (normalized) linear combinations

$$\begin{aligned} \sigma_+(1,2) &= (1/2^{1/2})\{\alpha(1)\beta(2) + \beta(1)\alpha(2)\} \\ \sigma_-(1,2) &= (1/2^{1/2})\{\alpha(1)\beta(2) - \beta(1)\alpha(2)\} \end{aligned} \quad (10.31)$$

because these combinations allow one spin to be α and the other β with equal probability. The total wavefunction of the system is therefore the product of the orbital part and one of the four spin states:

$$\psi(1)\psi(2)\alpha(1)\alpha(2) \quad \psi(1)\psi(2)\beta(1)\beta(2) \quad \psi(1)\psi(2)\sigma_+(1,2) \quad \psi(1)\psi(2)\sigma_-(1,2)$$

The Pauli principle says that for a wavefunction to be acceptable (for electrons), it must change sign when the electrons are exchanged. In each case, exchanging the labels 1 and 2 converts the factor $\psi(1)\psi(2)$ into $\psi(2)\psi(1)$, which is the same, because the order of multiplying the functions does not change the value of the product. The same is true of $\alpha(1)\alpha(2)$ and $\beta(1)\beta(2)$. Therefore, the first two overall products are not allowed, because they do not change sign. The combination $\sigma_+(1,2)$ changes to

$$\sigma_+(2,1) = (1/2^{1/2})\{\alpha(2)\beta(1) + \beta(2)\alpha(1)\} = \sigma_+(1,2)$$

because it is simply the original function written in a different order. The third overall product is therefore also disallowed. Finally, consider $\sigma_-(1,2)$:

$$\begin{aligned} \sigma_-(2,1) &= (1/2^{1/2})\{\alpha(2)\beta(1) - \beta(2)\alpha(1)\} \\ &= -(1/2^{1/2})\{\alpha(1)\beta(2) - \beta(1)\alpha(2)\} = -\sigma_-(1,2) \end{aligned}$$

This combination does change sign (it is ‘antisymmetric’). The product $\psi(1)\psi(2)\sigma_-(1,2)$ also changes sign under particle exchange, and therefore it is acceptable.

Comment 10.3

A stronger justification for taking linear combinations in eqn 10.31 is that they correspond to eigenfunctions of the total spin operators S^2 and S_z , with $M_S = 0$ and, respectively, $S = 1$ and 0 . See Section 10.7.

Now we see that only one of the four possible states is allowed by the Pauli principle, and the one that survives has paired α and β spins. This is the content of the Pauli exclusion principle. The exclusion principle is irrelevant when the orbitals occupied by the electrons are different, and both electrons may then have (but need not have) the same spin state. Nevertheless, even then the overall wavefunction must still be antisymmetric overall, and must still satisfy the Pauli principle itself.

A final point in this connection is that the acceptable product wavefunction $\psi(1)\psi(2)\sigma_{-}(1,2)$ can be expressed as a determinant:

$$\frac{1}{2^{1/2}} \begin{vmatrix} \psi(1)\alpha(1) & \psi(2)\alpha(2) \\ \psi(1)\beta(1) & \psi(2)\beta(2) \end{vmatrix} = \frac{1}{2^{1/2}} \{ \psi(1)\alpha(1)\psi(2)\beta(2) - \psi(2)\alpha(2)\psi(1)\beta(1) \} \\ = \psi(1)\psi(2)\sigma_{-}(1,2)$$

Any acceptable wavefunction for a closed-shell species can be expressed as a **Slater determinant**, as such determinants are known. In general, for N electrons in orbitals $\psi_a, \psi_b, \dots$

$$\psi(1,2,\dots,N) = \frac{1}{(N!)^{1/2}} \begin{vmatrix} \psi_a(1)\alpha(1) & \psi_a(2)\alpha(2) & \psi_a(3)\alpha(3) & \dots & \psi_a(N)\alpha(N) \\ \psi_a(1)\beta(1) & \psi_a(2)\beta(2) & \psi_a(3)\beta(3) & \dots & \psi_a(N)\beta(N) \\ \psi_b(1)\alpha(1) & \psi_b(2)\alpha(2) & \psi_b(3)\alpha(3) & \dots & \psi_b(N)\alpha(N) \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \psi_z(1)\beta(1) & \psi_z(2)\beta(2) & \psi_z(3)\beta(3) & \dots & \psi_z(N)\beta(N) \end{vmatrix} \quad [10.32]$$

Writing a many-electron wavefunction in this way ensures that it is antisymmetric under the interchange of any pair of electrons, as is explored in Problem 10.23.

Now we can return to lithium. In Li ($Z=3$), the third electron cannot enter the $1s$ orbital because that orbital is already full: we say the K shell is *complete* and that the two electrons form a **closed shell**. Because a similar closed shell is characteristic of the He atom, we denote it [He]. The third electron is excluded from the K shell and must occupy the next available orbital, which is one with $n=2$ and hence belonging to the L shell. However, we now have to decide whether the next available orbital is the $2s$ orbital or a $2p$ orbital, and therefore whether the lowest energy configuration of the atom is [He] $2s^1$ or [He] $2p^1$.

(c) Penetration and shielding

Unlike in hydrogenic atoms, the $2s$ and $2p$ orbitals (and, in general, all subshells of a given shell) are not degenerate in many-electron atoms. As will be familiar from introductory chemistry, an electron in a many-electron atom experiences a Coulombic repulsion from all the other electrons present. If it is at a distance r from the nucleus, it experiences an average repulsion that can be represented by a point negative charge located at the nucleus and equal in magnitude to the total charge of the electrons within a sphere of radius r (Fig. 10.19). The effect of this point negative charge, when averaged over all the locations of the electron, is to reduce the full charge of the nucleus from Ze to $Z_{\text{eff}}e$, the **effective nuclear charge**. In everyday parlance, Z_{eff} itself is commonly referred to as the ‘effective nuclear charge’. We say that the electron experiences a **shielded** nuclear charge, and the difference between Z and Z_{eff} is called the **shielding constant**, σ :

$$Z_{\text{eff}} = Z - \sigma \quad [10.33]$$

The electrons do not actually ‘block’ the full Coulombic attraction of the nucleus: the shielding constant is simply a way of expressing the net outcome of the nuclear

Fig. 10.19 An electron at a distance r from the nucleus experiences a Coulombic repulsion from all the electrons within a sphere of radius r and which is equivalent to a point negative charge located on the nucleus. The negative charge reduces the effective nuclear charge of the nucleus from Ze to $Z_{\text{eff}}e$.

Fig. 10.20 An electron in an s orbital (here a $3s$ orbital) is more likely to be found close to the nucleus than an electron in a p orbital of the same shell (note the closeness of the innermost peak of the $3s$ orbital to the nucleus at $r=0$). Hence an s electron experiences less shielding and is more tightly bound than a p electron.

 **Exploration** Calculate and plot the graphs given above for $n=4$.

Synoptic table 10.2* Effective nuclear charge, $Z_{\text{eff}} = Z - \sigma$

Element	Z	Orbital	Z_{eff}
He	2	1s	1.6875
C	6	1s	5.6727
		2s	3.2166
		2p	3.1358

* More values are given in the Data section.

attraction and the electronic repulsions in terms of a single equivalent charge at the centre of the atom.

The shielding constant is different for s and p electrons because they have different radial distributions (Fig. 10.20). An s electron has a greater **penetration** through inner shells than a p electron, in the sense that it is more likely to be found close to the nucleus than a p electron of the same shell (the wavefunction of a p orbital, remember, is zero at the nucleus). Because only electrons inside the sphere defined by the location of the electron (in effect, the core electrons) contribute to shielding, an s electron experiences less shielding than a p electron. Consequently, by the combined effects of penetration and shielding, an s electron is more tightly bound than a p electron of the same shell. Similarly, a d electron penetrates less than a p electron of the same shell (recall that the wavefunction of a d orbital varies as r^2 close to the nucleus, whereas a p orbital varies as r), and therefore experiences more shielding.

Shielding constants for different types of electrons in atoms have been calculated from their wavefunctions obtained by numerical solution of the Schrödinger equation for the atom (Table 10.2). We see that, in general, valence-shell s electrons do experience higher effective nuclear charges than p electrons, although there are some discrepancies. We return to this point shortly.

The consequence of penetration and shielding is that the energies of subshells of a shell in a many-electron atom in general lie in the order

$$s < p < d < f$$

The individual orbitals of a given subshell remain degenerate because they all have the same radial characteristics and so experience the same effective nuclear charge.

We can now complete the Li story. Because the shell with $n=2$ consists of two non-degenerate subshells, with the $2s$ orbital lower in energy than the three $2p$ orbitals, the third electron occupies the $2s$ orbital. This occupation results in the ground-state configuration $1s^2 2s^1$, with the central nucleus surrounded by a complete helium-like shell of two $1s$ electrons, and around that a more diffuse $2s$ electron. The electrons in the outermost shell of an atom in its ground state are called the **valence electrons** because they are largely responsible for the chemical bonds that the atom forms. Thus, the valence electron in Li is a $2s$ electron and its other two electrons belong to its core.

(d) The building-up principle

The extension of this argument is called the **building-up principle**, or the *Aufbau principle*, from the German word for building up, which will be familiar from introductory courses. In brief, we imagine the bare nucleus of atomic number Z , and then feed into the orbitals Z electrons in succession. The order of occupation is

$$1s \ 2s \ 2p \ 3s \ 3p \ 4s \ 3d \ 4p \ 5s \ 4d \ 5p \ 6s$$

and each orbital may accommodate up to two electrons. As an example, consider the carbon atom, for which $Z=6$ and there are six electrons to accommodate. Two electrons enter and fill the $1s$ orbital, two enter and fill the $2s$ orbital, leaving two electrons to occupy the orbitals of the $2p$ subshell. Hence the ground-state configuration of C is $1s^2 2s^2 2p^2$, or more succinctly $[\text{He}] 2s^2 2p^2$, with $[\text{He}]$ the helium-like $1s^2$ core. However, we can be more precise: we can expect the last two electrons to occupy different $2p$ orbitals because they will then be further apart on average and repel each other less than if they were in the same orbital. Thus, one electron can be thought of as occupying the $2p_x$ orbital and the other the $2p_y$ orbital (the x , y , z designation is arbitrary, and it would be equally valid to use the complex forms of these orbitals), and the lowest energy configuration of the atom is $[\text{He}] 2s^2 2p_x^1 2p_y^1$. The same rule

applies whenever degenerate orbitals of a subshell are available for occupation. Thus, another rule of the building-up principle is:

Electrons occupy different orbitals of a given subshell before doubly occupying any one of them.

For instance, nitrogen ($Z = 7$) has the configuration $[\text{He}]2s^2 2p_x^1 2p_y^1 2p_z^1$, and only when we get to oxygen ($Z = 8$) is a $2p$ orbital doubly occupied, giving $[\text{He}]2s^2 2p_x^2 2p_y^1 2p_z^1$. When electrons occupy orbitals singly we invoke **Hund's maximum multiplicity rule**:

An atom in its ground state adopts a configuration with the greatest number of unpaired electrons.

The explanation of Hund's rule is subtle, but it reflects the quantum mechanical property of **spin correlation**, that electrons with parallel spins behave as if they have a tendency to stay well apart, and hence repel each other less. In essence, the effect of spin correlation is to allow the atom to shrink slightly, so the electron–nucleus interaction is improved when the spins are parallel. We can now conclude that, in the ground state of the carbon atom, the two $2p$ electrons have the same spin, that all three $2p$ electrons in the N atoms have the same spin, and that the two $2p$ electrons in different orbitals in the O atom have the same spin (the two in the $2p_x$ orbital are necessarily paired).

Justification 10.6 Spin correlation

Suppose electron 1 is described by a wavefunction $\psi_a(\mathbf{r}_1)$ and electron 2 is described by a wavefunction $\psi_b(\mathbf{r}_2)$; then, in the orbital approximation, the joint wavefunction of the electrons is the product $\psi = \psi_a(\mathbf{r}_1)\psi_b(\mathbf{r}_2)$. However, this wavefunction is not acceptable, because it suggests that we know which electron is in which orbital, whereas we cannot keep track of electrons. According to quantum mechanics, the correct description is either of the two following wavefunctions:

$$\psi_{\pm} = (1/2^{1/2})\{\psi_a(\mathbf{r}_1)\psi_b(\mathbf{r}_2) \pm \psi_b(\mathbf{r}_1)\psi_a(\mathbf{r}_2)\}$$

According to the Pauli principle, because ψ_+ is symmetrical under particle interchange, it must be multiplied by an antisymmetric spin function (the one denoted σ_-). That combination corresponds to a spin-paired state. Conversely, ψ_- is antisymmetric, so it must be multiplied by one of the three symmetric spin states. These three symmetric states correspond to electrons with parallel spins (see Section 10.7 for an explanation).

Now consider the values of the two combinations when one electron approaches another, and $\mathbf{r}_1 = \mathbf{r}_2$. We see that ψ_- vanishes, which means that there is zero probability of finding the two electrons at the same point in space when they have parallel spins. The other combination does not vanish when the two electrons are at the same point in space. Because the two electrons have different relative spatial distributions depending on whether their spins are parallel or not, it follows that their Coulombic interaction is different, and hence that the two states have different energies.

Neon, with $Z = 10$, has the configuration $[\text{He}]2s^2 2p^6$, which completes the L shell. This closed-shell configuration is denoted $[\text{Ne}]$, and acts as a core for subsequent elements. The next electron must enter the $3s$ orbital and begin a new shell, so an Na atom, with $Z = 11$, has the configuration $[\text{Ne}]3s^1$. Like lithium with the configuration $[\text{He}]2s^1$, sodium has a single s electron outside a complete core. This analysis has brought us to the origin of chemical periodicity. The L shell is completed by eight electrons, so the element with $Z = 3$ (Li) should have similar properties to the element with $Z = 11$ (Na). Likewise, Be ($Z = 4$) should be similar to $Z = 12$ (Mg), and so on, up to the noble gases He ($Z = 2$), Ne ($Z = 10$), and Ar ($Z = 18$).

Fig. 10.21 Strong electron–electron repulsions in the $3d$ orbitals are minimized in the ground state of Sc if the atom has the configuration $[\text{Ar}]3d^1 4s^2$ (shown on the left) instead of $[\text{Ar}]3d^2 4s^1$ (shown on the right). The total energy of the atom is lower when it has the $[\text{Ar}]3d^1 4s^2$ configuration despite the cost of populating the high energy $4s$ orbital.

Ten electrons can be accommodated in the five $3d$ orbitals, which accounts for the electron configurations of scandium to zinc. Calculations of the type discussed in Section 10.5 show that for these atoms the energies of the $3d$ orbitals are always lower than the energy of the $4s$ orbital. However, spectroscopic results show that Sc has the configuration $[\text{Ar}]3d^1 4s^2$, instead of $[\text{Ar}]3d^3$ or $[\text{Ar}]3d^2 4s^1$. To understand this observation, we have to consider the nature of electron–electron repulsions in $3d$ and $4s$ orbitals. The most probable distance of a $3d$ electron from the nucleus is less than that for a $4s$ electron, so two $3d$ electrons repel each other more strongly than two $4s$ electrons. As a result, Sc has the configuration $[\text{Ar}]3d^1 4s^2$ rather than the two alternatives, for then the strong electron–electron repulsions in the $3d$ orbitals are minimized. The total energy of the atom is least despite the cost of allowing electrons to populate the high energy $4s$ orbital (Fig. 10.21). The effect just described is generally true for scandium through zinc, so their electron configurations are of the form $[\text{Ar}]3d^n 4s^2$, where $n = 1$ for scandium and $n = 10$ for zinc. Two notable exceptions, which are observed experimentally, are Cr, with electron configuration $[\text{Ar}]3d^5 4s^1$, and Cu, with electron configuration $[\text{Ar}]3d^{10} 4s^1$ (see *Further reading* for a discussion of the theoretical basis for these exceptions).

At gallium, the building-up principle is used in the same way as in preceding periods. Now the $4s$ and $4p$ subshells constitute the valence shell, and the period terminates with krypton. Because 18 electrons have intervened since argon, this period is the first ‘long period’ of the periodic table. The existence of the d -block elements (the ‘transition metals’) reflects the stepwise occupation of the $3d$ orbitals, and the subtle shades of energy differences and effects of electron–electron repulsion along this series gives rise to the rich complexity of inorganic d -metal chemistry. A similar intrusion of the f orbitals in Periods 6 and 7 accounts for the existence of the f block of the periodic table (the lanthanoids and actinoids).

We derive the configurations of cations of elements in the s , p , and d blocks of the periodic table by removing electrons from the ground-state configuration of the neutral atom in a specific order. First, we remove valence p electrons, then valence s electrons, and then as many d electrons as are necessary to achieve the specified charge. For instance, because the configuration of V is $[\text{Ar}]3d^3 4s^2$, the V^{2+} cation has the configuration $[\text{Ar}]3d^3$. It is reasonable that we remove the more energetic $4s$ electrons in order to form the cation, but it is not obvious why the $[\text{Ar}]3d^3$ configuration is preferred in V^{2+} over the $[\text{Ar}]3d^1 4s^2$ configuration, which is found in the isoelectronic Sc atom. Calculations show that the energy difference between $[\text{Ar}]3d^3$ and $[\text{Ar}]3d^1 4s^2$ depends on Z_{eff} . As Z_{eff} increases, transfer of a $4s$ electron to a $3d$ orbital becomes more favourable because the electron–electron repulsions are compensated by attractive interactions between the nucleus and the electrons in the spatially compact $3d$ orbital. Indeed, calculations reveal that, for a sufficiently large Z_{eff} , $[\text{Ar}]3d^3$ is lower in energy than $[\text{Ar}]3d^1 4s^2$. This conclusion explains why V^{2+} has a $[\text{Ar}]3d^3$ configuration and also accounts for the observed $[\text{Ar}]4s^0 3d^n$ configurations of the M^{2+} cations of Sc through Zn.

The configurations of anions of the p -block elements are derived by continuing the building-up procedure and adding electrons to the neutral atom until the configuration of the next noble gas has been reached. Thus, the configuration of the O^{2-} ion is achieved by adding two electrons to $[\text{He}]2s^2 2p^4$, giving $[\text{He}]2s^2 2p^6$, the same as the configuration of neon.

Comment 10.4

The web site for this text contains links to databases of atomic properties.

(e) Ionization energies and electron affinities

The minimum energy necessary to remove an electron from a many-electron atom in the gas phase is the **first ionization energy**, I_1 , of the element. The **second ionization energy**, I_2 , is the minimum energy needed to remove a second electron (from the

Fig. 10.22 The first ionization energies of the elements plotted against atomic number.

singly charged cation). The variation of the first ionization energy through the periodic table is shown in Fig. 10.22 and some numerical values are given in Table 10.3. In thermodynamic calculations we often need the **standard enthalpy of ionization**, $\Delta_{\text{ion}}H^\circ$. As shown in the *Justification* below, the two are related by

$$\Delta_{\text{ion}}H^\circ(T) = I + \frac{5}{2}RT \quad (10.34)$$

At 298 K, the difference between the ionization enthalpy and the corresponding ionization energy is 6.20 kJ mol^{-1} .

Justification 10.7 *The ionization enthalpy and the ionization energy*

It follows from Kirchhoff's law (Section 2.9 and eqn 2.36) that the reaction enthalpy for

at a temperature T is related to the value at $T = 0$ by

$$\Delta_{\text{r}}H^\circ(T) = \Delta_{\text{r}}H^\circ(0) + \int_0^T \Delta_{\text{r}}C_p^\circ dT$$

The molar constant-pressure heat capacity of each species in the reaction is $\frac{5}{2}R$, so $\Delta_{\text{r}}C_p^\circ = +\frac{5}{2}R$. The integral in this expression therefore evaluates to $+\frac{5}{2}RT$. The reaction enthalpy at $T = 0$ is the same as the (molar) ionization energy, I . Equation 10.33 then follows. The same expression applies to each successive ionization step, so the overall ionization enthalpy for the formation of M^{2+} is

$$\Delta_{\text{r}}H^\circ(T) = I_1 + I_2 + 5RT$$

The **electron affinity**, E_{ea} , is the energy released when an electron attaches to a gas-phase atom (Table 10.4). In a common, logical, but not universal convention (which we adopt), the electron affinity is positive if energy is released when the electron attaches to the atom (that is, $E_{\text{ea}} > 0$ implies that electron attachment is exothermic). It follows from a similar argument to that given in the *Justification* above that the **standard enthalpy of electron gain**, $\Delta_{\text{eg}}H^\circ$, at a temperature T is related to the electron affinity by

$$\Delta_{\text{eg}}H^\circ(T) = -E_{\text{ea}} - \frac{5}{2}RT \quad (10.35)$$

Note the change of sign. In typical thermodynamic cycles the $\frac{5}{2}RT$ that appears in eqn 10.35 cancels that in eqn 10.34, so ionization energies and electron affinities can be used directly. A final preliminary point is that the electron-gain enthalpy of a species X is the negative of the ionization enthalpy of its negative ion:

$$\Delta_{\text{eg}}H^\circ(X) = -\Delta_{\text{ion}}H^\circ(X^-) \quad (10.36)$$

As ionization energy is often easier to measure than electron affinity, this relation can be used to determine numerical values of the latter.

As will be familiar from introductory chemistry, ionization energies and electron affinities show periodicities. The former is more regular and we concentrate on it. Lithium has a low first ionization energy because its outermost electron is well shielded from the nucleus by the core ($Z_{\text{eff}} = 1.3$, compared with $Z = 3$). The ionization energy of beryllium ($Z = 4$) is greater but that of boron is lower because in the latter the outermost electron occupies a $2p$ orbital and is less strongly bound than if it had been a $2s$ electron. The ionization energy increases from boron to nitrogen on account of the increasing nuclear charge. However, the ionization energy of oxygen is less than would be expected by simple extrapolation. The explanation is that at oxygen a $2p$ orbital must become doubly occupied, and the electron–electron repulsions are increased above what would be expected by simple extrapolation along the row. In addition, the loss of a $2p$ electron results in a configuration with a half-filled subshell (like that of N), which is an arrangement of low energy, so the energy of $\text{O}^+ + e^-$ is lower than might be expected, and the ionization energy is correspondingly low too. (The kink is less pronounced in the next row, between phosphorus and sulfur because their orbitals are more diffuse.) The values for oxygen, fluorine, and neon fall roughly on the same line, the increase of their ionization energies reflecting the increasing attraction of the more highly charged nuclei for the outermost electrons.

The outermost electron in sodium is $3s$. It is far from the nucleus, and the latter's charge is shielded by the compact, complete neon-like core. As a result, the ionization energy of sodium is substantially lower than that of neon. The periodic cycle starts again along this row, and the variation of the ionization energy can be traced to similar reasons.

Electron affinities are greatest close to fluorine, for the incoming electron enters a vacancy in a compact valence shell and can interact strongly with the nucleus. The attachment of an electron to an anion (as in the formation of O^{2-} from O^-) is invariably endothermic, so E_{ea} is negative. The incoming electron is repelled by the charge already present. Electron affinities are also small, and may be negative, when an electron enters an orbital that is far from the nucleus (as in the heavier alkali metal atoms) or is forced by the Pauli principle to occupy a new shell (as in the noble gas atoms).

10.5 Self-consistent field orbitals

The central difficulty of the Schrödinger equation is the presence of the electron–electron interaction terms. The potential energy of the electrons is

$$V = -\sum_i \frac{Ze^2}{4\pi\epsilon_0 r_i} + \frac{1}{2} \sum'_{i,j} \frac{e^2}{4\pi\epsilon_0 r_{ij}} \quad (10.37)$$

The prime on the second sum indicates that $i \neq j$, and the factor of one-half prevents double-counting of electron pair repulsions (1 with 2 is the same as 2 with 1). The first term is the total attractive interaction between the electrons and the nucleus. The second term is the total repulsive interaction between the electrons; r_{ij} is the distance between electrons i and j . It is hopeless to expect to find analytical solutions of a Schrödinger equation with such a complicated potential energy term, but computational techniques are available that give very detailed and reliable numerical solutions for the wavefunctions and energies. The techniques were originally introduced by D.R. Hartree (before computers were available) and then modified by V. Fock to take into account the Pauli principle correctly. In broad outline, the **Hartree–Fock self-consistent field** (HF-SCF) procedure is as follows.

Imagine that we have a rough idea of the structure of the atom. In the Ne atom, for instance, the orbital approximation suggests the configuration $1s^2 2s^2 2p^6$ with the orbitals approximated by hydrogenic atomic orbitals. Now consider one of the $2p$ electrons. A Schrödinger equation can be written for this electron by ascribing to it a potential energy due to the nuclear attraction and the repulsion from the other electrons. This equation has the form

$$H(1)\psi_{2p}(1) + V(\text{other electrons})\psi_{2p}(1) - V(\text{exchange correction})\psi_{2p}(1) = E_{2p}\psi_{2p}(1) \quad (10.38)$$

A similar equation can be written for the $1s$ and $2s$ orbitals in the atom. The various terms are as follows:

- 1 The first term on the left is the contribution of the kinetic energy and the attraction of the electron to the nucleus, just as in a hydrogenic atom.
- 2 The second takes into account the potential energy of the electron of interest due to the electrons in the other occupied orbitals.
- 3 The third term takes into account the spin correlation effects discussed earlier.

Although the equation is for the $2p$ orbital in neon, it depends on the wavefunctions of all the other occupied orbitals in the atom.

There is no hope of solving eqn 10.38 analytically. However, it can be solved numerically if we guess an approximate form of the wavefunctions of all the orbitals except $2p$. The procedure is then repeated for the other orbitals in the atom, the $1s$ and $2s$ orbitals. This sequence of calculations gives the form of the $2p$, $2s$, and $1s$ orbitals, and in general they will differ from the set used initially to start the calculation. These improved orbitals can be used in another cycle of calculation, and a second improved set of orbitals is obtained. The recycling continues until the orbitals and energies obtained are insignificantly different from those used at the start of the current cycle. The solutions are then self-consistent and accepted as solutions of the problem.

Figure 10.23 shows plots of some of the HF-SCF radial distribution functions for sodium. They show the grouping of electron density into shells, as was anticipated by the early chemists, and the differences of penetration as discussed above. These SCF calculations therefore support the qualitative discussions that are used to explain chemical periodicity. They also considerably extend that discussion by providing detailed wavefunctions and precise energies.

Fig. 10.23 The radial distribution functions for the orbitals of Na based on SCF calculations. Note the shell-like structure, with the $3s$ orbital outside the inner K and L shells.

The spectra of complex atoms

The spectra of atoms rapidly become very complicated as the number of electrons increases, but there are some important and moderately simple features that make atomic spectroscopy useful in the study of the composition of samples as large and as complex as stars (*Impact I10.1*). The general idea is straightforward: lines in the spectrum (in either emission or absorption) occur when the atom undergoes a transition with a change of energy $|\Delta E|$, and emits or absorbs a photon of frequency $\nu = |\Delta E|/h$ and $\tilde{\nu} = |\Delta E|/hc$. Hence, we can expect the spectrum to give information about the energies of electrons in atoms. However, the actual energy levels are not given solely by the energies of the orbitals, because the electrons interact with one another in various ways, and there are contributions to the energy in addition to those we have already considered.

Comment 10.5

The web site for this text contains links to databases of atomic spectra.

IMPACT ON ASTROPHYSICS

10.1 Spectroscopy of stars

The bulk of stellar material consists of neutral and ionized forms of hydrogen and helium atoms, with helium being the product of ‘hydrogen burning’ by nuclear fusion. However, nuclear fusion also makes heavier elements. It is generally accepted that the outer layers of stars are composed of lighter elements, such as H, He, C, N, O, and Ne in both neutral and ionized forms. Heavier elements, including neutral and ionized forms of Si, Mg, Ca, S, and Ar, are found closer to the stellar core. The core itself contains the heaviest elements and ^{56}Fe is particularly abundant because it is a very stable nuclide. All these elements are in the gas phase on account of the very high temperatures in stellar interiors. For example, the temperature is estimated to be 3.6 MK half way to the centre of the Sun.

Astronomers use spectroscopic techniques to determine the chemical composition of stars because each element, and indeed each isotope of an element, has a characteristic spectral signature that is transmitted through space by the star’s light. To understand the spectra of stars, we must first know why they shine. Nuclear reactions in the dense stellar interior generate radiation that travels to less dense outer layers. Absorption and re-emission of photons by the atoms and ions in the interior give rise to a quasi-continuum of radiation energy that is emitted into space by a thin layer of gas called the *photosphere*. To a good approximation, the distribution of energy emitted from a star’s photosphere resembles the Planck distribution for a very hot black body (Section 8.1). For example, the energy distribution of our Sun’s photosphere may be modelled by a Planck distribution with an effective temperature of 5.8 kK. Superimposed on the black-body radiation continuum are sharp absorption and emission lines from neutral atoms and ions present in the photosphere. Analysis of stellar radiation with a spectrometer mounted on to a telescope yields the chemical composition of the star’s photosphere by comparison with known spectra of the elements. The data can also reveal the presence of small molecules, such as CN, C_2 , TiO, and ZrO, in certain ‘cold’ stars, which are stars with relatively low effective temperatures.

The two outermost layers of a star are the *chromosphere*, a region just above the photosphere, and the *corona*, a region above the chromosphere that can be seen (with proper care) during eclipses. The photosphere, chromosphere, and corona comprise a star’s ‘atmosphere’. Our Sun’s chromosphere is much less dense than its photosphere and its temperature is much higher, rising to about 10 kK. The reasons for this increase in temperature are not fully understood. The temperature of our Sun’s corona is very high, rising up to 1.5 MK, so black-body emission is strong from the X-ray to the radio-frequency region of the spectrum. The spectrum of the Sun’s corona is dominated by emission lines from electronically excited species, such as neutral atoms and a number of highly ionized species. The most intense emission lines in the visible range are from the Fe^{13+} ion at 530.3 nm, the Fe^{9+} ion at 637.4 nm, and the Ca^{4+} ion at 569.4 nm.

Because only light from the photosphere reaches our telescopes, the overall chemical composition of a star must be inferred from theoretical work on its interior and from spectral analysis of its atmosphere. Data on the Sun indicate that it is 92 per cent hydrogen and 7.8 per cent helium. The remaining 0.2 per cent is due to heavier elements, among which C, N, O, Ne, and Fe are the most abundant. More advanced analysis of spectra also permit the determination of other properties of stars, such as their relative speeds (Problem 10.27) and their effective temperatures (Problem 13.29).

10.6 Quantum defects and ionization limits

One application of atomic spectroscopy is to the determination of ionization energies. However, we cannot use the procedure illustrated in Example 10.1 indiscriminately

because the energy levels of a many-electron atom do not in general vary as $1/n^2$. If we confine attention to the outermost electrons, then we know that, as a result of penetration and shielding, they experience a nuclear charge of slightly more than $1e$ because in a neutral atom the other $Z - 1$ electrons cancel all but about one unit of nuclear charge. Typical values of Z_{eff} are a little more than 1, so we expect binding energies to be given by a term of the form $-hcR/n^2$, but lying slightly lower in energy than this formula predicts. We therefore introduce a **quantum defect**, δ , and write the energy as $-hcR/(n - \delta)^2$. The quantum defect is best regarded as a purely empirical quantity.

There are some excited states that are so diffuse that the $1/n^2$ variation is valid: these states are called **Rydberg states**. In such cases we can write

$$\tilde{\nu} = \frac{I}{hc} - \frac{R}{n^2} \quad (10.39)$$

and a plot of wavenumber against $1/n^2$ can be used to obtain I by extrapolation; in practice, one would use a linear regression fit using a computer. If the lower state is not the ground state (a possibility if we wish to generalize the concept of ionization energy), the ionization energy of the ground state can be determined by adding the appropriate energy difference to the ionization energy obtained as described here.

10.7 Singlet and triplet states

Suppose we were interested in the energy levels of a He atom, with its two electrons. We know that the ground-state configuration is $1s^2$, and can anticipate that an excited configuration will be one in which one of the electrons has been promoted into a $2s$ orbital, giving the configuration $1s^1 2s^1$. The two electrons need not be paired because they occupy different orbitals. According to Hund's maximum multiplicity rule, the state of the atom with the spins parallel lies lower in energy than the state in which they are paired. Both states are permissible, and can contribute to the spectrum of the atom.

Parallel and antiparallel (paired) spins differ in their overall spin angular momentum. In the paired case, the two spin momenta cancel each other, and there is zero net spin (as was depicted in Fig. 10.18). The paired-spin arrangement is called a **singlet**. Its spin state is the one we denoted σ_- in the discussion of the Pauli principle:

$$\sigma_-(1,2) = (1/2^{1/2})\{\alpha(1)\beta(2) - \beta(1)\alpha(2)\} \quad (10.40a)$$

The angular momenta of two parallel spins add together to give a nonzero total spin, and the resulting state is called a **triplet**. As illustrated in Fig. 10.24, there are three ways of achieving a nonzero total spin, but only one way to achieve zero spin. The three spin states are the symmetric combinations introduced earlier:

$$\alpha(1)\alpha(2) \quad \sigma_+(1,2) = (1/2^{1/2})\{\alpha(1)\beta(2) + \beta(1)\alpha(2)\} \quad \beta(1)\beta(2) \quad (10.40b)$$

The fact that the parallel arrangement of spins in the $1s^1 2s^1$ configuration of the He atom lies lower in energy than the antiparallel arrangement can now be expressed by saying that the triplet state of the $1s^1 2s^1$ configuration of He lies lower in energy than the singlet state. This is a general conclusion that applies to other atoms (and molecules) and, *for states arising from the same configuration, the triplet state generally lies lower than the singlet state*. The origin of the energy difference lies in the effect of spin correlation on the Coulombic interactions between electrons, as we saw in the case of Hund's rule for ground-state configurations. Because the Coulombic interaction between electrons in an atom is strong, the difference in energies between singlet and triplet states of the same configuration can be large. The two states of $1s^1 2s^1$ He, for instance, differ by 6421 cm^{-1} (corresponding to 0.80 eV).

Fig. 10.24 When two electrons have parallel spins, they have a nonzero total spin angular momentum. There are three ways of achieving this resultant, which are shown by these vector representations. Note that, although we cannot know the orientation of the spin vectors on the cones, the angle between the vectors is the same in all three cases, for all three arrangements have the same total spin angular momentum (that is, the resultant of the two vectors has the same length in each case, but points in different directions). Compare this diagram with Fig. 10.18, which shows the antiparallel case. Note that, whereas two paired spins are precisely antiparallel, two 'parallel' spins are not strictly parallel.

Fig. 10.25 Part of the Grotrian diagram for a helium atom. Note that there are no transitions between the singlet and triplet levels.

The spectrum of atomic helium is more complicated than that of atomic hydrogen, but there are two simplifying features. One is that the only excited configurations it is necessary to consider are of the form $1s^1nl^1$: that is, only one electron is excited. Excitation of two electrons requires an energy greater than the ionization energy of the atom, so the He^+ ion is formed instead of the doubly excited atom. Second, no radiative transitions take place between singlet and triplet states because the relative orientation of the two electron spins cannot change during a transition. Thus, there is a spectrum arising from transitions between singlet states (including the ground state) and between triplet states, but not between the two. Spectroscopically, helium behaves like two distinct species, and the early spectroscopists actually thought of helium as consisting of ‘parahelium’ and ‘orthohelium’. The Grotrian diagram for helium in Fig. 10.25 shows the two sets of transitions.

Comment 10.6

We have already remarked that the electron’s spin is a purely quantum mechanical phenomenon that has no classical counterpart. However a classical model can give us partial insight into the origin of an electron’s magnetic moment. Namely, the magnetic field generated by a spinning electron, regarded classically as a moving charge, induces a magnetic moment. This model is merely a visualization aid and cannot be used to explain the magnitude of the magnetic moment of the electron or the origin of spin magnetic moments in electrically neutral particles, such as the neutron.

10.8 Spin–orbit coupling

An electron has a magnetic moment that arises from its spin (Fig. 10.26). Similarly, an electron with orbital angular momentum (that is, an electron in an orbital with $l > 0$) is in effect a circulating current, and possesses a magnetic moment that arises from its orbital momentum. The interaction of the spin magnetic moment with the magnetic field arising from the orbital angular momentum is called **spin–orbit coupling**. The strength of the coupling, and its effect on the energy levels of the atom, depend on the relative orientations of the spin and orbital magnetic moments, and therefore on the relative orientations of the two angular momenta (Fig. 10.27).

(a) The total angular momentum

One way of expressing the dependence of the spin–orbit interaction on the relative orientation of the spin and orbital momenta is to say that it depends on the total angular momentum of the electron, the vector sum of its spin and orbital momenta. Thus, when the spin and orbital angular momenta are nearly parallel, the total angular

Fig. 10.26 Angular momentum gives rise to a magnetic moment (μ). For an electron, the magnetic moment is antiparallel to the orbital angular momentum, but proportional to it. For spin angular momentum, there is a factor 2, which increases the magnetic moment to twice its expected value (see Section 10.10).

Fig. 10.27 Spin-orbit coupling is a magnetic interaction between spin and orbital magnetic moments. When the angular momenta are parallel, as in (a), the magnetic moments are aligned unfavourably; when they are opposed, as in (b), the interaction is favourable. This magnetic coupling is the cause of the splitting of a configuration into levels.

momentum is high; when the two angular momenta are opposed, the total angular momentum is low.

The total angular momentum of an electron is described by the quantum numbers j and m_j , with $j = l + \frac{1}{2}$ (when the two angular momenta are in the same direction) or $j = l - \frac{1}{2}$ (when they are opposed, Fig. 10.28). The different values of j that can arise for a given value of l label **levels** of a term. For $l = 0$, the only permitted value is $j = \frac{1}{2}$ (the total angular momentum is the same as the spin angular momentum because there is no other source of angular momentum in the atom). When $l = 1$, j may be either $\frac{3}{2}$ (the spin and orbital angular momenta are in the same sense) or $\frac{1}{2}$ (the spin and angular momenta are in opposite senses).

Fig. 10.28 The coupling of the spin and orbital angular momenta of a d electron ($l = 2$) gives two possible values of j depending on the relative orientations of the spin and orbital angular momenta of the electron.

Example 10.4 Identifying the levels of a configuration

Identify the levels that may arise from the configurations (a) d^1 , (b) s^1 .

Method In each case, identify the value of l and then the possible values of j . For these one-electron systems, the total angular momentum is the sum and difference of the orbital and spin momenta.

Answer (a) For a d electron, $l = 2$ and there are two levels in the configuration, one with $j = 2 + \frac{1}{2} = \frac{5}{2}$ and the other with $j = 2 - \frac{1}{2} = \frac{3}{2}$. (b) For an s electron $l = 0$, so only one level is possible, and $j = \frac{1}{2}$.

Self-test 10.8 Identify the levels of the configurations (a) p^1 and (b) f^1 .

[(a) $\frac{3}{2}, \frac{1}{2}$; (b) $\frac{7}{2}, \frac{5}{2}$]

The dependence of the spin–orbit interaction on the value of j is expressed in terms of the **spin–orbit coupling constant**, A (which is typically expressed as a wavenumber). A quantum mechanical calculation leads to the result that the energies of the levels with quantum numbers s , l , and j are given by

$$E_{l,s,j} = \frac{1}{2}hcA\{j(j+1) - l(l+1) - s(s+1)\} \quad (10.41)$$

Comment 10.7

The scalar product (or dot product) $\mathbf{u} \cdot \mathbf{v}$ of two vectors $\mathbf{u}$ and $\mathbf{v}$ with magnitudes u and v is $\mathbf{u} \cdot \mathbf{v} = uv \cos \theta$, where θ is the angle between the two vectors.

Justification 10.8 The energy of spin–orbit interaction

The energy of a magnetic moment $\boldsymbol{\mu}$ in a magnetic field $\mathbf{B}$ is equal to their scalar product $-\boldsymbol{\mu} \cdot \mathbf{B}$. If the magnetic field arises from the orbital angular momentum of the electron, it is proportional to $\mathbf{l}$; if the magnetic moment $\boldsymbol{\mu}$ is that of the electron spin, then it is proportional to $\mathbf{s}$. It then follows that the energy of interaction is proportional to the scalar product $\mathbf{s} \cdot \mathbf{l}$:

$$\text{Energy of interaction} = -\boldsymbol{\mu} \cdot \mathbf{B} \propto \mathbf{s} \cdot \mathbf{l}$$

We take this expression to be the first-order perturbation contribution to the hamiltonian. Next, we note that the total angular momentum is the vector sum of the spin and orbital momenta: $\mathbf{j} = \mathbf{l} + \mathbf{s}$. The magnitude of the vector $\mathbf{j}$ is calculated by evaluating

$$\mathbf{j} \cdot \mathbf{j} = (\mathbf{l} + \mathbf{s}) \cdot (\mathbf{l} + \mathbf{s}) = \mathbf{l} \cdot \mathbf{l} + \mathbf{s} \cdot \mathbf{s} + 2\mathbf{s} \cdot \mathbf{l}$$

That is,

$$\mathbf{s} \cdot \mathbf{l} = \frac{1}{2}\{j^2 - l^2 - s^2\}$$

where we have used the fact that the scalar product of two vectors $\mathbf{u}$ and $\mathbf{v}$ is $\mathbf{u} \cdot \mathbf{v} = uv \cos \theta$, from which it follows that $\mathbf{u} \cdot \mathbf{u} = u^2$.

The preceding equation is a classical result. To make the transition to quantum mechanics, we treat all the quantities as operators, and write

$$\hat{\mathbf{s}} \cdot \hat{\mathbf{l}} = \frac{1}{2}\{\hat{j}^2 - \hat{l}^2 - \hat{s}^2\} \quad (10.42)$$

At this point, we calculate the first-order correction to the energy by evaluating the expectation value:

$$\langle j, l, s | \hat{\mathbf{s}} \cdot \hat{\mathbf{l}} | j, l, s \rangle = \frac{1}{2} \langle j, l, s | \hat{j}^2 - \hat{l}^2 - \hat{s}^2 | j, l, s \rangle = \frac{1}{2} \{j(j+1) - l(l+1) - s(s+1)\} \hbar^2 \quad (10.43)$$

Then, by inserting this expression into the formula for the energy of interaction ($E \propto \mathbf{s} \cdot \mathbf{l}$), and writing the constant of proportionality as $hcA/\hbar^2$, we obtain eqn 10.42. The calculation of A is much more complicated: see *Further reading*.

Fig. 10.29 The levels of a $2p$ term arising from spin–orbit coupling. Note that the low- j level lies below the high- j level in energy.

Illustration 10.3 Calculating the energies of levels

The unpaired electron in the ground state of an alkali metal atom has $l = 0$, so $j = \frac{1}{2}$. Because the orbital angular momentum is zero in this state, the spin–orbit coupling energy is zero (as is confirmed by setting $j = s$ and $l = 0$ in eqn 10.41). When the electron is excited to an orbital with $l = 1$, it has orbital angular momentum and can give rise to a magnetic field that interacts with its spin. In this configuration the electron can have $j = \frac{3}{2}$ or $j = \frac{1}{2}$, and the energies of these levels are

$$E_{3/2} = \frac{1}{2}hcA\left\{\frac{3}{2} \times \frac{5}{2} - 1 \times 2 - \frac{1}{2} \times \frac{3}{2}\right\} = \frac{1}{2}hcA$$

$$E_{1/2} = \frac{1}{2}hcA\left\{\frac{1}{2} \times \frac{3}{2} - 1 \times 2 - \frac{1}{2} \times \frac{3}{2}\right\} = -hcA$$

The corresponding energies are shown in Fig. 10.29. Note that the baricentre (the ‘centre of gravity’) of the levels is unchanged, because there are four states of energy $\frac{1}{2}hcA$ and two of energy $-hcA$.

The strength of the spin-orbit coupling depends on the nuclear charge. To understand why this is so, imagine riding on the orbiting electron and seeing a charged nucleus apparently orbiting around us (like the Sun rising and setting). As a result, we find ourselves at the centre of a ring of current. The greater the nuclear charge, the greater this current, and therefore the stronger the magnetic field we detect. Because the spin magnetic moment of the electron interacts with this orbital magnetic field, it follows that the greater the nuclear charge, the stronger the spin-orbit interaction. The coupling increases sharply with atomic number (as Z^4). Whereas it is only small in H (giving rise to shifts of energy levels of no more than about 0.4 cm^{-1}), in heavy atoms like Pb it is very large (giving shifts of the order of thousands of reciprocal centimetres).

(b) Fine structure

Two spectral lines are observed when the p electron of an electronically excited alkali metal atom undergoes a transition and falls into a lower s orbital. One line is due to a transition starting in a $j = \frac{3}{2}$ level and the other line is due to a transition starting in the $j = \frac{1}{2}$ level of the same configuration. The two lines are an example of the **fine structure** of a spectrum, the structure in a spectrum due to spin-orbit coupling. Fine structure can be clearly seen in the emission spectrum from sodium vapour excited by an electric discharge (for example, in one kind of street lighting). The yellow line at 589 nm (close to $17\,000 \text{ cm}^{-1}$) is actually a doublet composed of one line at 589.76 nm ($16\,956.2 \text{ cm}^{-1}$) and another at 589.16 nm ($16\,973.4 \text{ cm}^{-1}$); the components of this doublet are the 'D lines' of the spectrum (Fig. 10.30). Therefore, in Na, the spin-orbit coupling affects the energies by about 17 cm^{-1} .

Fig. 10.30 The energy-level diagram for the formation of the sodium D lines. The splitting of the spectral lines (by 17 cm^{-1}) reflects the splitting of the levels of the ^2P term.

Example 10.5 Analysing a spectrum for the spin-orbit coupling constant

The origin of the D lines in the spectrum of atomic sodium is shown in Fig. 10.30. Calculate the spin-orbit coupling constant for the upper configuration of the Na atom.

Method We see from Fig. 10.30 that the splitting of the lines is equal to the energy separation of the $j = \frac{3}{2}$ and $\frac{1}{2}$ levels of the excited configuration. This separation can be expressed in terms of A by using eqn 10.40. Therefore, set the observed splitting equal to the energy separation calculated from eqn 10.40 and solve the equation for A .

Answer The two levels are split by

$$\Delta\tilde{\nu} = A \left\{ \frac{1}{2} \left(\frac{3}{2} + 1 \right) - \frac{1}{2} \left(\frac{1}{2} + 1 \right) \right\} = \frac{3}{2}A$$

The experimental value is 17.2 cm^{-1} ; therefore

$$A = \frac{2}{3} \times (17.2 \text{ cm}^{-1}) = 11.5 \text{ cm}^{-1}$$

The same calculation repeated for the other alkali metal atoms gives Li: 0.23 cm^{-1} , K: 38.5 cm^{-1} , Rb: 158 cm^{-1} , Cs: 370 cm^{-1} . Note the increase of A with atomic number (but more slowly than Z^4 for these many-electron atoms).

Self-test 10.9 The configuration $\dots 4p^65d^1$ of rubidium has two levels at $25\,700.56 \text{ cm}^{-1}$ and $25\,703.52 \text{ cm}^{-1}$ above the ground state. What is the spin-orbit coupling constant in this excited state? $[1.18 \text{ cm}^{-1}]$

Fig. 10.31 A summary of the types of interaction that are responsible for the various kinds of splitting of energy levels in atoms. For light atoms, magnetic interactions are small, but in heavy atoms they may dominate the electrostatic (charge-charge) interactions.

Fig. 10.32 The total angular orbital momenta of a p electron and a d electron correspond to $L = 3, 2$, and 1 and reflect the different relative orientations of the two momenta.

10.9 Term symbols and selection rules

We have used expressions such as ‘the $j = \frac{3}{2}$ level of a configuration’. A **term symbol**, which is a symbol looking like $^2P_{3/2}$ or $^3D_2$, conveys this information much more succinctly. The convention of using lowercase letters to label orbitals and uppercase letters to label overall states applies throughout spectroscopy, not just to atoms.

A term symbol gives three pieces of information:

- 1 The letter (P or D in the examples) indicates the total orbital angular momentum quantum number, L .
- 2 The left superscript in the term symbol (the 2 in $^2P_{3/2}$) gives the multiplicity of the term.
- 3 The right subscript on the term symbol (the $\frac{3}{2}$ in $^2P_{3/2}$) is the value of the total angular momentum quantum number, J .

We shall now say what each of these statements means; the contributions to the energies which we are about to discuss are summarized in Fig. 10.31.

(a) The total orbital angular momentum

When several electrons are present, it is necessary to judge how their individual orbital angular momenta add together or oppose each other. The **total orbital angular momentum quantum number**, L , tells us the magnitude of the angular momentum through $\{L(L+1)\}^{1/2}\hbar$. It has $2L+1$ orientations distinguished by the quantum number M_L , which can take the values $L, L-1, \dots, -L$. Similar remarks apply to the **total spin quantum number**, S , and the quantum number M_S , and the **total angular momentum quantum number**, J , and the quantum number M_J .

The value of L (a non-negative integer) is obtained by coupling the individual orbital angular momenta by using the **Clebsch–Gordan series**:

$$L = l_1 + l_2, l_1 + l_2 - 1, \dots, |l_1 - l_2| \quad (10.44)$$

The modulus signs are attached to $l_1 - l_2$ because L is non-negative. The maximum value, $L = l_1 + l_2$, is obtained when the two orbital angular momenta are in the same direction; the lowest value, $|l_1 - l_2|$, is obtained when they are in opposite directions. The intermediate values represent possible intermediate relative orientations of the two momenta (Fig. 10.32). For two p electrons (for which $l_1 = l_2 = 1$), $L = 2, 1, 0$. The code for converting the value of L into a letter is the same as for the $s, p, d, f, \dots$ designation of orbitals, but uses uppercase Roman letters:

L :	0	1	2	3	4	5	6...
	S	P	D	F	G	H	I...

Thus, a p^2 configuration can give rise to D, P, and S terms. The terms differ in energy on account of the different spatial distribution of the electrons and the consequent differences in repulsion between them.

A closed shell has zero orbital angular momentum because all the individual orbital angular momenta sum to zero. Therefore, when working out term symbols, we need consider only the electrons of the unfilled shell. In the case of a single electron outside a closed shell, the value of L is the same as the value of l ; so the configuration $[\text{Ne}]3s^1$ has only an S term.

Example 10.6 Deriving the total orbital angular momentum of a configuration

Find the terms that can arise from the configurations (a) d^2 , (b) p^3 .

Method Use the Clebsch–Gordan series and begin by finding the minimum value of L (so that we know where the series terminates). When there are more than two electrons to couple together, use two series in succession: first couple two electrons, and then couple the third to each combined state, and so on.

Answer (a) The minimum value is $|l_1 - l_2| = |2 - 2| = 0$. Therefore,

$$L = 2 + 2, 2 + 2 - 1, \dots, 0 = 4, 3, 2, 1, 0$$

corresponding to G, F, D, P, S terms, respectively. (b) Coupling two electrons gives a minimum value of $|1 - 1| = 0$. Therefore,

$$L' = 1 + 1, 1 + 1 - 1, \dots, 0 = 2, 1, 0$$

Now couple l_3 with $L' = 2$, to give $L = 3, 2, 1$; with $L' = 1$, to give $L = 2, 1, 0$; and with $L' = 0$, to give $L = 1$. The overall result is

$$L = 3, 2, 2, 1, 1, 1, 0$$

giving one F, two D, three P, and one S term.

Self-test 10.10 Repeat the question for the configurations (a) $f^1 d^1$ and (b) d^3 .

[(a) H, G, F, D, P; (b) I, 2H, 3G, 4F, 5D, 3P, S]

(b) The multiplicity

When there are several electrons to be taken into account, we must assess their total spin angular momentum quantum number, S (a non-negative integer or half integer). Once again, we use the Clebsch–Gordan series in the form

$$S = s_1 + s_2, s_1 + s_2 - 1, \dots, |s_1 - s_2| \quad (10.45)$$

to decide on the value of S , noting that each electron has $s = \frac{1}{2}$, which gives $S = 1, 0$ for two electrons (Fig. 10.33). If there are three electrons, the total spin angular momentum is obtained by coupling the third spin to each of the values of S for the first two spins, which results in $S = \frac{3}{2}$, and $S = \frac{1}{2}$.

The **multiplicity** of a term is the value of $2S + 1$. When $S = 0$ (as for a closed shell, like $1s^2$) the electrons are all paired and there is no net spin: this arrangement gives a singlet term, ^1S . A single electron has $S = s = \frac{1}{2}$, so a configuration such as $[\text{Ne}]3s^1$ can give rise to a doublet term, ^2S . Likewise, the configuration $[\text{Ne}]3p^1$ is a doublet, ^2P . When there are two unpaired electrons $S = 1$, so $2S + 1 = 3$, giving a triplet term, such as ^3D . We discussed the relative energies of singlets and triplets in Section 10.7 and saw that their energies differ on account of the different effects of spin correlation.

(c) The total angular momentum

As we have seen, the quantum number j tells us the relative orientation of the spin and orbital angular momenta of a single electron. The **total angular momentum quantum number**, J (a non-negative integer or half integer), does the same for several electrons. If there is a single electron outside a closed shell, $J = j$, with j either $l + \frac{1}{2}$ or $|l - \frac{1}{2}|$. The $[\text{Ne}]3s^1$ configuration has $j = \frac{1}{2}$ (because $l = 0$ and $s = \frac{1}{2}$), so the $2s$ term has a single level, which we denote $^2S_{1/2}$. The $[\text{Ne}]3p^1$ configuration has $l = 1$; therefore

Comment 10.8

Throughout our discussion of atomic spectroscopy, distinguish *italic S*, the total spin quantum number, from **Roman S**, the term label.

Fig. 10.33 For two electrons (each of which has $s = \frac{1}{2}$), only two total spin states are permitted ($S = 0, 1$). The state with $S = 0$ can have only one value of M_S ($M_S = 0$) and is a singlet; the state with $S = 1$ can have any of three values of M_S ($+1, 0, -1$) and is a triplet. The vector representation of the singlet and triplet states are shown in Figs. 10.18 and 10.24, respectively.

$j = \frac{3}{2}$ and $\frac{1}{2}$; the ^2P term therefore has two levels, $^2P_{3/2}$ and $^2P_{1/2}$. These levels lie at different energies on account of the magnetic spin–orbit interaction.

If there are several electrons outside a closed shell we have to consider the coupling of all the spins and all the orbital angular momenta. This complicated problem can be simplified when the spin–orbit coupling is weak (for atoms of low atomic number), for then we can use the **Russell–Saunders coupling** scheme. This scheme is based on the view that, if spin–orbit coupling is weak, then it is effective only when all the orbital momenta are operating cooperatively. We therefore imagine that all the orbital angular momenta of the electrons couple to give a total L , and that all the spins are similarly coupled to give a total S . Only at this stage do we imagine the two kinds of momenta coupling through the spin–orbit interaction to give a total J . The permitted values of J are given by the Clebsch–Gordan series

$$J = L + S, L + S - 1, \dots, |L - S| \quad (10.46)$$

For example, in the case of the ^3D term of the configuration $[\text{Ne}]2p^13p^1$, the permitted values of J are 3, 2, 1 (because ^3D has $L = 2$ and $S = 1$), so the term has three levels, $^3D_3$, $^3D_2$, and $^3D_1$.

When $L \geq S$, the multiplicity is equal to the number of levels. For example, a ^2P term has the two levels $^2P_{3/2}$ and $^2P_{1/2}$, and ^3D has the three levels $^3D_3$, $^3D_2$, and $^3D_1$. However, this is not the case when $L < S$: the term ^2S , for example, has only the one level $^2S_{1/2}$.

Example 10.7 Deriving term symbols

Write the term symbols arising from the ground-state configurations of (a) Na and (b) F, and (c) the excited configuration $1s^22s^22p^13p^1$ of C.

Method Begin by writing the configurations, but ignore inner closed shells. Then couple the orbital momenta to find L and the spins to find S . Next, couple L and S to find J . Finally, express the term as $^{2S+1}\{L\}_J$, where $\{L\}$ is the appropriate letter. For F, for which the valence configuration is $2p^5$, treat the single gap in the closed-shell $2p^6$ configuration as a single particle.

Answer (a) For Na, the configuration is $[\text{Ne}]3s^1$, and we consider the single $3s$ electron. Because $L = l = 0$ and $S = s = \frac{1}{2}$, it is possible for $J = j = s = \frac{1}{2}$ only. Hence the term symbol is $^2S_{1/2}$. (b) For F, the configuration is $[\text{He}]2s^22p^5$, which we can treat as $[\text{Ne}]2p^{-1}$ (where the notation $2p^{-1}$ signifies the absence of a $2p$ electron). Hence $L = 1$, and $S = s = \frac{1}{2}$. Two values of $J = j$ are allowed: $J = \frac{3}{2}, \frac{1}{2}$. Hence, the term symbols for the two levels are $^2P_{3/2}$, $^2P_{1/2}$. (c) We are treating an excited configuration of carbon because, in the ground configuration, $2p^2$, the Pauli principle forbids some terms, and deciding which survive (^1D , ^3P , ^1S , in fact) is quite complicated. That is, there is a distinction between ‘equivalent electrons’, which are electrons that occupy the same orbitals, and ‘inequivalent electrons’, which are electrons that occupy different orbitals. For information about how to deal with equivalent electrons, see *Further reading*. The excited configuration of C under consideration is effectively $2p^13p^1$. This is a two-electron problem, and $l_1 = l_2 = 1$, $s_1 = s_2 = \frac{1}{2}$. It follows that $L = 2, 1, 0$ and $S = 1, 0$. The terms are therefore ^3D and ^1D , ^3P and ^1P , and ^3S and ^1S . For ^3D , $L = 2$ and $S = 1$; hence $J = 3, 2, 1$ and the levels are $^3D_3$, $^3D_2$, and $^3D_1$. For ^1D , $L = 2$ and $S = 0$, so the single level is $^1D_2$. The triplet of levels of ^3P is $^3P_2$, $^3P_1$, and $^3P_0$, and the singlet is $^1P_1$. For the ^3S term there is only one level, $^3S_1$ (because $J = 1$ only), and the singlet term is $^1S_0$.

Self-test 10.11 Write down the terms arising from the configurations (a) $2s^1 2p^1$, (b) $2p^1 3d^1$.

$$\begin{aligned} &[(a) \ ^3P_2, \ ^3P_1, \ ^3P_0, \ ^1P_1; \\ &(b) \ ^3F_4, \ ^3F_3, \ ^3F_2, \ ^1F_3, \ ^3D_3, \ ^3D_2, \ ^3D_1, \ ^1D_2, \ ^3P_1, \ ^3P_0, \ ^1P_1] \end{aligned}$$

Russell–Saunders coupling fails when the spin–orbit coupling is large (in heavy atoms). In that case, the individual spin and orbital momenta of the electrons are coupled into individual j values; then these momenta are combined into a grand total, J . This scheme is called ***jj*-coupling**. For example, in a p^2 configuration, the individual values of j are $\frac{3}{2}$ and $\frac{1}{2}$ for each electron. If the spin and the orbital angular momentum of each electron are coupled together strongly, it is best to consider each electron as a particle with angular momentum $j = \frac{3}{2}$ or $\frac{1}{2}$. These individual total momenta then couple as follows:

$$\begin{aligned} j_1 = \frac{3}{2} \text{ and } j_2 = \frac{3}{2} & \quad J = 3, 2, 1, 0 \\ j_1 = \frac{3}{2} \text{ and } j_2 = \frac{1}{2} & \quad J = 2, 1 \\ j_1 = \frac{1}{2} \text{ and } j_2 = \frac{3}{2} & \quad J = 2, 1 \\ j_1 = \frac{1}{2} \text{ and } j_2 = \frac{1}{2} & \quad J = 1, 0 \end{aligned}$$

For heavy atoms, in which *jj*-coupling is appropriate, it is best to discuss their energies using these quantum numbers.

Although *jj*-coupling should be used for assessing the energies of heavy atoms, the term symbols derived from Russell–Saunders coupling can still be used as labels. To see why this procedure is valid, we need to examine how the energies of the atomic states change as the spin–orbit coupling increases in strength. Such a **correlation diagram** is shown in Fig. 10.34. It shows that there is a correspondence between the low spin–orbit coupling (Russell–Saunders coupling) and high spin–orbit coupling (*jj*-coupling) schemes, so the labels derived by using the Russell–Saunders scheme can be used to label the states of the *jj*-coupling scheme.

(d) Selection rules

Any state of the atom, and any spectral transition, can be specified by using term symbols. For example, the transitions giving rise to the yellow sodium doublet (which were shown in Fig. 10.30) are

By convention, the upper term precedes the lower. The corresponding absorptions are therefore denoted

(The configurations have been omitted.)

We have seen that selection rules arise from the conservation of angular momentum during a transition and from the fact that a photon has a spin of 1. They can therefore be expressed in terms of the term symbols, because the latter carry information about angular momentum. A detailed analysis leads to the following rules:

$$\Delta S = 0 \quad \Delta L = 0, \pm 1 \quad \Delta l = \pm 1 \quad \Delta J = 0, \pm 1, \text{ but } J = 0 \leftarrow J = 0 \quad (10.47)$$

where the symbol $\leftarrow$ denotes a forbidden transition. The rule about ΔS (no change of overall spin) stems from the fact that the light does not affect the spin directly. The rules about ΔL and Δl express the fact that the orbital angular momentum of an

Fig. 10.34 The correlation diagram for some of the states of a two-electron system. All atoms lie between the two extremes, but the heavier the atom, the closer it lies to the pure *jj*-coupling case.

individual electron must change (so $\Delta l = \pm 1$), but whether or not this results in an overall change of orbital momentum depends on the coupling.

The selection rules given above apply when Russell–Saunders coupling is valid (in light atoms). If we insist on labelling the terms of heavy atoms with symbols like ^3D , then we shall find that the selection rules progressively fail as the atomic number increases because the quantum numbers S and L become ill defined as jj -coupling becomes more appropriate. As explained above, Russell–Saunders term symbols are only a convenient way of labelling the terms of heavy atoms: they do not bear any direct relation to the actual angular momenta of the electrons in a heavy atom. For this reason, transitions between singlet and triplet states (for which $\Delta S = \pm 1$), while forbidden in light atoms, are allowed in heavy atoms.

Checklist of key ideas

- ☐ 1. A hydrogenic atom is a one-electron atom or ion of general atomic number Z . A many-electron (polyelectronic) atom is an atom or ion with more than one electron.
- ☐ 2. The Lyman, Balmer, and Paschen series in the spectrum of atomic hydrogen arise, respectively, from the transitions $n \rightarrow 1$, $n \rightarrow 2$, and $n \rightarrow 3$.
- ☐ 3. The wavenumbers of all the spectral lines of a hydrogen atom can be expressed as $\tilde{\nu} = R_H(1/n_1^2 - 1/n_2^2)$, where R_H is the Rydberg constant for hydrogen.
- ☐ 4. The Ritz combination principle states that the wavenumber of any spectral line is the difference between two spectroscopic energy levels, or terms: $\tilde{\nu} = T_1 - T_2$.
- ☐ 5. The wavefunction of the hydrogen atom is the product of a radial wavefunction and a radial wavefunction: $\psi(r, \theta, \phi) = R(r)Y(\theta, \phi)$.
- ☐ 6. An atomic orbital is a one-electron wavefunction for an electron in an atom.
- ☐ 7. The energies of an electron in a hydrogen atom are given by $E_n = -Z^2 \mu e^4 / 32 \pi^2 \epsilon_0^2 \hbar^2 n^2$, where n is the principal quantum number, $n = 1, 2, \dots$.
- ☐ 8. All the orbitals of a given value of n belong to a given shell; orbitals with the same value of n but different values of l belong to different subshells.
- ☐ 9. The radial distribution function is a probability density that, when it is multiplied by dr , gives the probability of finding the electron anywhere in a shell of thickness dr at the radius r ; $P(r) = r^2 R(r)^2$.
- ☐ 10. A selection rule is a statement about which spectroscopic transitions are allowed; a Grottrian diagram is a diagram summarizing the energies of the states and atom and the transitions between them.
- ☐ 11. In the orbital approximation it is supposed that each electron occupies its 'own' orbital, $\psi(\mathbf{r}_1, \mathbf{r}_2, \dots) = \psi(\mathbf{r}_1)\psi(\mathbf{r}_2) \dots$.
- ☐ 12. The Pauli exclusion principle states that no more than two electrons may occupy any given orbital and, if two do occupy one orbital, then their spins must be paired.
- ☐ 13. The Pauli principle states that, when the labels of any two identical fermions are exchanged, the total wavefunction changes sign; when the labels of any two identical bosons are exchanged, the total wavefunction retains the same sign.
- ☐ 14. The effective nuclear charge Z_{eff} is the net charge experienced by an electron allowing for electron–electron repulsions.
- ☐ 15. Shielding is the effective reduction in charge of a nucleus by surrounding electrons; the shielding constant σ is given by $Z_{\text{eff}} = Z - \sigma$.
- ☐ 16. Penetration is the ability of an electron to be found inside inner shells and close to the nucleus.
- ☐ 17. The building-up (*Aufbau*) principle is the procedure for filling atomic orbitals that leads to the ground-state configuration of an atom.
- ☐ 18. Hund's maximum multiplicity rule states that an atom in its ground state adopts a configuration with the greatest number of unpaired electrons.
- ☐ 19. The first ionization energy I_1 is the minimum energy necessary to remove an electron from a many-electron atom in the gas phase; the second ionization energy I_2 is the minimum energy necessary to remove an electron from an ionized many-electron atom in the gas phase.
- ☐ 20. The electron affinity E_{ea} is the energy released when an electron attaches to a gas-phase atom.
- ☐ 21. A singlet term has $S = 0$; a triplet term has $S = 1$.
- ☐ 22. Spin–orbit coupling is the interaction of the spin magnetic moment with the magnetic field arising from the orbital angular momentum.
- ☐ 23. Fine structure is the structure in a spectrum due to spin–orbit coupling.
- ☐ 24. A term symbol is a symbolic specification of the state of an atom, $^{2S+1}\{L\}_J$.
- ☐ 25. The allowed values of a combined angular momenta are obtained by using the Clebsch–Gordan series: $J = j_1 + j_2, j_1 + j_2 - 1, \dots, |j_1 - j_2|$.

26. The multiplicity of a term is the value of $2S + 1$; provided $L \geq S$, the multiplicity is the number of levels of the term.
28. A level is a group of states with a common value of J .
29. Russell–Saunders coupling is a coupling scheme based on the view that, if spin–orbit coupling is weak, then it is effective only when all the orbital momenta are operating cooperatively.
30. *jj*-Coupling is a coupling scheme based on the view that the individual spin and orbital momenta of the electrons are coupled into individual j values and these momenta are combined into a grand total, J .
31. The selection rules for spectroscopic transitions in polyelectronic atoms are: $\Delta S = 0$, $\Delta L = 0, \pm 1$, $\Delta l = \pm 1$, $\Delta J = 0, \pm 1$, but $J = 0 \leftrightarrow J = 0$.

Further information

Further information 10.1 The separation of motion

The separation of internal and external motion

Consider a one-dimensional system in which the potential energy depends only on the separation of the two particles. The total energy is

$$E = \frac{p_1^2}{2m_1} + \frac{p_2^2}{2m_2} + V$$

where $p_1 = m_1 \dot{x}_1$ and $p_2 = m_2 \dot{x}_2$, the dot signifying differentiation with respect to time. The centre of mass (Fig. 10.35) is located at

$$X = \frac{m_1}{m} x_1 + \frac{m_2}{m} x_2 \quad m = m_1 + m_2$$

and the separation of the particles is $x = x_1 - x_2$. It follows that

$$x_1 = X + \frac{m_2}{m} x \quad x_2 = X - \frac{m_1}{m} x$$

The linear momenta of the particles can be expressed in terms of the rates of change of x and X :

Fig. 10.35 The coordinates used for discussing the separation of the relative motion of two particles from the motion of the centre of mass.

$$p_1 = m_1 \dot{x}_1 = m_1 \dot{X} + \frac{m_1 m_2}{m} \dot{x} \quad p_2 = m_2 \dot{x}_2 = m_2 \dot{X} - \frac{m_1 m_2}{m} \dot{x}$$

Then it follows that

$$\frac{p_1^2}{2m_1} + \frac{p_2^2}{2m_2} = \frac{1}{2} m \dot{X}^2 + \frac{1}{2} \mu \dot{x}^2$$

where μ is given in eqn 10.6. By writing $P = m \dot{X}$ for the linear momentum of the system as a whole and defining p as $\mu \dot{x}$, we find

$$E = \frac{p^2}{2m} + \frac{p^2}{2\mu} + V$$

The corresponding hamiltonian (generalized to three dimensions) is therefore

$$\hat{H} = -\frac{\hbar^2}{2m}\nabla_{\text{c.m.}}^2 - \frac{\hbar^2}{2\mu}\nabla^2 + V$$

where the first term differentiates with respect to the centre of mass coordinates and the second with respect to the relative coordinates.

Now we write the overall wavefunction as the product $\psi_{\text{total}} = \psi_{\text{c.m.}}\psi$, where the first factor is a function of only the centre of mass coordinates and the second is a function of only the relative coordinates. The overall Schrödinger equation, $H\psi_{\text{total}} = E_{\text{total}}\psi_{\text{total}}$, then separates by the argument that we have used in Sections 9.2a and 9.7, with $E_{\text{total}} = E_{\text{c.m.}} + E$.

The separation of angular and radial motion

The laplacian in three dimensions is given in eqn 9.51a. It follows that the Schrödinger equation in eqn 10.6 is

$$-\frac{\hbar^2}{2\mu} \left(\frac{\partial^2}{\partial r^2} + \frac{2}{r} \frac{\partial}{\partial r} + \frac{1}{r^2} \Lambda^2 \right) RY + VRY = ERY$$

Because R depends only on r and Y depends only on the angular coordinates, this equation becomes

$$-\frac{\hbar^2}{2\mu} \left(Y \frac{d^2 R}{dr^2} + \frac{2Y}{r} \frac{dR}{dr} + \frac{R}{r^2} \Lambda^2 Y \right) + VRY = ERY$$

If we multiply through by r^2/R , we obtain

$$-\frac{\hbar^2}{2\mu R} \left(r^2 \frac{d^2 R}{dr^2} + 2r \frac{dR}{dr} \right) + Vr^2 - \frac{\hbar^2}{2\mu Y} \Lambda^2 Y = Er^2$$

At this point we employ the usual argument. The term in Y is the only one that depends on the angular variables, so it must be a constant. When we write this constant as $\hbar^2 l(l+1)/2\mu$, eqn 10.10 follows immediately.

Discussion questions

10.1 Describe the separation of variables procedure as it is applied to simplify the description of a hydrogenic atom free to move through space.

10.2 List and describe the significance of the quantum numbers needed to specify the internal state of a hydrogenic atom.

10.3 Specify and account for the selection rules for transitions in hydrogenic atoms.

10.4 Explain the significance of (a) a boundary surface and (b) the radial distribution function for hydrogenic orbitals.

10.5 Outline the electron configurations of many-electron atoms in terms of their location in the periodic table.

10.6 Describe and account for the variation of first ionization energies along Period 2 of the periodic table.

10.7 Describe the orbital approximation for the wavefunction of a many-electron atom. What are the limitations of the approximation?

10.8 Explain the origin of spin-orbit coupling and how it affects the appearance of a spectrum.

Exercises

10.1a When ultraviolet radiation of wavelength 58.4 nm from a helium lamp is directed on to a sample of krypton, electrons are ejected with a speed of 1.59 Mm s^{-1} . Calculate the ionization energy of krypton.

10.1b When ultraviolet radiation of wavelength 58.4 nm from a helium lamp is directed on to a sample of xenon, electrons are ejected with a speed of 1.79 Mm s^{-1} . Calculate the ionization energy of xenon.

10.2a By differentiation of the 2s radial wavefunction, show that it has two extrema in its amplitude, and locate them.

10.2b By differentiation of the 3s radial wavefunction, show that it has three extrema in its amplitude, and locate them.

10.3a Locate the radial nodes in the 3s orbital of an H atom.

10.3b Locate the radial nodes in the 4p orbital of an H atom where, in the notation of Table 10.1, the radial wavefunction is proportional to $20 - 10\rho + \rho^2$.

10.4a The wavefunction for the ground state of a hydrogen atom is $N e^{-r/a_0}$. Determine the normalization constant N .

10.4b The wavefunction for the 2s orbital of a hydrogen atom is $N(2 - r/a_0)e^{-r/2a_0}$. Determine the normalization constant N .

10.5a Calculate the average kinetic and potential energies of an electron in the ground state of a hydrogen atom.

10.5b Calculate the average kinetic and potential energies of a 2s electron in a hydrogenic atom of atomic number Z .

10.6a Write down the expression for the radial distribution function of a 2s electron in a hydrogenic atom and determine the radius at which the electron is most likely to be found.

10.6b Write down the expression for the radial distribution function of a 3s electron in a hydrogenic atom and determine the radius at which the electron is most likely to be found.

10.7a Write down the expression for the radial distribution function of a 2p electron in a hydrogenic atom and determine the radius at which the electron is most likely to be found.

10.7b Write down the expression for the radial distribution function of a $3p$ electron in a hydrogenic atom and determine the radius at which the electron is most likely to be found.

10.8a What is the orbital angular momentum of an electron in the orbitals (a) $1s$, (b) $3s$, (c) $3d$? Give the numbers of angular and radial nodes in each case.

10.8b What is the orbital angular momentum of an electron in the orbitals (a) $4d$, (b) $2p$, (c) $3p$? Give the numbers of angular and radial nodes in each case.

10.9a Calculate the permitted values of j for (a) a d electron, (b) an f electron.

10.9b Calculate the permitted values of j for (a) a p electron, (b) an h electron.

10.10a An electron in two different states of an atom is known to have $j = \frac{3}{2}$ and $\frac{1}{2}$. What is its orbital angular momentum quantum number in each case?

10.10b What are the allowed total angular momentum quantum numbers of a composite system in which $j_1 = 5$ and $j_2 = 3$?

10.11a State the orbital degeneracy of the levels in a hydrogen atom that have energy (a) $-hcR_H$; (b) $-\frac{1}{9}hcR_H$; (c) $-\frac{1}{25}hcR_H$.

10.11b State the orbital degeneracy of the levels in a hydrogenic atom (Z in parentheses) that have energy (a) $-4hcR_{\text{atom}}$ (2); (b) $-\frac{1}{4}hcR_{\text{atom}}$ (4), and (c) $-hcR_{\text{atom}}$ (5).

10.12a What information does the term symbol $^1D_2$ provide about the angular momentum of an atom?

10.12b What information does the term symbol $^3F_4$ provide about the angular momentum of an atom?

10.13a At what radius does the probability of finding an electron at a point in the H atom fall to 50 per cent of its maximum value?

10.13b At what radius in the H atom does the radial distribution function of the ground state have (a) 50 per cent, (b) 75 per cent of its maximum value?

10.14a Which of the following transitions are allowed in the normal electronic emission spectrum of an atom: (a) $2s \rightarrow 1s$, (b) $2p \rightarrow 1s$, (c) $3d \rightarrow 2p$?

10.14b Which of the following transitions are allowed in the normal electronic emission spectrum of an atom: (a) $5d \rightarrow 2s$, (b) $5p \rightarrow 3s$, (c) $6p \rightarrow 4f$?

10.15a (a) Write the electronic configuration of the Ni^{2+} ion. (b) What are the possible values of the total spin quantum numbers S and M_S for this ion?

10.15b (a) Write the electronic configuration of the V^{2+} ion. (b) What are the possible values of the total spin quantum numbers S and M_S for this ion?

10.16a Suppose that an atom has (a) 2, (b) 3 electrons in different orbitals. What are the possible values of the total spin quantum number S ? What is the multiplicity in each case?

10.16b Suppose that an atom has (a) 4, (b) 5 electrons in different orbitals. What are the possible values of the total spin quantum number S ? What is the multiplicity in each case?

10.17a What atomic terms are possible for the electron configuration ns^1nd^1 ? Which term is likely to lie lowest in energy?

10.17b What atomic terms are possible for the electron configuration np^1nd^1 ? Which term is likely to lie lowest in energy?

10.18a What values of J may occur in the terms (a) ^1S , (b) ^2P , (c) ^3P ? How many states (distinguished by the quantum number M_J) belong to each level?

10.18b What values of J may occur in the terms (a) ^3D , (b) ^4D , (c) ^2G ? How many states (distinguished by the quantum number M_J) belong to each level?

10.19a Give the possible term symbols for (a) $\text{Li } [\text{He}]2s^1$, (b) $\text{Na } [\text{Ne}]3p^1$.

10.19b Give the possible term symbols for (a) $\text{Sc } [\text{Ar}]3d^14s^2$, (b) $\text{Br } [\text{Ar}]3d^{10}4s^24p^5$.

Problems*

Numerical problems

10.1 The *Humphreys series* is a group of lines in the spectrum of atomic hydrogen. It begins at 12 368 nm and has been traced to 3281.4 nm. What are the transitions involved? What are the wavelengths of the intermediate transitions?

10.2 A series of lines in the spectrum of atomic hydrogen lies at 656.46 nm, 486.27 nm, 434.17 nm, and 410.29 nm. What is the wavelength of the next line in the series? What is the ionization energy of the atom when it is in the lower state of the transitions?

10.3 The Li^{2+} ion is hydrogenic and has a Lyman series at 740 747 cm^{-1} , 877 924 cm^{-1} , 925 933 cm^{-1} , and beyond. Show that the energy levels are of the form $-hcR/n^2$ and find the value of R for this ion. Go on to predict the wavenumbers of the two longest-wavelength transitions of the Balmer series of the ion and find the ionization energy of the ion.

10.4 A series of lines in the spectrum of neutral Li atoms rise from combinations of $1s^22p^1\ ^2P$ with $1s^2nd^1\ ^2D$ and occur at 610.36 nm, 460.29 nm, and 413.23 nm. The d orbitals are hydrogenic. It is known that the ^2P term lies at 670.78 nm above the ground state, which is $1s^22s^1\ ^2S$. Calculate the ionization energy of the ground-state atom.

10.5‡ W.P. Wijesundera, S.H. Vosko, and F.A. Parpia (*Phys. Rev. A* **51**, 278 (1995)) attempted to determine the electron configuration of the ground state of lawrencium, element 103. The two contending configurations are $[\text{Rn}]5f^{14}7s^27p^1$ and $[\text{Rn}]5f^{14}6d7s^2$. Write down the term symbols for each of these configurations, and identify the lowest level within each configuration. Which level would be lowest according to a simple estimate of spin-orbit coupling?

10.6 The characteristic emission from K atoms when heated is purple and lies at 770 nm. On close inspection, the line is found to have two closely spaced components, one at 766.70 nm and the other at 770.11 nm. Account for this observation, and deduce what information you can.

10.7 Calculate the mass of the deuteron given that the first line in the Lyman series of H lies at 82 259.098 cm^{-1} whereas that of D lies at 82 281.476 cm^{-1} . Calculate the ratio of the ionization energies of H and D.

10.8 Positronium consists of an electron and a positron (same mass, opposite charge) orbiting round their common centre of mass. The broad features of the spectrum are therefore expected to be hydrogen-like, the differences arising largely from the mass differences. Predict the wavenumbers of the first three lines of the Balmer series of positronium. What is the binding energy of the ground state of positronium?

* Problems denoted with the symbol ‡ were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

10.9 The Zeeman effect is the modification of an atomic spectrum by the application of a strong magnetic field. It arises from the interaction between applied magnetic fields and the magnetic moments due to orbital and spin angular momenta (recall the evidence provided for electron spin by the Stern–Gerlach experiment, Section 9.8). To gain some appreciation for the so-called *normal Zeeman effect*, which is observed in transitions involving singlet states, consider a p electron, with $l = 1$ and $m_l = 0, \pm 1$. In the absence of a magnetic field, these three states are degenerate. When a field of magnitude B is present, the degeneracy is removed and it is observed that the state with $m_l = +1$ moves up in energy by $\mu_B B$, the state with $m_l = 0$ is unchanged, and the state with $m_l = -1$ moves down in energy by $\mu_B B$, where $\mu_B = e\hbar/2m_e = 9.274 \times 10^{-24} \text{ J T}^{-1}$ is the Bohr magneton (see Section 15.1). Therefore, a transition between a $^1S_0$ term and a $^1P_1$ term consists of three spectral lines in the presence of a magnetic field where, in the absence of the magnetic field, there is only one. (a) Calculate the splitting in reciprocal centimetres between the three spectral lines of a transition between a $^1S_0$ term and a $^1P_1$ term in the presence of a magnetic field of 2 T (where $1 \text{ T} = 1 \text{ kg s}^{-2} \text{ A}^{-1}$). (b) Compare the value you calculated in (a) with typical optical transition wavenumbers, such as those for the Balmer series of the H atom. Is the line splitting caused by the normal Zeeman effect relatively small or relatively large?

10.10 In 1976 it was mistakenly believed that the first of the ‘superheavy’ elements had been discovered in a sample of mica. Its atomic number was believed to be 126. What is the most probable distance of the innermost electrons from the nucleus of an atom of this element? (In such elements, relativistic effects are very important, but ignore them here.)

Theoretical problems

10.11 What is the most probable point (not radius) at which a $2p$ electron will be found in the hydrogen atom?

10.12 Show by explicit integration that (a) hydrogenic $1s$ and $2s$ orbitals, (b) $2p_x$ and $2p_y$ orbitals are mutually orthogonal.

10.13† Explicit expressions for hydrogenic orbitals are given in Tables 10.1 and 9.3. (a) Verify both that the $3p_x$ orbital is normalized (to 1) and that $3p_x$ and $3d_{xy}$ are mutually orthogonal. (b) Determine the positions of both the radial nodes and nodal planes of the $3s$, $3p_x$, and $3d_{xy}$ orbitals. (c) Determine the mean radius of the $3s$ orbital. (d) Draw a graph of the radial distribution function for the three orbitals (of part (b)) and discuss the significance of the graphs for interpreting the properties of many-electron atoms. (e) Create both xy -plane polar plots and boundary surface plots for these orbitals. Construct the boundary plots so that the distance from the origin to the surface is the absolute value of the angular part of the wavefunction. Compare the s , p , and d boundary surface plots with that of an f -orbital; e.g. $\psi_f \propto x(5z^2 - r^2) \propto \sin \theta (5 \cos^2 \theta - 1) \cos \phi$.

10.14 Determine whether the p_x and p_y orbitals are eigenfunctions of l_z . If not, does a linear combination exist that is an eigenfunction of l_z ?

10.15 Show that l_z and l^2 both commute with the hamiltonian for a hydrogen atom. What is the significance of this result?

10.16 The ‘size’ of an atom is sometimes considered to be measured by the radius of a sphere that contains 90 per cent of the charge density of the electrons in the outermost occupied orbital. Calculate the ‘size’ of a hydrogen atom in its ground state according to this definition. Go on to explore how the ‘size’ varies as the definition is changed to other percentages, and plot your conclusion.

10.17 Some atomic properties depend on the average value of $1/r$ rather than the average value of r itself. Evaluate the expectation value of $1/r$ for (a) a hydrogen $1s$ orbital, (b) a hydrogenic $2s$ orbital, (c) a hydrogenic $2p$ orbital.

10.18 One of the most famous of the obsolete theories of the hydrogen atom was proposed by Bohr. It has been replaced by quantum mechanics but, by a remarkable coincidence (not the only one where the Coulomb potential is

concerned), the energies it predicts agree exactly with those obtained from the Schrödinger equation. In the Bohr atom, an electron travels in a circle around the nucleus. The Coulombic force of attraction ($Ze^2/4\pi\epsilon_0 r^2$) is balanced by the centrifugal effect of the orbital motion. Bohr proposed that the angular momentum is limited to integral values of $\hbar$. When the two forces are balanced, the atom remains in a stationary state until it makes a spectral transition. Calculate the energies of a hydrogenic atom using the Bohr model.

10.19 The Bohr model of the atom is specified in Problem 10.18. What features of it are untenable according to quantum mechanics? How does the Bohr ground state differ from the actual ground state? Is there an experimental distinction between the Bohr and quantum mechanical models of the ground state?

10.20 Atomic units of length and energy may be based on the properties of a particular atom. The usual choice is that of a hydrogen atom, with the unit of length being the Bohr radius, a_0 , and the unit of energy being the (negative of the) energy of the $1s$ orbital. If the positronium atom (e^+e^-) were used instead, with analogous definitions of units of length and energy, what would be the relation between these two sets of atomic units?

10.21 Some of the selection rules for hydrogenic atoms were derived in *Justification* 10.4. Complete the derivation by considering the x - and y -components of the electric dipole moment operator.

10.22† Stern–Gerlach splittings of atomic beams are small and require either large magnetic field gradients or long magnets for their observation. For a beam of atoms with zero orbital angular momentum, such as H or Ag, the deflection is given by $x = \pm(\mu_B L^2/4E_K)dB/dz$, where μ_B is the Bohr magneton (Problem 10.9), L is the length of the magnet, E_K is the average kinetic energy of the atoms in the beam, and dB/dz is the magnetic field gradient across the beam. (a) Use the Maxwell–Boltzmann velocity distribution to show that the average translational kinetic energy of the atoms emerging as a beam from a pinhole in an oven at temperature T is $2kT$. (b) Calculate the magnetic field gradient required to produce a splitting of 1.00 mm in a beam of Ag atoms from an oven at 1000 K with a magnet of length 50 cm.

10.23 The wavefunction of a many-electron closed-shell atom can be expressed as a Slater determinant (Section 10.4b). A useful property of determinants is that interchanging any two rows or columns changes their sign and therefore, if any two rows or columns are identical, then the determinant vanishes. Use this property to show that (a) the wavefunction is antisymmetric under particle exchange, (b) no two electrons can occupy the same orbital with the same spin.

Applications: to astrophysics and biochemistry

10.24 Hydrogen is the most abundant element in all stars. However, neither absorption nor emission lines due to neutral hydrogen are found in the spectra of stars with effective temperatures higher than 25 000 K. Account for this observation.

10.25 The distribution of isotopes of an element may yield clues about the nuclear reactions that occur in the interior of a star. Show that it is possible to use spectroscopy to confirm the presence of both $^4\text{He}^+$ and $^3\text{He}^+$ in a star by calculating the wavenumbers of the $n = 3 \rightarrow n = 2$ and of the $n = 2 \rightarrow n = 1$ transitions for each isotope.

10.26† Highly excited atoms have electrons with large principal quantum numbers. Such *Rydberg atoms* have unique properties and are of interest to astrophysicists. For hydrogen atoms with large n , derive a relation for the separation of energy levels. Calculate this separation for $n = 100$; also calculate the average radius, the geometric cross-section, and the ionization energy. Could a thermal collision with another hydrogen atom ionize this Rydberg atom? What minimum velocity of the second atom is required? Could a normal-sized neutral H atom simply pass through the Rydberg atom leaving it undisturbed? What might the radial wavefunction for a 100s orbital be like?

10.27 The spectrum of a star is used to measure its *radial velocity* with respect to the Sun, the component of the star's velocity vector that is parallel to a vector connecting the star's centre to the centre of the Sun. The measurement relies on the *Doppler effect*, in which radiation is shifted in frequency when the source is moving towards or away from the observer. When a star emitting electromagnetic radiation of frequency ν moves with a speed s relative to an observer, the observer detects radiation of frequency $\nu_{\text{receding}} = \nu f$ or $\nu_{\text{approaching}} = \nu/f$, where $f = \{(1 - s/c)/(1 + s/c)\}^{1/2}$ and c is the speed of light. It is easy to see that $\nu_{\text{receding}} < \nu$ and a receding star is characterized by a *red shift* of its spectrum with respect to the spectrum of an identical, but stationary source. Furthermore, $\nu_{\text{approaching}} > \nu$ and an approaching star is characterized by a *blue shift* of its spectrum with respect to the spectrum of an identical, but stationary source. In a typical experiment, ν is the frequency of a spectral line of an element measured in a stationary Earth-bound laboratory from a calibration source, such as an arc lamp. Measurement of the same spectral line in a star gives ν_{star} and the speed of recession or approach may be calculated from the value of ν and the equations above. (a) Three Fe I lines of the star HDE 271 182, which belongs to the Large Magellanic Cloud, occur at 438.882 nm, 441.000 nm, and 442.020 nm. The same lines occur at 438.392 nm, 440.510 nm, and 441.510 nm in the spectrum of an Earth-bound iron arc. Determine

whether HDE 271 182 is receding from or approaching the Earth and estimate the star's radial speed with respect to the Earth. (b) What additional information would you need to calculate the radial velocity of HDE 271 182 with respect to the Sun?

10.28 The *d*-metals iron, copper, and manganese form cations with different oxidation states. For this reason, they are found in many oxidoreductases and in several proteins of oxidative phosphorylation and photosynthesis (*Impact* I7.2 and I23.2). Explain why many *d*-metals form cations with different oxidation states.

10.29 Thallium, a neurotoxin, is the heaviest member of Group 13 of the periodic table and is found most usually in the +1 oxidation state. Aluminium, which causes anaemia and dementia, is also a member of the group but its chemical properties are dominated by the +3 oxidation state. Examine this issue by plotting the first, second, and third ionization energies for the Group 13 elements against atomic number. Explain the trends you observe. *Hints.* The third ionization energy, I_3 , is the minimum energy needed to remove an electron from the doubly charged cation: $E^{2+}(\text{g}) \rightarrow E^{3+}(\text{g}) + e^{-}(\text{g})$, $I_3 = E(E^{3+}) - E(E^{2+})$. The concepts developed in Chapter 10, particularly those of orbitals, can be extended to a description of the electronic structures of molecules. There are two principal quantum mechanical theories of molecular electronic structure. In valence-bond theory, the starting point is the concept of the shared electron pair. We see how to write the wavefunction for such a pair, and how it may be extended to account for the structures of a wide variety of molecules. The theory introduces the concepts of σ and π bonds, promotion, and hybridization that are used widely in chemistry. In molecular orbital theory (with which the bulk of the chapter is concerned), the concept of atomic orbital is extended to that of molecular orbital, which is a wavefunction that spreads over all the atoms in a molecule.

In this chapter we consider the origin of the strengths, numbers, and three-dimensional arrangement of chemical bonds between atoms. The quantum mechanical description of chemical bonding has become highly developed through the use of computers, and it is now possible to consider the structures of molecules of almost any complexity. We shall concentrate on the quantum mechanical description of the **covalent bond**, which was identified by G.N. Lewis (in 1916, before quantum mechanics was fully established) as an electron pair shared between two neighbouring atoms. We shall see, however, that the other principal type of bond, an **ionic bond**, in which the cohesion arises from the Coulombic attraction between ions of opposite charge, is also captured as a limiting case of a covalent bond between dissimilar atoms. In fact, although the Schrödinger equation might shroud the fact in mystery, all chemical bonding can be traced to the interplay between the attraction of opposite charges, the repulsion of like charges, and the effect of changing kinetic energy as the electrons are confined to various regions when bonds form.

There are two major approaches to the calculation of molecular structure, **valence-bond theory** (VB theory) and **molecular orbital theory** (MO theory). Almost all modern computational work makes use of MO theory, and we concentrate on that theory in this chapter. Valence-bond theory, though, has left its imprint on the language of chemistry, and it is important to know the significance of terms that chemists use every day. Therefore, our discussion is organized as follows. First, we set out the concepts common to all levels of description. Then we present VB theory, which gives us a simple qualitative understanding of bond formation. Next, we present the basic ideas of MO theory. Finally, we see how computational techniques pervade all current discussions of molecular structure, including the prediction of chemical reactivity.

The Born–Oppenheimer approximation

All theories of molecular structure make the same simplification at the outset. Whereas the Schrödinger equation for a hydrogen atom can be solved exactly, an exact solution

is not possible for any molecule because the simplest molecule consists of three particles (two nuclei and one electron). We therefore adopt the **Born–Oppenheimer approximation** in which it is supposed that the nuclei, being so much heavier than an electron, move relatively slowly and may be treated as stationary while the electrons move in their field. We can therefore think of the nuclei as being fixed at arbitrary locations, and then solve the Schrödinger equation for the wavefunction of the electrons alone.

The approximation is quite good for ground-state molecules, for calculations suggest that the nuclei in H_2 move through only about 1 pm while the electron speeds through 1000 pm, so the error of assuming that the nuclei are stationary is small. Exceptions to the approximation's validity include certain excited states of polyatomic molecules and the ground states of cations; both types of species are important when considering photoelectron spectroscopy (Section 11.4) and mass spectrometry.

The Born–Oppenheimer approximation allows us to select an internuclear separation in a diatomic molecule and then to solve the Schrödinger equation for the electrons at that nuclear separation. Then we choose a different separation and repeat the calculation, and so on. In this way we can explore how the energy of the molecule varies with bond length (in polyatomic molecules, with angles too) and obtain a **molecular potential energy curve** (Fig. 11.1). When more than one molecular parameter is changed in a polyatomic molecule, we obtain a potential energy surface. It is called a *potential* energy curve because the kinetic energy of the stationary nuclei is zero. Once the curve has been calculated or determined experimentally (by using the spectroscopic techniques described in Chapters 13 and 14), we can identify the **equilibrium bond length**, R_e , the internuclear separation at the minimum of the curve, and the **bond dissociation energy**, D_0 , which is closely related to the depth, D_e , of the minimum below the energy of the infinitely widely separated and stationary atoms.

Fig. 11.1 A molecular potential energy curve. The equilibrium bond length corresponds to the energy minimum.

Comment 11.1

The dissociation energy differs from the depth of the well by an energy equal to the zero-point vibrational energy of the bonded atoms: $D_0 = D_e - \frac{1}{2}\hbar\omega$, where ω is the vibrational frequency of the bond (Section 13.9).

Valence-bond theory

Valence-bond theory was the first quantum mechanical theory of bonding to be developed. The language it introduced, which includes concepts such as spin pairing, orbital overlap, σ and π bonds, and hybridization, is widely used throughout chemistry, especially in the description of the properties and reactions of organic compounds. Here we summarize essential topics of VB theory that are familiar from introductory chemistry and set the stage for the development of MO theory.

11.1 Homonuclear diatomic molecules

In VB theory, a bond is regarded as forming when an electron in an atomic orbital on one atom pairs its spin with that of an electron in an atomic orbital on another atom. To understand why this pairing leads to bonding, we have to examine the wavefunction for the two electrons that form the bond. We begin by considering the simplest possible chemical bond, the one in molecular hydrogen, H_2 .

The spatial wavefunction for an electron on each of two widely separated H atoms is

$$\psi = \chi_{\text{H}1s_A}(\mathbf{r}_1)\chi_{\text{H}1s_B}(\mathbf{r}_2)$$

if electron 1 is on atom A and electron 2 is on atom B; in this chapter we use χ (chi) to denote atomic orbitals. For simplicity, we shall write this wavefunction as $\psi = A(1)B(2)$. When the atoms are close, it is not possible to know whether it is electron 1 that is on A or electron 2. An equally valid description is therefore $\psi = A(2)B(1)$, in which electron 2 is on A and electron 1 is on B. When two outcomes are equally probable,

Fig. 11.2 It is very difficult to represent valence-bond wavefunctions because they refer to two electrons simultaneously. However, this illustration is an attempt. The atomic orbital for electron 1 is represented by the black contours, and that of electron 2 is represented by the blue contours. The top illustration represents $A(1)B(2)$, and the middle illustration represents the contribution $A(2)B(1)$. When the two contributions are superimposed, there is interference between the black contributions and between the blue contributions, resulting in an enhanced (two-electron) density in the internuclear region.

Fig. 11.3 The orbital overlap and spin pairing between electrons in two collinear p orbitals that results in the formation of a σ bond.

quantum mechanics instructs us to describe the true state of the system as a superposition of the wavefunctions for each possibility (Section 8.5d), so a better description of the molecule than either wavefunction alone is the (unnormalized) linear combination

$$\psi = A(1)B(2) \pm A(2)B(1) \quad (11.1)$$

It turns out that the combination with lower energy is the one with a + sign, so the valence-bond wavefunction of the H_2 molecule is

$$\psi = A(1)B(2) + A(2)B(1) \quad (11.2)$$

The formation of the bond in H_2 can be pictured as due to the high probability that the two electrons will be found between the two nuclei and hence will bind them together. More formally, the wave pattern represented by the term $A(1)B(2)$ interferes constructively with the wave pattern represented by the contribution $A(2)B(1)$, and there is an enhancement in the value of the wavefunction in the internuclear region (Fig. 11.2).

The electron distribution described by the wavefunction in eqn 11.2 is called a **σ bond**. A σ bond has cylindrical symmetry around the internuclear axis, and is so called because, when viewed along the internuclear axis, it resembles a pair of electrons in an s orbital (and σ is the Greek equivalent of s).

A chemist's picture of a covalent bond is one in which the spins of two electrons pair as the atomic orbitals overlap. The origin of the role of spin is that the wavefunction given in eqn 11.2 can be formed only by a pair of electrons with opposed spins. Spin pairing is not an end in itself: it is a means of achieving a wavefunction (and the probability distribution it implies) that corresponds to a low energy.

Justification 11.1 Electron pairing in VB theory

The Pauli principle requires the wavefunction of two electrons to change sign when the labels of the electrons are interchanged (see Section 10.4b). The total VB wavefunction for two electrons is

$$\psi(1,2) = \{A(1)B(2) + A(2)B(1)\}\sigma(1,2)$$

where σ represents the spin component of the wavefunction. When the labels 1 and 2 are interchanged, this wavefunction becomes

$$\psi(2,1) = \{A(2)B(1) + A(1)B(2)\}\sigma(2,1) = \{A(1)B(2) + A(2)B(1)\}\sigma(2,1)$$

The Pauli principle requires that $\psi(2,1) = -\psi(1,2)$, which is satisfied only if $\sigma(2,1) = -\sigma(1,2)$. The combination of two spins that has this property is

$$\sigma_-(1,2) = (1/2^{1/2})\{\alpha(1)\beta(2) - \alpha(2)\beta(1)\}$$

which corresponds to paired electron spins (Section 10.7). Therefore, we conclude that the state of lower energy (and hence the formation of a chemical bond) is achieved if the electron spins are paired.

The VB description of H_2 can be applied to other homonuclear diatomic molecules, such as nitrogen, N_2 . To construct the valence bond description of N_2 , we consider the valence electron configuration of each atom, which is $2s^2 2p_x^1 2p_y^1 2p_z^1$. It is conventional to take the z -axis to be the internuclear axis, so we can imagine each atom as having a $2p_z$ orbital pointing towards a $2p_z$ orbital on the other atom (Fig. 11.3), with the $2p_x$ and $2p_y$ orbitals perpendicular to the axis. A σ bond is then formed by spin pairing between the two electrons in the two $2p_z$ orbitals. Its spatial wavefunction is given by eqn 11.2, but now A and B stand for the two $2p_z$ orbitals.

The remaining $2p$ orbitals cannot merge to give σ bonds as they do not have cylindrical symmetry around the internuclear axis. Instead, they merge to form two π bonds. A π bond arises from the spin pairing of electrons in two p orbitals that approach side-by-side (Fig. 11.4). It is so called because, viewed along the internuclear axis, a π bond resembles a pair of electrons in a p orbital (and π is the Greek equivalent of p).

There are two π bonds in N_2 , one formed by spin pairing in two neighbouring $2p_x$ orbitals and the other by spin pairing in two neighbouring $2p_y$ orbitals. The overall bonding pattern in N_2 is therefore a σ bond plus two π bonds (Fig. 11.5), which is consistent with the Lewis structure $:N\equiv N:$ for nitrogen.

11.2 Polyatomic molecules

Each σ bond in a polyatomic molecule is formed by the spin pairing of electrons in atomic orbitals with cylindrical symmetry about the relevant internuclear axis. Likewise, π bonds are formed by pairing electrons that occupy atomic orbitals of the appropriate symmetry.

The VB description of H_2O will make this clear. The valence electron configuration of an O atom is $2s^2 2p_x^2 2p_y^1 2p_z^1$. The two unpaired electrons in the O $2p$ orbitals can each pair with an electron in an H $1s$ orbital, and each combination results in the formation of a σ bond (each bond has cylindrical symmetry about the respective O—H internuclear axis). Because the $2p_y$ and $2p_z$ orbitals lie at 90° to each other, the two σ bonds also lie at 90° to each other (Fig. 11.6). We can predict, therefore, that H_2O should be an angular molecule, which it is. However, the theory predicts a bond angle of 90° , whereas the actual bond angle is 104.5° .

Self-test 11.1 Use valence-bond theory to suggest a shape for the ammonia molecule, NH_3 .

[A trigonal pyramidal molecule with each N—H bond 90° ; experimental: 107°]

Another deficiency of VB theory is its inability to account for carbon's tetravalence (its ability to form four bonds). The ground-state configuration of C is $2s^2 2p_x^1 2p_y^1$, which suggests that a carbon atom should be capable of forming only two bonds, not four. This deficiency is overcome by allowing for **promotion**, the excitation of an electron to an orbital of higher energy. In carbon, for example, the promotion of a $2s$ electron to a $2p$ orbital can be thought of as leading to the configuration $2s^1 2p_x^1 2p_y^1 2p_z^1$, with four unpaired electrons in separate orbitals. These electrons may pair with four electrons in orbitals provided by four other atoms (such as four H $1s$ orbitals if the molecule is CH_4), and hence form four σ bonds. Although energy was required to promote the electron, it is more than recovered by the promoted atom's ability to form four bonds in place of the two bonds of the unpromoted atom. Promotion, and the formation of four bonds, is a characteristic feature of carbon because the promotion energy is quite small: the promoted electron leaves a doubly occupied $2s$ orbital and enters a vacant $2p$ orbital, hence significantly relieving the electron–electron repulsion it experiences in the former. However, we need to remember that promotion is not a 'real' process in which an atom somehow becomes excited and then forms bonds: it is a notional contribution to the overall energy change that occurs when bonds form.

The description of the bonding in CH_4 (and other alkanes) is still incomplete because it implies the presence of three σ bonds of one type (formed from H $1s$ and C $2p$

Fig. 11.4 A π bond results from orbital overlap and spin pairing between electrons in p orbitals with their axes perpendicular to the internuclear axis. The bond has two lobes of electron density separated by a nodal plane.

Fig. 11.5 The structure of bonds in a nitrogen molecule: there is one σ bond and two π bonds. As explained later, the overall electron density has cylindrical symmetry around the internuclear axis.

Fig. 11.6 A first approximation to the valence-bond description of bonding in an H_2O molecule. Each σ bond arises from the overlap of an H $1s$ orbital with one of the O $2p$ orbitals. This model suggests that the bond angle should be 90° , which is significantly different from the experimental value.

Comment 11.2

A characteristic property of waves is that they interfere with one another, resulting in a greater displacement where peaks or troughs coincide, giving rise to *constructive interference*, and a smaller displacement where peaks coincide with troughs, giving rise to *destructive interference*. The physics of waves is reviewed in *Appendix 3*.

orbitals) and a fourth σ bond of a distinctly different character (formed from $H1s$ and $C2s$). This problem is overcome by realizing that the electron density distribution in the promoted atom is equivalent to the electron density in which each electron occupies a **hybrid orbital** formed by interference between the $C2s$ and $C2p$ orbitals. The origin of the hybridization can be appreciated by thinking of the four atomic orbitals centred on a nucleus as waves that interfere destructively and constructively in different regions, and give rise to four new shapes.

The specific linear combinations that give rise to four equivalent hybrid orbitals are

$$\begin{aligned} h_1 &= s + p_x + p_y + p_z & h_2 &= s - p_x - p_y + p_z \\ h_3 &= s - p_x + p_y - p_z & h_4 &= s + p_x - p_y - p_z \end{aligned} \quad (11.3)$$

As a result of the interference between the component orbitals, each hybrid orbital consists of a large lobe pointing in the direction of one corner of a regular tetrahedron (Fig. 11.7). The angle between the axes of the hybrid orbitals is the tetrahedral angle, 109.47° . Because each hybrid is built from one s orbital and three p orbitals, it is called an **sp^3 hybrid orbital**.

It is now easy to see how the valence-bond description of the CH_4 molecule leads to a tetrahedral molecule containing four equivalent C—H bonds. Each hybrid orbital of the promoted C atom contains a single unpaired electron; an $H1s$ electron can pair with each one, giving rise to a σ bond pointing in a tetrahedral direction. For example, the (un-normalized) wavefunction for the bond formed by the hybrid orbital h_1 and the $1s_A$ orbital (with wavefunction that we shall denote A) is

$$\psi = h_1(1)A(2) + h_1(2)A(1)$$

Because each sp^3 hybrid orbital has the same composition, all four σ bonds are identical apart from their orientation in space (Fig. 11.8).

A hybrid orbital has enhanced amplitude in the internuclear region, which arises from the constructive interference between the s orbital and the positive lobes of the p orbitals (Fig. 11.9). As a result, the bond strength is greater than for a bond formed

Fig. 11.7 An sp^3 hybrid orbital formed from the superposition of s and p orbitals on the same atom. There are four such hybrids: each one points towards the corner of a regular tetrahedron. The overall electron density remains spherically symmetrical.

Fig. 11.8 Each sp^3 hybrid orbital forms a σ bond by overlap with an $H1s$ orbital located at the corner of the tetrahedron. This model accounts for the equivalence of the four bonds in CH_4 .

Fig. 11.9 A more detailed representation of the formation of an sp^3 hybrid by interference between wavefunctions centred on the same atomic nucleus. (To simplify the representation, we have ignored the radial node of the $2s$ orbital.)

from an s or p orbital alone. This increased bond strength is another factor that helps to repay the promotion energy.

Hybridization can also be used to describe the structure of an ethene molecule, $\text{H}_2\text{C}=\text{CH}_2$, and the torsional rigidity of double bonds. An ethene molecule is planar, with HCH and HCC bond angles close to 120° . To reproduce the σ bonding structure, we promote each C atom to a $2s^1 2p^3$ configuration. However, instead of using all four orbitals to form hybrids, we form **sp^2 hybrid orbitals**:

$$h_1 = s + 2^{1/2}p_y \quad h_2 = s + (\tfrac{3}{2})^{1/2}p_x - (\tfrac{1}{2})^{1/2}p_y \quad h_3 = s - (\tfrac{3}{2})^{1/2}p_x - (\tfrac{1}{2})^{1/2}p_y \quad (11.4)$$

that lie in a plane and point towards the corners of an equilateral triangle (Fig. 11.10). The third $2p$ orbital ($2p_z$) is not included in the hybridization; its axis is perpendicular to the plane in which the hybrids lie. As always in superpositions, the proportion of each orbital in the mixture is given by the *square* of the corresponding coefficient. Thus, in the first of these hybrids the ratio of s to p contributions is 1:2. Similarly, the total p contribution in each of h_2 and h_3 is $\frac{3}{2} + \frac{1}{2} = 2$, so the ratio for these orbitals is also 1:2. The different signs of the coefficients ensure that constructive interference takes place in different regions of space, so giving the patterns in the illustration.

We can now describe the structure of $\text{CH}_2=\text{CH}_2$ as follows. The sp^2 -hybridized C atoms each form three σ bonds by spin pairing with either the h_1 hybrid of the other C atom or with H1s orbitals. The σ framework therefore consists of C—H and C—C σ bonds at 120° to each other. When the two CH_2 groups lie in the same plane, the two electrons in the unhybridized p orbitals can pair and form a π bond (Fig. 11.11). The formation of this π bond locks the framework into the planar arrangement, for any rotation of one CH_2 group relative to the other leads to a weakening of the π bond (and consequently an increase in energy of the molecule).

A similar description applies to ethyne, $\text{HC}\equiv\text{CH}$, a linear molecule. Now the C atoms are **sp hybridized**, and the σ bonds are formed using hybrid atomic orbitals of the form

$$h_1 = s + p_z \quad h_2 = s - p_z \quad (11.5)$$

These two orbitals lie along the internuclear axis. The electrons in them pair either with an electron in the corresponding hybrid orbital on the other C atom or with an electron in one of the H1s orbitals. Electrons in the two remaining p orbitals on each atom, which are perpendicular to the molecular axis, pair to form two perpendicular π bonds (Fig. 11.12).

Self-test 11.2 Hybrid orbitals do not always form bonds. They may also contain lone pairs of electrons. Use valence-bond theory to suggest possible shapes for the hydrogen peroxide molecule, H_2O_2 .

[Each H—O—O bond angle is predicted to be approximately 109° (experimental: 94.8°); rotation around the O—O bond is possible, so the molecule interconverts between planar and non-planar geometries at high temperatures.]

Other hybridization schemes, particularly those involving d orbitals, are often invoked in elementary work to be consistent with other molecular geometries (Table 11.1). The hybridization of N atomic orbitals always results in the formation of N hybrid orbitals, which may either form bonds or may contain lone pairs of electrons. For example, sp^3d^2 hybridization results in six equivalent hybrid orbitals pointing towards the corners of a regular octahedron and is sometimes invoked to account for the structure of octahedral molecules, such as SF_6 .

Fig. 11.10 (a) An s orbital and two p orbitals can be hybridized to form three equivalent orbitals that point towards the corners of an equilateral triangle. (b) The remaining, unhybridized p orbital is perpendicular to the plane.

Fig. 11.11 A representation of the structure of a double bond in ethene; only the π bond is shown explicitly.

Fig. 11.12 A representation of the structure of a triple bond in ethyne; only the π bonds are shown explicitly. The overall electron density has cylindrical symmetry around the axis of the molecule.

Table 11.1* Some hybridization schemes

Coordination number	Arrangement	Composition
2	Linear	sp, pd, sd
	Angular	sd
3	Trigonal planar	sp^2, p^2d
	Unsymmetrical planar	spd
	Trigonal pyramidal	pd^2
4	Tetrahedral	sp^3, sd^3
	Irregular tetrahedral	sp^2d^2, p^3d, dp^3
	Square planar	p^2d^2, sp^2d
5	Trigonal bipyramidal	sp^3d, spd^2
	Tetragonal pyramidal	$sp^2d^2, sd^4, pd^4, p^3d^2$
	Pentagonal planar	p^2d^3
6	Octahedral	sp^3d^2
	Trigonal prismatic	sp^4d, pd^5
	Trigonal antiprismatic	p^3d^2

Molecular orbital theory

In MO theory, it is accepted that electrons should not be regarded as belonging to particular bonds but should be treated as spreading throughout the entire molecule. This theory has been more fully developed than VB theory and provides the language that is widely used in modern discussions of bonding. To introduce it, we follow the same strategy as in Chapter 10, where the one-electron H atom was taken as the fundamental species for discussing atomic structure and then developed into a description of many-electron atoms. In this chapter we use the simplest molecular species of all, the hydrogen molecule-ion, H_2^+ , to introduce the essential features of bonding, and then use it as a guide to the structures of more complex systems. To that end, we will progress to **homonuclear diatomic molecules**, which, like the H_2^+ molecule-ion, are formed from two atoms of the same element, then describe **heteronuclear diatomic molecules**, which are diatomic molecules formed from atoms of two different elements (such as CO and HCl), and end with a treatment of polyatomic molecules that forms the basis for modern computational models of molecular structure and chemical reactivity.

11.3 The hydrogen molecule-ion

The hamiltonian for the single electron in H_2^+ is

$$H = -\frac{\hbar^2}{2m_e} \nabla^2 + V \quad V = -\frac{e^2}{4\pi\epsilon_0} \left(\frac{1}{r_{A1}} + \frac{1}{r_{B1}} - \frac{1}{R} \right) \quad (11.6)$$

where r_{A1} and r_{B1} are the distances of the electron from the two nuclei (1) and R is the distance between the two nuclei. In the expression for V , the first two terms in parentheses are the attractive contribution from the interaction between the electron and the nuclei; the remaining term is the repulsive interaction between the nuclei.

The one-electron wavefunctions obtained by solving the Schrödinger equation $H\psi = E\psi$ are called **molecular orbitals** (MO). A molecular orbital ψ gives, through

the value of $|\psi|^2$, the distribution of the electron in the molecule. A molecular orbital is like an atomic orbital, but spreads throughout the molecule.

The Schrödinger equation can be solved analytically for H_2^+ (within the Born–Oppenheimer approximation), but the wavefunctions are very complicated functions; moreover, the solution cannot be extended to polyatomic systems. Therefore, we adopt a simpler procedure that, while more approximate, can be extended readily to other molecules.

(a) Linear combinations of atomic orbitals

If an electron can be found in an atomic orbital belonging to atom A and also in an atomic orbital belonging to atom B, then the overall wavefunction is a superposition of the two atomic orbitals:

$$\psi_{\pm} = N(A \pm B) \quad (11.7)$$

where, for H_2^+ , A denotes $\chi_{\text{H}1s_A}$, B denotes $\chi_{\text{H}1s_B}$, and N is a normalization factor. The technical term for the superposition in eqn 11.7 is a **linear combination of atomic orbitals** (LCAO). An approximate molecular orbital formed from a linear combination of atomic orbitals is called an **LCAO-MO**. A molecular orbital that has cylindrical symmetry around the internuclear axis, such as the one we are discussing, is called a **σ orbital** because it resembles an s orbital when viewed along the axis and, more precisely, because it has zero orbital angular momentum around the internuclear axis.

Example 11.1 Normalizing a molecular orbital

Normalize the molecular orbital ψ_+ in eqn 11.7.

Method We need to find the factor N such that

$$\int \psi^* \psi \, d\tau = 1$$

To proceed, substitute the LCAO into this integral, and make use of the fact that the atomic orbitals are individually normalized.

Answer When we substitute the wavefunction, we find

$$\int \psi^* \psi \, d\tau = N^2 \left\{ \int A^2 \, d\tau + \int B^2 \, d\tau + 2 \int AB \, d\tau \right\} = N^2(1 + 1 + 2S)$$

where $S = \int AB \, d\tau$. For the integral to be equal to 1, we require

$$N = \frac{1}{\{2(1 + S)\}^{1/2}}$$

In H_2^+ , $S \approx 0.59$, so $N = 0.56$.

Self-test 11.3 Normalize the orbital ψ_- in eqn 11.7.

$$[N = 1/\{2(1 - S)\}^{1/2}, \text{ so } N = 1.10]$$

Figure 11.13 shows the contours of constant amplitude for the two molecular orbitals in eqn 11.7, and Fig. 11.14 shows their boundary surfaces. Plots like these are readily obtained using commercially available software. The calculation is quite straightforward, because all we need do is feed in the mathematical forms of the two atomic orbitals and then let the program do the rest. In this case, we use

Fig. 11.13 (a) The amplitude of the bonding molecular orbital in a hydrogen molecule-ion in a plane containing the two nuclei and (b) a contour representation of the amplitude.

Exploration Plot the 1σ orbital for different values of the internuclear distance. Point to the features of the 1σ orbital that lead to bonding.

Fig. 11.14 A general indication of the shape of the boundary surface of a σ orbital.

Comment 11.3

The *law of cosines* states that for a triangle such as that shown in (2) with sides r_A , r_B , and R , and angle θ facing side r_B we may write: $r_B^2 = r_A^2 + R^2 - 2r_A R \cos \theta$.

Fig. 11.15 The electron density calculated by forming the square of the wavefunction used to construct Fig. 11.13. Note the accumulation of electron density in the internuclear region.

$$A = \frac{e^{-r_A/a_0}}{(\pi a_0^3)^{1/2}} \quad B = \frac{e^{-r_B/a_0}}{(\pi a_0^3)^{1/2}} \quad (11.8)$$

and note that r_A and r_B are not independent (2), but related by the *law of cosines* (see Comment 11.3):

$$r_B = \{r_A^2 + R^2 - 2r_A R \cos \theta\}^{1/2} \quad (11.9)$$

To make this plot, we have taken $N^2 = 0.31$ (Example 11.1).

(b) Bonding orbitals

According to the Born interpretation, the probability density of the electron in H_2^+ is proportional to the square modulus of its wavefunction. The probability density corresponding to the (real) wavefunction ψ_+ in eqn 11.7 is

$$\psi_+^2 = N^2(A^2 + B^2 + 2AB) \quad (11.10)$$

This probability density is plotted in Fig. 11.15.

An important feature of the probability density becomes apparent when we examine the internuclear region, where both atomic orbitals have similar amplitudes. According to eqn 11.10, the total probability density is proportional to the sum of

- 1 A^2 , the probability density if the electron were confined to the atomic orbital A.
- 2 B^2 , the probability density if the electron were confined to the atomic orbital B.
- 3 $2AB$, an extra contribution to the density.

This last contribution, the **overlap density**, is crucial, because it represents an enhancement of the probability of finding the electron in the internuclear region. The enhancement can be traced to the constructive interference of the two atomic orbitals: each has a positive amplitude in the internuclear region, so the total amplitude is greater there than if the electron were confined to a single atomic orbital.

We shall frequently make use of the result that *electrons accumulate in regions where atomic orbitals overlap and interfere constructively*. The conventional explanation is based on the notion that accumulation of electron density between the nuclei puts the electron in a position where it interacts strongly with both nuclei. Hence, the energy of the molecule is lower than that of the separate atoms, where each electron can interact strongly with only one nucleus. This conventional explanation, however, has been called into question, because shifting an electron away from a nucleus into the internuclear region *raises* its potential energy. The modern (and still controversial) explanation does not emerge from the simple LCAO treatment given here. It seems that, at the same time as the electron shifts into the internuclear region, the atomic orbitals shrink. This orbital shrinkage improves the electron–nucleus attraction more than it is decreased by the migration to the internuclear region, so there is a net lowering of potential energy. The kinetic energy of the electron is also modified because the curvature of the wavefunction is changed, but the change in kinetic energy is dominated by the change in potential energy. Throughout the following discussion we ascribe the strength of chemical bonds to the accumulation of electron density in the internuclear region. We leave open the question whether in molecules more complicated than H_2^+ the true source of energy lowering is that accumulation itself or some indirect but related effect.

The σ orbital we have described is an example of a **bonding orbital**, an orbital which, if occupied, helps to bind two atoms together. Specifically, we label it 1σ as it is the σ orbital of lowest energy. An electron that occupies a σ orbital is called a **σ electron**, and if that is the only electron present in the molecule (as in the ground state of H_2^+), then we report the configuration of the molecule as $1\sigma^1$.

The energy $E_{1\sigma}$ of the 1σ orbital is (see Problem 11.23):

$$E_{1\sigma} = E_{\text{H}1s} + \frac{e^2}{4\pi\epsilon_0 R} - \frac{j+k}{1+S} \quad (11.11)$$

where

$$S = \int AB \, d\tau = \left\{ 1 + \frac{R}{a_0} + \frac{1}{3} \left(\frac{R}{a_0} \right)^2 \right\} e^{-R/a_0} \quad (11.12a)$$

$$j = \frac{e^2}{4\pi\epsilon_0} \int \frac{A^2}{r_B} d\tau = \frac{e^2}{4\pi\epsilon_0 R} \left\{ 1 - \left(1 + \frac{R}{a_0} \right) e^{-2R/a_0} \right\} \quad (11.12b)$$

$$k = \frac{e^2}{4\pi\epsilon_0} \int \frac{AB}{r_B} d\tau = \frac{e^2}{4\pi\epsilon_0 a_0} \left(1 + \frac{R}{a_0} \right) e^{-R/a_0} \quad (11.12c)$$

We can interpret the preceding integrals as follows:

- 1 All three integrals are positive and decline towards zero at large internuclear separations (S and k on account of the exponential term, j on account of the factor $1/R$).
- 2 The integral j is a measure of the interaction between a nucleus and electron density centred on the other nucleus.
- 3 The integral k is a measure of the interaction between a nucleus and the excess probability in the internuclear region arising from overlap.

Figure 11.16 is a plot of $E_{1\sigma}$ against R relative to the energy of the separated atoms. The energy of the 1σ orbital decreases as the internuclear separation decreases from large values because electron density accumulates in the internuclear region as the constructive interference between the atomic orbitals increases (Fig. 11.17). However, at small separations there is too little space between the nuclei for significant accumulation of electron density there. In addition, the nucleus–nucleus repulsion (which is proportional to $1/R$) becomes large. As a result, the energy of the molecule rises at short distances, and there is a minimum in the potential energy curve. Calculations on H_2^+ give $R_e = 130 \text{ pm}$ and $D_e = 1.77 \text{ eV}$ (171 kJ mol^{-1}); the experimental values are 106 pm and 2.6 eV , so this simple LCAO-MO description of the molecule, while inaccurate, is not absurdly wrong.

(c) Antibonding orbitals

The linear combination ψ_- in eqn 11.7 corresponds to a higher energy than that of ψ_+ . Because it is also a σ orbital we label it 2σ . This orbital has an internuclear nodal plane where A and B cancel exactly (Figs. 11.18 and 11.19). The probability density is

$$\psi_-^2 = N^2(A^2 + B^2 - 2AB) \quad (11.13)$$

There is a reduction in probability density between the nuclei due to the $-2AB$ term (Fig. 11.20); in physical terms, there is destructive interference where the two atomic orbitals overlap. The 2σ orbital is an example of an **antibonding orbital**, an orbital that, if occupied, contributes to a reduction in the cohesion between two atoms and helps to raise the energy of the molecule relative to the separated atoms.

The energy $E_{2\sigma}$ of the 2σ antibonding orbital is given by (see Problem 11.23)

$$E_{2\sigma} = E_{\text{H}1s} + \frac{e^2}{4\pi\epsilon_0 R} - \frac{j-k}{1-S} \quad (11.14)$$

where the integrals S , j , and k are given by eqn 11.12. The variation of $E_{2\sigma}$ with R is shown in Fig. 11.16, where we see the destabilizing effect of an antibonding electron.

Fig. 11.16 The calculated and experimental molecular potential energy curves for a hydrogen molecule-ion showing the variation of the energy of the molecule as the bond length is changed. The alternative g,u notation is introduced in Section 11.3c.

Fig. 11.17 A representation of the constructive interference that occurs when two $\text{H}1s$ orbitals overlap and form a bonding σ orbital.

Fig. 11.18 A representation of the destructive interference that occurs when two $1s$ orbitals overlap and form an antibonding 2σ orbital.

Fig. 11.21 A partial explanation of the origin of bonding and antibonding effects. (a) In a bonding orbital, the nuclei are attracted to the accumulation of electron density in the internuclear region. (b) In an antibonding orbital, the nuclei are attracted to an accumulation of electron density outside the internuclear region.

Fig. 11.22 The parity of an orbital is even (g) if its wavefunction is unchanged under inversion through the centre of symmetry of the molecule, but odd (u) if the wavefunction changes sign. Heteronuclear diatomic molecules do not have a centre of inversion, so for them the g, u classification is irrelevant.

Fig. 11.19 (a) The amplitude of the antibonding molecular orbital in a hydrogen molecule-ion in a plane containing the two nuclei and (b) a contour representation of the amplitude. Note the internuclear node.

Exploration Plot the 2σ orbital for different values of the internuclear distance. Point to the features of the 2σ orbital that lead to antibonding.

Fig. 11.20 The electron density calculated by forming the square of the wavefunction used to construct Fig. 11.19. Note the elimination of electron density from the internuclear region.

The effect is partly due to the fact that an antibonding electron is excluded from the internuclear region, and hence is distributed largely outside the bonding region. In effect, whereas a bonding electron pulls two nuclei together, an antibonding electron pulls the nuclei apart (Fig. 11.21). Figure 11.16 also shows another feature that we draw on later: $|E_- - E_{H1s}| > |E_+ - E_{H1s}|$, which indicates that *the antibonding orbital is more antibonding than the bonding orbital is bonding*. This important conclusion stems in part from the presence of the nucleus–nucleus repulsion ($e^2/4\pi\epsilon_0 R$): this contribution raises the energy of both molecular orbitals. Antibonding orbitals are often labelled with an asterisk (*), so the 2σ orbital could also be denoted $2\sigma^*$ (and read ‘2 sigma star’).

For homonuclear diatomic molecules, it is helpful to describe a molecular orbital by identifying its **inversion symmetry**, the behaviour of the wavefunction when it is inverted through the centre (more formally, the centre of inversion) of the molecule. Thus, if we consider any point on the bonding σ orbital, and then project it through the centre of the molecule and out an equal distance on the other side, then we arrive at an identical value of the wavefunction (Fig. 11.22). This so-called **gerade symmetry** (from the German word for ‘even’) is denoted by a subscript g , as in σ_g . On the other hand, the same procedure applied to the antibonding 2σ orbital results in the same size but opposite sign of the wavefunction. This **ungerade symmetry** (‘odd symmetry’) is denoted by a subscript u , as in σ_u . This inversion symmetry classification is not applicable to diatomic molecules formed by atoms from two different elements (such as CO) because these molecules do not have a centre of inversion. When using the g, u notation, each set of orbitals of the same inversion symmetry are labelled separately

so, whereas 1σ becomes $1\sigma_g$, its antibonding partner, which so far we have called 2σ , is the first orbital of a different symmetry, and is denoted $1\sigma_u$. The general rule is that *each set of orbitals of the same symmetry designation is labelled separately*.

11.4 Homonuclear diatomic molecules

In Chapter 10 we used the hydrogenic atomic orbitals and the building-up principle to deduce the ground electronic configurations of many-electron atoms. We now do the same for many-electron diatomic molecules by using the H_2^+ molecular orbitals. The general procedure is to construct molecular orbitals by combining the available atomic orbitals. The electrons supplied by the atoms are then accommodated in the orbitals so as to achieve the lowest overall energy subject to the constraint of the Pauli exclusion principle, that no more than two electrons may occupy a single orbital (and then must be paired). As in the case of atoms, if several degenerate molecular orbitals are available, we add the electrons singly to each individual orbital before doubly occupying any one orbital (because that minimizes electron–electron repulsions). We also take note of Hund’s maximum multiplicity rule (Section 10.4) that, if electrons do occupy different degenerate orbitals, then a lower energy is obtained if they do so with parallel spins.

(a) σ orbitals

Consider H_2 , the simplest many-electron diatomic molecule. Each H atom contributes a $1s$ orbital (as in H_2^+), so we can form the $1\sigma_g$ and $1\sigma_u$ orbitals from them, as we have seen already. At the experimental internuclear separation these orbitals will have the energies shown in Fig. 11.23, which is called a **molecular orbital energy level diagram**. Note that from two atomic orbitals we can build two molecular orbitals. In general, from N atomic orbitals we can build N molecular orbitals.

There are two electrons to accommodate, and both can enter $1\sigma_g$ by pairing their spins, as required by the Pauli principle (see the following *Justification*). The ground-state configuration is therefore $1\sigma_g^2$ and the atoms are joined by a bond consisting of an electron pair in a bonding σ orbital. This approach shows that an electron pair, which was the focus of Lewis’s account of chemical bonding, represents the maximum number of electrons that can enter a bonding molecular orbital.

Justification 11.2 Electron pairing in MO theory

The spatial wavefunction for two electrons in a bonding molecular orbital ψ such as the bonding orbital in eqn 11.7, is $\psi(1)\psi(2)$. This two-electron wavefunction is obviously symmetric under interchange of the electron labels. To satisfy the Pauli principle, it must be multiplied by the antisymmetric spin state $\alpha(1)\beta(2) - \beta(1)\alpha(2)$ to give the overall antisymmetric state

$$\psi(1,2) = \psi(1)\psi(2)\{\alpha(1)\beta(2) - \beta(1)\alpha(2)\}$$

Because $\alpha(1)\beta(2) - \beta(1)\alpha(2)$ corresponds to paired electron spins, we see that two electrons can occupy the same molecular orbital (in this case, the bonding orbital) only if their spins are paired.

The same argument shows why He does not form diatomic molecules. Each He atom contributes a $1s$ orbital, so $1\sigma_g$ and $1\sigma_u$ molecular orbitals can be constructed. Although these orbitals differ in detail from those in H_2 , the general shape is the same, and we can use the same qualitative energy level diagram in the discussion. There are four electrons to accommodate. Two can enter the $1\sigma_g$ orbital, but then it is full, and the next two must enter the $1\sigma_u$ orbital (Fig. 11.24). The ground electronic configuration

Comment 11.4

When treating homonuclear diatomic molecules, we shall favour the more modern notation that focuses attention on the symmetry properties of the orbital. For all other molecules, we shall use asterisks from time to time to denote antibonding orbitals.

Fig. 11.23 A molecular orbital energy level diagram for orbitals constructed from the overlap of $H1s$ orbitals; the separation of the levels corresponds to that found at the equilibrium bond length. The ground electronic configuration of H_2 is obtained by accommodating the two electrons in the lowest available orbital (the bonding orbital).

Fig. 11.24 The ground electronic configuration of the hypothetical four-electron molecule He_2 has two bonding electrons and two antibonding electrons. It has a higher energy than the separated atoms, and so is unstable.

Comment 11.5

Diatomic helium ‘molecules’ have been prepared: they consist of pairs of atoms held together by weak van der Waals forces of the type described in Chapter 18.

Fig. 11.25 According to molecular orbital theory, σ orbitals are built from all orbitals that have the appropriate symmetry. In homonuclear diatomic molecules of Period 2, that means that two $2s$ and two $2p_z$ orbitals should be used. From these four orbitals, four molecular orbitals can be built.

Fig. 11.26 A representation of the composition of bonding and antibonding σ orbitals built from the overlap of p orbitals. These illustrations are schematic.

Comment 11.6

Note that we number only the molecular orbitals formed from atomic orbitals in the valence shell. In an alternative system of notation, $1\sigma_g$ and $1\sigma_u$ are used to designate the molecular orbitals formed from the core $1s$ orbitals of the atoms; the orbitals we are considering would then be labelled starting from 2.

Fig. 11.27 A schematic representation of the structure of π bonding and antibonding molecular orbitals. The figure also shows that the bonding π orbital has odd parity, whereas the antibonding π orbital has even parity.

of He_2 is therefore $1\sigma_g^2 1\sigma_u^2$. We see that there is one bond and one antibond. Because an antibond is slightly more antibonding than a bond is bonding, an He_2 molecule has a higher energy than the separated atoms, so it is unstable relative to the individual atoms.

We shall now see how the concepts we have introduced apply to homonuclear diatomic molecules in general. In elementary treatments, only the orbitals of the valence shell are used to form molecular orbitals so, for molecules formed with atoms from Period 2 elements, only the $2s$ and $2p$ atomic orbitals are considered.

A general principle of molecular orbital theory is that *all orbitals of the appropriate symmetry contribute to a molecular orbital*. Thus, to build σ orbitals, we form linear combinations of all atomic orbitals that have cylindrical symmetry about the internuclear axis. These orbitals include the $2s$ orbitals on each atom and the $2p_z$ orbitals on the two atoms (Fig. 11.25). The general form of the σ orbitals that may be formed is therefore

$$\psi = c_{A2s}\chi_{A2s} + c_{B2s}\chi_{B2s} + c_{A2p_z}\chi_{A2p_z} + c_{B2p_z}\chi_{B2p_z} \quad (11.15)$$

From these four atomic orbitals we can form four molecular orbitals of σ symmetry by an appropriate choice of the coefficients c .

The procedure for calculating the coefficients will be described in Section 11.6. At this stage we adopt a simpler route, and suppose that, because the $2s$ and $2p_z$ orbitals have distinctly different energies, they may be treated separately. That is, the four σ orbitals fall approximately into two sets, one consisting of two molecular orbitals of the form

$$\psi = c_{A2s}\chi_{A2s} + c_{B2s}\chi_{B2s} \quad (11.16a)$$

and another consisting of two orbitals of the form

$$\psi = c_{A2p_z}\chi_{A2p_z} + c_{B2p_z}\chi_{B2p_z} \quad (11.16b)$$

Because atoms A and B are identical, the energies of their $2s$ orbitals are the same, so the coefficients are equal (apart from a possible difference in sign); the same is true of the $2p_z$ orbitals. Therefore, the two sets of orbitals have the form $\chi_{A2s} \pm \chi_{B2s}$ and $\chi_{A2p_z} \pm \chi_{B2p_z}$.

The $2s$ orbitals on the two atoms overlap to give a bonding and an antibonding σ orbital ($1\sigma_g$ and $1\sigma_u$, respectively) in exactly the same way as we have already seen for $1s$ orbitals. The two $2p_z$ orbitals directed along the internuclear axis overlap strongly. They may interfere either constructively or destructively, and give a bonding or antibonding σ orbital, respectively (Fig. 11.26). These two σ orbitals are labelled $2\sigma_g$ and $2\sigma_u$, respectively. In general, note how the numbering follows the order of increasing energy.

(b) π orbitals

Now consider the $2p_x$ and $2p_y$ orbitals of each atom. These orbitals are perpendicular to the internuclear axis and may overlap broadside-on. This overlap may be constructive or destructive, and results in a bonding or an antibonding π orbital (Fig. 11.27). The notation π is the analogue of p in atoms, for when viewed along the axis of the molecule, a π orbital looks like a p orbital, and has one unit of orbital angular momentum around the internuclear axis. The two $2p_x$ orbitals overlap to give a bonding and antibonding π_x orbital, and the two $2p_y$ orbitals overlap to give two π_y orbitals. The π_x and π_y bonding orbitals are degenerate; so too are their antibonding partners. We also see from Fig. 11.27 that a bonding π orbital has odd parity and is denoted π_u and an antibonding π orbital has even parity, denoted π_g .

Fig. 11.28 (a) When two orbitals are on atoms that are far apart, the wavefunctions are small where they overlap, so S is small. (b) When the atoms are closer, both orbitals have significant amplitudes where they overlap, and S may approach 1. Note that S will decrease again as the two atoms approach more closely than shown here, because the region of negative amplitude of the p orbital starts to overlap the positive overlap of the s orbital. When the centres of the atoms coincide, $S = 0$.

Fig. 11.29 The overlap integral, S , between two $H1s$ orbitals as a function of their separation R .

Fig. 11.30 A p orbital in the orientation shown here has zero net overlap ($S = 0$) with the s orbital at all internuclear separations.

(c) The overlap integral

The extent to which two atomic orbitals on different atoms overlap is measured by the **overlap integral**, S :

$$S = \int \chi_A^* \chi_B d\tau \quad [11.17]$$

If the atomic orbital χ_A on A is small wherever the orbital χ_B on B is large, or vice versa, then the product of their amplitudes is everywhere small and the integral—the sum of these products—is small (Fig. 11.28). If χ_A and χ_B are simultaneously large in some region of space, then S may be large. If the two normalized atomic orbitals are identical (for instance, $1s$ orbitals on the same nucleus), then $S = 1$. In some cases, simple formulas can be given for overlap integrals and the variation of S with bond length plotted (Fig. 11.29). It follows that $S = 0.59$ for two $H1s$ orbitals at the equilibrium bond length in H_2^+ , which is an unusually large value. Typical values for orbitals with $n = 2$ are in the range 0.2 to 0.3.

Now consider the arrangement in which an s orbital is superimposed on a p_x orbital of a different atom (Fig. 11.30). The integral over the region where the product of orbitals is positive exactly cancels the integral over the region where the product of orbitals is negative, so overall $S = 0$ exactly. Therefore, there is no net overlap between the s and p orbitals in this arrangement.

(d) The electronic structures of homonuclear diatomic molecules

To construct the molecular orbital energy level diagram for Period 2 homonuclear diatomic molecules, we form eight molecular orbitals from the eight valence shell orbitals (four from each atom). In some cases, π orbitals are less strongly bonding than σ orbitals because their maximum overlap occurs off-axis. This relative weakness suggests that the molecular orbital energy level diagram ought to be as shown in Fig. 11.31. However, we must remember that we have assumed that $2s$ and $2p_z$ orbitals

Fig. 11.31 The molecular orbital energy level diagram for homonuclear diatomic molecules. The lines in the middle are an indication of the energies of the molecular orbitals that can be formed by overlap of atomic orbitals. As remarked in the text, this diagram should be used for O_2 (the configuration shown) and F_2 .

Fig. 11.32 The variation of the orbital energies of Period 2 homonuclear diatomics.

Fig. 11.33 An alternative molecular orbital energy level diagram for homonuclear diatomic molecules. As remarked in the text, this diagram should be used for diatomics up to and including N_2 (the configuration shown).

contribute to different sets of molecular orbitals whereas in fact all four atomic orbitals contribute jointly to the four σ orbitals. Hence, there is no guarantee that this order of energies should prevail, and it is found experimentally (by spectroscopy) and by detailed calculation that the order varies along Period 2 (Fig. 11.32). The order shown in Fig. 11.33 is appropriate as far as N_2 , and Fig. 11.31 applies for O_2 and F_2 . The relative order is controlled by the separation of the $2s$ and $2p$ orbitals in the atoms, which increases across the group. The consequent switch in order occurs at about N_2 .

With the orbitals established, we can deduce the ground configurations of the molecules by adding the appropriate number of electrons to the orbitals and following the building-up rules. Anionic species (such as the peroxide ion, O_2^{2-}) need more electrons than the parent neutral molecules; cationic species (such as O_2^+) need fewer.

Consider N_2 , which has 10 valence electrons. Two electrons pair, occupy, and fill the $1\sigma_g$ orbital; the next two occupy and fill the $1\sigma_u$ orbital. Six electrons remain. There are two $1\pi_u$ orbitals, so four electrons can be accommodated in them. The last two enter the $2\sigma_g$ orbital. Therefore, the ground-state configuration of N_2 is $1\sigma_g^2 1\sigma_u^2 1\pi_u^4 2\sigma_g^2$.

A measure of the net bonding in a diatomic molecule is its **bond order**, b :

$$b = \frac{1}{2}(n - n^*) \quad [11.18]$$

where n is the number of electrons in bonding orbitals and n^* is the number of electrons in antibonding orbitals. Thus each electron pair in a bonding orbital increases the bond order by 1 and each pair in an antibonding orbital decreases b by 1. For H_2 , $b = 1$, corresponding to a single bond, $H-H$, between the two atoms. In He_2 , $b = 0$, and there is no bond. In N_2 , $b = \frac{1}{2}(8 - 2) = 3$. This bond order accords with the Lewis structure of the molecule ($:N \equiv N:$).

The ground-state electron configuration of O_2 , with 12 valence electrons, is based on Fig. 11.31, and is $1\sigma_g^2 1\sigma_u^2 2\sigma_g^2 1\pi_u^4 1\pi_g^2$. Its bond order is 2. According to the building-up principle, however, the two $1\pi_g$ electrons occupy different orbitals: one will enter $1\pi_{u,x}$ and the other will enter $1\pi_{u,y}$. Because the electrons are in different orbitals, they will have parallel spins. Therefore, we can predict that an O_2 molecule will have a net spin angular momentum $S = 1$ and, in the language introduced in Section 10.7, be in a triplet state. Because electron spin is the source of a magnetic moment, we can go on to predict that oxygen should be paramagnetic. This prediction, which VB theory does not make, is confirmed by experiment.

CC	2	720
CC	3	962

* More values will be found in the *Data section*.
Numbers in italics are mean values for polyatomic molecules.

An F_2 molecule has two more electrons than an O_2 molecule. Its configuration is therefore $1\sigma_g^2 1\sigma_u^2 2\sigma_g^2 1\pi_u^4 1\pi_g^4$ and $b = 1$. We conclude that F_2 is a singly-bonded molecule, in agreement with its Lewis structure. The hypothetical molecule dineon, Ne_2 , has two further electrons: its configuration is $1\sigma_g^2 1\sigma_u^2 2\sigma_g^2 1\pi_u^4 1\pi_g^2 2\sigma_u^2$ and $b = 0$. The zero bond order is consistent with the monatomic nature of Ne.

The bond order is a useful parameter for discussing the characteristics of bonds, because it correlates with bond length and bond strength. For bonds between atoms of a given pair of elements:

- 1 The greater the bond order, the shorter the bond.
- 2 The greater the bond order, the greater the bond strength.

Table 11.2 lists some typical bond lengths in diatomic and polyatomic molecules. The strength of a bond is measured by its bond dissociation energy, D_e , the energy required to separate the atoms to infinity. Table 11.3 lists some experimental values of dissociation energies.

Example 11.2 Judging the relative bond strengths of molecules and ions

Judge whether N_2^+ is likely to have a larger or smaller dissociation energy than N_2 .

Method Because the molecule with the larger bond order is likely to have the larger dissociation energy, compare their electronic configurations and assess their bond orders.

Answer From Fig. 11.33, the electron configurations and bond orders are

$$\begin{array}{lll} \text{N}_2 & 1\sigma_g^2 1\sigma_u^2 1\pi_u^4 2\sigma_g^2 & b = 3 \\ \text{N}_2^+ & 1\sigma_g^2 1\sigma_u^2 1\pi_u^4 2\sigma_g^1 & b = 2\frac{1}{2} \end{array}$$

Because the cation has the smaller bond order, we expect it to have the smaller dissociation energy. The experimental dissociation energies are 945 kJ mol^{-1} for N_2 and 842 kJ mol^{-1} for N_2^+ .

Self-test 11.4 Which can be expected to have the higher dissociation energy, F_2 or F_2^+ ?

Comment 11.7

A paramagnetic substance tends to move into a magnetic field; a diamagnetic substance tends to move out of one. Paramagnetism, the rarer property, arises when the molecules have unpaired electron spins. Both properties are discussed in more detail in Chapter 20.

Comment 11.8

Bond dissociation energies are commonly used in thermodynamic cycles, where bond enthalpies, $\Delta_{\text{bond}}H^\circ$, should be used instead. It follows from the same kind of argument used in *Justification 10.7* concerning ionization enthalpies, that

To derive this relation, we have supposed that the molar constant-pressure heat capacity of X_2 is $\frac{7}{2}R$ (*Molecular interpretation 2.2*) for there is a contribution from two rotational modes as well as three translational modes.

Fig. 11.34 An incoming photon carries an energy $h\nu$; an energy I_i is needed to remove an electron from an orbital i , and the difference appears as the kinetic energy of the electron.

(e) Photoelectron spectroscopy

So far we have treated molecular orbitals as purely theoretical constructs, but is there experimental evidence for their existence? **Photoelectron spectroscopy** (PES) measures the ionization energies of molecules when electrons are ejected from different orbitals by absorption of a photon of the proper energy, and uses the information to infer the energies of molecular orbitals. The technique is also used to study solids, and in Chapter 25 we shall see the important information that it gives about species at or on surfaces.

Because energy is conserved when a photon ionizes a sample, the energy of the incident photon $h\nu$ must be equal to the sum of the ionization energy, I , of the sample and the kinetic energy of the **photoelectron**, the ejected electron (Fig. 11.34):

$$h\nu = \frac{1}{2}m_e v^2 + I \quad (11.19)$$

This equation (which is like the one used for the photoelectric effect, Section 8.2a) can be refined in two ways. First, photoelectrons may originate from one of a number of different orbitals, and each one has a different ionization energy. Hence, a series of different kinetic energies of the photoelectrons will be obtained, each one satisfying

$$h\nu = \frac{1}{2}m_e v^2 + I_i \quad (11.20)$$

where I_i is the ionization energy for ejection of an electron from an orbital i . Therefore, by measuring the kinetic energies of the photoelectrons, and knowing v , these ionization energies can be determined. Photoelectron spectra are interpreted in terms of an approximation called **Koopmans' theorem**, which states that the ionization energy I_i is equal to the orbital energy of the ejected electron (formally: $I_i = -\epsilon_i$). That is, we can identify the ionization energy with the energy of the orbital from which it is ejected. Similarly, the energy of unfilled ('virtual orbitals') is related to the electron affinity. The theorem is only an approximation because it ignores the fact that the remaining electrons adjust their distributions when ionization occurs.

The ionization energies of molecules are several electronvolts even for valence electrons, so it is essential to work in at least the ultraviolet region of the spectrum and with wavelengths of less than about 200 nm. Much work has been done with radiation generated by a discharge through helium: the He(I) line ($1s^1 2p^1 \rightarrow 1s^2$) lies at 58.43 nm, corresponding to a photon energy of 21.22 eV. Its use gives rise to the technique of **ultraviolet photoelectron spectroscopy** (UPS). When core electrons are being studied, photons of even higher energy are needed to expel them: X-rays are used, and the technique is denoted XPS.

The kinetic energies of the photoelectrons are measured using an electrostatic deflector that produces different deflections in the paths of the photoelectrons as they pass between charged plates (Fig. 11.35). As the field strength is increased, electrons of different speeds, and therefore kinetic energies, reach the detector. The electron flux can be recorded and plotted against kinetic energy to obtain the photoelectron spectrum.

Fig. 11.35 A photoelectron spectrometer consists of a source of ionizing radiation (such as a helium discharge lamp for UPS and an X-ray source for XPS), an electrostatic analyser, and an electron detector. The deflection of the electron path caused by the analyser depends on their speed.

Illustration 11.1 Interpreting a photoelectron spectrum

Photoelectrons ejected from N_2 with He(I) radiation had kinetic energies of 5.63 eV ($1 \text{ eV} = 8065.5 \text{ cm}^{-1}$). Helium(I) radiation of wavelength 58.43 nm has wavenumber $1.711 \times 10^5 \text{ cm}^{-1}$ and therefore corresponds to an energy of 21.22 eV. Then, from eqn 11.20, $21.22 \text{ eV} = 5.63 \text{ eV} + I_i$, so $I_i = 15.59 \text{ eV}$. This ionization energy is the energy needed to remove an electron from the occupied molecular orbital with the highest energy of the N_2 molecule, the $2\sigma_g$ bonding orbital (see Fig. 11.33).

Self-test 11.5 Under the same circumstances, photoelectrons are also detected at 4.53 eV. To what ionization energy does that correspond? Suggest an origin.

[16.7 eV, $1\pi_u$]

11.5 Heteronuclear diatomic molecules

The electron distribution in the covalent bond between the atoms in a heteronuclear diatomic molecule is not shared evenly because it is energetically favourable for the electron pair to be found closer to one atom than the other. This imbalance results in a **polar bond**, a covalent bond in which the electron pair is shared unequally by the two atoms. The bond in HF, for instance, is polar, with the electron pair closer to the F atom. The accumulation of the electron pair near the F atom results in that atom having a net negative charge, which is called a **partial negative charge** and denoted δ^- . There is a matching **partial positive charge**, δ^+ , on the H atom.

(a) Polar bonds

A polar bond consists of two electrons in an orbital of the form

$$\psi = c_A A + c_B B \quad (11.21)$$

with unequal coefficients. The proportion of the atomic orbital A in the bond is $|c_A|^2$ and that of B is $|c_B|^2$. A nonpolar bond has $|c_A|^2 = |c_B|^2$ and a pure ionic bond has one coefficient zero (so the species A^+B^- would have $c_A = 0$ and $c_B = 1$). The atomic orbital with the lower energy makes the larger contribution to the bonding molecular orbital. The opposite is true of the antibonding orbital, for which the dominant component comes from the atomic orbital with higher energy.

These points can be illustrated by considering HF, and judging the energies of the atomic orbitals from the ionization energies of the atoms. The general form of the molecular orbitals is

$$\psi = c_H \chi_H + c_F \chi_F \quad (11.22)$$

where χ_H is an H1s orbital and χ_F is an F2p orbital. The H1s orbital lies 13.6 eV below the zero of energy (the separated proton and electron) and the F2p orbital lies at 18.6 eV (Fig. 11.36). Hence, the bonding σ orbital in HF is mainly F2p and the antibonding σ orbital is mainly H1s orbital in character. The two electrons in the bonding orbital are most likely to be found in the F2p orbital, so there is a partial negative charge on the F atom and a partial positive charge on the H atom.

(b) Electronegativity

The charge distribution in bonds is commonly discussed in terms of the **electronegativity**, χ , of the elements involved (there should be little danger of confusing this use of χ with its use to denote an atomic orbital, which is another common convention). The electronegativity is a parameter introduced by Linus Pauling as a measure of the power of an atom to attract electrons to itself when it is part of a compound. Pauling used valence-bond arguments to suggest that an appropriate numerical scale of electronegativities could be defined in terms of bond dissociation energies, D , in electronvolts and proposed that the difference in electronegativities could be expressed as

$$|\chi_A - \chi_B| = 0.102 \{D(A-B) - \frac{1}{2}[D(A-A) + D(B-B)]\}^{1/2} \quad [11.23]$$

Electronegativities based on this definition are called **Pauling electronegativities**. A list of Pauling electronegativities is given in Table 11.4. The most electronegative

Fig. 11.36 The atomic orbital energy levels of H and F atoms and the molecular orbitals they form.

Synoptic table 11.4* Pauling electronegativities

Element	χ_p
H	2.2
C	2.6
N	3.0
O	3.4
F	4.0
Cl	3.2
Cs	0.79

* More values will be found in the Data section.

elements are those close to fluorine; the least are those close to caesium. It is found that the greater the difference in electronegativities, the greater the polar character of the bond. The difference for HF, for instance, is 1.78; a C—H bond, which is commonly regarded as almost nonpolar, has an electronegativity difference of 0.51.

The spectroscopist Robert Mulliken proposed an alternative definition of electronegativity. He argued that an element is likely to be highly electronegative if it has a high ionization energy (so it will not release electrons readily) and a high electron affinity (so it is energetically favorable to acquire electrons). The **Mulliken electronegativity scale** is therefore based on the definition

$$\chi_M = \frac{1}{2}(I + E_{\text{ea}}) \quad [11.24]$$

where I is the ionization energy of the element and E_{ea} is its electron affinity (both in electronvolts, Section 10.4e). The Mulliken and Pauling scales are approximately in line with each other. A reasonably reliable conversion between the two is $\chi_P = 1.35\chi_M^{1/2} - 1.37$.

(c) The variation principle

A more systematic way of discussing bond polarity and finding the coefficients in the linear combinations used to build molecular orbitals is provided by the **variation principle**:

If an arbitrary wavefunction is used to calculate the energy, the value calculated is never less than the true energy.

This principle is the basis of all modern molecular structure calculations (Section 11.7). The arbitrary wavefunction is called the **trial wavefunction**. The principle implies that, if we vary the coefficients in the trial wavefunction until the lowest energy is achieved (by evaluating the expectation value of the hamiltonian for each wavefunction), then those coefficients will be the best. We might get a lower energy if we use a more complicated wavefunction (for example, by taking a linear combination of several atomic orbitals on each atom), but we shall have the optimum (minimum energy) molecular orbital that can be built from the chosen **basis set**, the given set of atomic orbitals.

The method can be illustrated by the trial wavefunction in eqn 11.21. We show in the *Justification* below that the coefficients are given by the solutions of the two **secular equations**

$$(\alpha_A - E)c_A + (\beta - ES)c_B = 0 \quad (11.25a)$$

$$(\beta - ES)c_A + (\alpha_B - E)c_B = 0 \quad (11.25b)$$

The parameter α is called a **Coulomb integral**. It is negative and can be interpreted as the energy of the electron when it occupies A (for α_A) or B (for α_B). In a homonuclear diatomic molecule, $\alpha_A = \alpha_B$. The parameter β is called a **resonance integral** (for classical reasons). It vanishes when the orbitals do not overlap, and at equilibrium bond lengths it is normally negative.

Comment 11.9

The name ‘secular’ is derived from the Latin word for age or generation. The term comes via astronomy, where the same equations appear in connection with slowly accumulating modifications of planetary orbits.

Justification 11.3 *The variation principle applied to a heteronuclear diatomic molecule*

The trial wavefunction in eqn 11.21 is real but not normalized because at this stage the coefficients can take arbitrary values. Therefore, we can write $\psi^* = \psi$ but do not assume that $\int \psi^2 d\tau = 1$. The energy of the trial wavefunction is the expectation value of the energy operator (the hamiltonian, $\hat{H}$, Section 8.5):

$$E = \frac{\int \psi^* \hat{H} \psi d\tau}{\int \psi^* \psi d\tau} \quad (11.26)$$

We must search for values of the coefficients in the trial function that minimize the value of E . This is a standard problem in calculus, and is solved by finding the coefficients for which

$$\frac{\partial E}{\partial c_A} = 0 \quad \frac{\partial E}{\partial c_B} = 0$$

The first step is to express the two integrals in terms of the coefficients. The denominator is

$$\begin{aligned} \int \psi^2 d\tau &= \int (c_A A + c_B B)^2 d\tau \\ &= c_A^2 \int A^2 d\tau + c_B^2 \int B^2 d\tau + 2c_A c_B \int AB d\tau \\ &= c_A^2 + c_B^2 + 2c_A c_B S \end{aligned}$$

because the individual atomic orbitals are normalized and the third integral is the overlap integral S (eqn 11.17). The numerator is

$$\begin{aligned} \int \psi \hat{H} \psi d\tau &= \int (c_A A + c_B B) \hat{H} (c_A A + c_B B) d\tau \\ &= c_A^2 \int A \hat{H} A d\tau + c_B^2 \int B \hat{H} B d\tau + c_A c_B \int A \hat{H} B d\tau + c_A c_B \int B \hat{H} A d\tau \end{aligned}$$

There are some complicated integrals in this expression, but we can combine them all into the parameters

$$\alpha_A = \int A \hat{H} A d\tau \quad \alpha_B = \int B \hat{H} B d\tau \quad [11.27]$$

$$\beta = \int A \hat{H} B d\tau = \int B \hat{H} A d\tau \text{ (by the hermiticity of } \hat{H} \text{)}$$

Then

$$\int \psi \hat{H} \psi d\tau = c_A^2 \alpha_A + c_B^2 \alpha_B + 2c_A c_B \beta$$

The complete expression for E is

$$E = \frac{c_A^2 \alpha_A + c_B^2 \alpha_B + 2c_A c_B \beta}{c_A^2 + c_B^2 + 2c_A c_B S} \quad (11.28)$$

Its minimum is found by differentiation with respect to the two coefficients and setting the results equal to 0. After a bit of work, we obtain

$$\begin{aligned} \frac{\partial E}{\partial c_A} &= \frac{2 \times (c_A \alpha_A - c_A E + c_B \beta - c_B S E)}{c_A^2 + c_B^2 + 2c_A c_B S} = 0 \\ \frac{\partial E}{\partial c_B} &= \frac{2 \times (c_B \alpha_B - c_B E + c_A \beta - c_A S E)}{c_A^2 + c_B^2 + 2c_A c_B S} = 0 \end{aligned}$$

For the derivatives to vanish, the numerators of the expressions above must vanish. That is, we must find values of c_A and c_B that satisfy the conditions

$$\begin{aligned} c_A\alpha_A - c_A E + c_B\beta - c_B S E &= (\alpha_A - E)c_A + (\beta - ES)c_B = 0 \\ c_A\beta - c_A S E + c_B\alpha_B - c_B E &= (\beta - ES)c_A + (\alpha_B - E)c_B = 0 \end{aligned}$$

which are the secular equations (eqn 11.25).

To solve the secular equations for the coefficients we need to know the energy E of the orbital. As for any set of simultaneous equations, the secular equations have a solution if the **secular determinant**, the determinant of the coefficients, is zero; that is, if

$$\begin{vmatrix} \alpha_A - E & \beta - ES \\ \beta - ES & \alpha_B - E \end{vmatrix} = 0 \quad (11.29)$$

Comment 11.10

We need to know that a 2×2 determinant expands as follows:

$$\begin{vmatrix} a & b \\ c & d \end{vmatrix} = ad - bc$$

This determinant expands to a quadratic equation in E (see *Illustration 11.2*). Its two roots give the energies of the bonding and antibonding molecular orbitals formed from the atomic orbitals and, according to the variation principle, the lower root is the best energy achievable with the given basis set.

Illustration 11.2 Using the variation principle (1)

To find the energies E of the bonding and antibonding orbitals of a homonuclear diatomic molecule set with $\alpha_A = \alpha_B = \alpha$ in eqn 11.29 and get

$$\begin{vmatrix} \alpha - E & \beta - ES \\ \beta - ES & \alpha - E \end{vmatrix} = (\alpha - E)^2 - (\beta - ES)^2 = 0$$

The solutions of this equation are

$$E_{\pm} = \frac{\alpha \pm \beta}{1 \pm S}$$

The values of the coefficients in the linear combination are obtained by solving the secular equations using the two energies obtained from the secular determinant. The lower energy (E_+ in the *Illustration*) gives the coefficients for the bonding molecular orbital, the upper energy (E_-) the coefficients for the antibonding molecular orbital. The secular equations give expressions for the ratio of the coefficients in each case, so we need a further equation in order to find their individual values. This equation is obtained by demanding that the best wavefunction should also be normalized. This condition means that, at this final stage, we must also ensure that

$$\int \psi^2 d\tau = c_A^2 + c_B^2 + 2c_A c_B S = 1 \quad (11.30)$$

Illustration 11.3 Using the variation principle (2)

To find the values of the coefficients c_A and c_B in the linear combination that corresponds to the energy E_+ from *Illustration 11.2*, we use eqn 11.28 (with $\alpha_A = \alpha_B = \alpha$) to write

$$E_+ = \frac{\alpha + \beta}{1 + S} = \frac{c_A^2 \alpha + c_B^2 \alpha + 2c_A c_B \beta}{c_A^2 + c_B^2 + 2c_A c_B S}$$

Now we use the normalization condition, eqn 11.30, to set $c_A^2 + c_B^2 + 2c_Ac_BS = 1$, and so write

$$\frac{\alpha + \beta}{1 + S} = (c_A^2 + c_B^2)\alpha + 2c_Ac_B\beta$$

This expression implies that

$$c_A^2 + c_B^2 = 2c_Ac_B = \frac{1}{1 + S} \quad \text{and} \quad |c_A| = \frac{1}{\{2(1 + S)\}^{1/2}} \quad c_B = c_A$$

Proceeding in a similar way to find the coefficients in the linear combination that corresponds to the energy E_- , we write

$$E_- = \frac{\alpha - \beta}{1 - S} = (c_A^2 + c_B^2)\alpha + 2c_Ac_B\beta$$

which implies that

$$c_A^2 + c_B^2 = -2c_Ac_B = \frac{1}{1 - S} \quad \text{and} \quad |c_A| = \frac{1}{\{2(1 - S)\}^{1/2}} \quad c_B = -c_A$$

(d) Two simple cases

The complete solutions of the secular equations are very cumbersome, even for 2×2 determinants, but there are two cases where the roots can be written down very simply.

We saw in *Illustrations* 11.2 and 11.3 that, when the two atoms are the same, and we can write $\alpha_A = \alpha_B = \alpha$, the solutions are

$$E_+ = \frac{\alpha + \beta}{1 + S} \quad c_A = \frac{1}{\{2(1 + S)\}^{1/2}} \quad c_B = c_A \quad (11.31a)$$

$$E_- = \frac{\alpha - \beta}{1 - S} \quad c_A = \frac{1}{\{2(1 - S)\}^{1/2}} \quad c_B = -c_A \quad (11.31b)$$

In this case, the bonding orbital has the form

$$\psi_+ = \frac{A + B}{\{2(1 + S)\}^{1/2}} \quad (11.32a)$$

and the corresponding antibonding orbital is

$$\psi_- = \frac{A - B}{\{2(1 - S)\}^{1/2}} \quad (11.32b)$$

in agreement with the discussion of homonuclear diatomics we have already given, but now with the normalization constant in place.

The second simple case is for a heteronuclear diatomic molecule but with $S = 0$ (a common approximation in elementary work). The secular determinant is then

$$\begin{vmatrix} \alpha_A - E & \beta \\ \beta & \alpha_B - E \end{vmatrix} = (\alpha_A - E)(\alpha_B - E) - \beta^2 = 0$$

The solutions can be expressed in terms of the parameter ζ (zeta), with

$$\zeta = \frac{1}{2} \arctan \frac{2|\beta|}{\alpha_B - \alpha_A} \quad (11.33)$$

and are

$$E_- = \alpha_B - \beta \tan \zeta \quad \psi_- = -A \sin \zeta + B \cos \zeta \quad (11.34a)$$

$$E_+ = \alpha_A + \beta \tan \zeta \quad \psi_+ = A \cos \zeta + B \sin \zeta \quad (11.34b)$$

An important feature revealed by these solutions is that as the energy difference $|\alpha_B - \alpha_A|$ between the interacting atomic orbitals increases, the value of ζ decreases. We show in the following *Justification* that, when the energy difference is very large, in the sense that $|\alpha_B - \alpha_A| \gg 2|\beta|$, the energies of the resulting molecular orbitals differ only slightly from those of the atomic orbitals, which implies in turn that the bonding and antibonding effects are small. That is, the strongest bonding and antibonding effects are obtained when the two contributing orbitals have closely similar energies. The difference in energy between core and valence orbitals is the justification for neglecting the contribution of core orbitals to bonding. The core orbitals of one atom have a similar energy to the core orbitals of the other atom; but core–core interaction is largely negligible because the overlap between them (and hence the value of β) is so small.

Justification 11.4 Bonding and antibonding effects in heteronuclear diatomic molecules

When $|\alpha_B - \alpha_A| \gg 2|\beta|$ and $2|\beta|/|\alpha_B - \alpha_A| \ll 1$, we can write $\arctan 2|\beta|/|\alpha_B - \alpha_A| \approx 2|\beta|/|\alpha_B - \alpha_A|$ and, from eqn 11.33, $\zeta \approx |\beta|/(\alpha_B - \alpha_A)$. It follows that $\tan \zeta \approx |\beta|/(\alpha_B - \alpha_A)$. Noting that β is normally a negative number, so that $\beta/|\beta| = -1$, we can use eqn 11.34 to write

$$E_- = \alpha_B + \frac{\beta^2}{\alpha_B - \alpha_A} \quad E_+ = \alpha_A - \frac{\beta^2}{\alpha_B - \alpha_A}$$

(In Problem 11.25 you are invited to derive these expressions via a different route.) It follows that, when the energy difference between the atomic orbitals is so large that $|\alpha_B - \alpha_A| \gg 2|\beta|$, the energies of the two molecular orbitals are $E_- \approx \alpha_B$ and $E_+ \approx \alpha_A$.

Now we consider the behaviour of the wavefunctions in the limit of large $|\alpha_B - \alpha_A|$, when $\zeta \ll 1$. In this case, $\sin \zeta \approx \zeta$ and $\cos \zeta \approx 1$ and, from eqn 11.34, we write $\psi_- \approx B$ and $\psi_+ \approx A$. That is, the molecular orbitals are respectively almost pure B and almost pure A .

Comment 11.11

For $x \ll 1$, we can write: $\sin x \approx x$, $\cos x \approx 1$, $\tan x \approx x$, and $\arctan x = \tan^{-1} x \approx x$.

Example 11.3 Calculating the molecular orbitals of HF

Calculate the wavefunctions and energies of the σ orbitals in the HF molecule, taking $\beta = -1.0$ eV and the following ionization energies: H1s: 13.6 eV, F2s: 40.2 eV, F2p: 17.4 eV.

Method Because the F2p and H1s orbitals are much closer in energy than the F2s and H1s orbitals, to a first approximation neglect the contribution of the F2s orbital. To use eqn 11.34, we need to know the values of the Coulomb integrals α_H and α_F . Because these integrals represent the energies of the H1s and F2p electrons, respectively, they are approximately equal to (the negative of) the ionization energies of the atoms. Calculate ζ from eqn 11.33 (with A identified as F and B as H), and then write the wavefunctions by using eqn 11.34.

Answer Setting $\alpha_H = -13.6$ eV and $\alpha_F = -17.4$ eV gives $\tan 2\zeta = 0.58$; so $\zeta = 13.9^\circ$. Then

$$E_- = -13.4 \text{ eV} \quad \psi_- = 0.97\chi_{\text{H}} - 0.24\chi_{\text{F}}$$

$$E_+ = -17.6 \text{ eV} \quad \psi_+ = 0.24\chi_{\text{H}} + 0.97\chi_{\text{F}}$$

Notice how the lower energy orbital (the one with energy -17.6 eV) has a composition that is more F2p orbital than H1s, and that the opposite is true of the higher energy, antibonding orbital.

Self-test 11.6 The ionization energy of Cl is 13.1 eV ; find the form and energies of the σ orbitals in the HCl molecule using $\beta = -1.0 \text{ eV}$.

$$[E_- = -12.8 \text{ eV}, \psi_- = -0.62\chi_{\text{H}} + 0.79\chi_{\text{Cl}}; E_+ = -13.9 \text{ eV}, \psi_+ = 0.79\chi_{\text{H}} + 0.62\chi_{\text{Cl}}]$$

IMPACT ON BIOCHEMISTRY

111.1 The biochemical reactivity of O₂, N₂, and NO

We can now see how some of these concepts are applied to diatomic molecules that play a vital biochemical role. At sea level, air contains approximately 23.1 per cent O₂ and 75.5 per cent N₂ by mass. Molecular orbital theory predicts—correctly—that O₂ has unpaired electron spins and, consequently, is a reactive component of the Earth's atmosphere; its most important biological role is as an oxidizing agent. By contrast N₂, the major component of the air we breathe, is so stable (on account of the triple bond connecting the atoms) and unreactive that *nitrogen fixation*, the reduction of atmospheric N₂ to NH₃, is among the most thermodynamically demanding of biochemical reactions, in the sense that it requires a great deal of energy derived from metabolism. So taxing is the process that only certain bacteria and archaea are capable of carrying it out, making nitrogen available first to plants and other microorganisms in the form of ammonia. Only after incorporation into amino acids by plants does nitrogen adopt a chemical form that, when consumed, can be used by animals in the synthesis of proteins and other nitrogen-containing molecules.

The reactivity of O₂, while important for biological energy conversion, also poses serious physiological problems. During the course of metabolism, some electrons escape from complexes I, II, and III of the respiratory chain and reduce O₂ to superoxide ion, O₂[−]. The ground-state electronic configuration of O₂[−] is $1\sigma_g^2 1\sigma_u^2 2\sigma_g^2 1\pi_u^4 1\pi_g^3$, so the ion is a radical with a bond order $b = \frac{3}{2}$. We predict that the superoxide ion is a reactive species that must be scavenged to prevent damage to cellular components. The enzyme superoxide dismutase protects cells by catalysing the disproportionation (or dismutation) of O₂[−] into O₂ and H₂O₂:

However, H₂O₂ (hydrogen peroxide), formed by the reaction above and by leakage of electrons out of the respiratory chain, is a powerful oxidizing agent and also harmful to cells. It is metabolized further by catalases and peroxidases. A catalase catalyses the reaction

and a peroxidase reduces hydrogen peroxide to water by oxidizing an organic molecule. For example, the enzyme glutathione peroxidase catalyses the reaction

There is growing evidence for the involvement of the damage caused by reactive oxygen species (ROS), such as O₂[−], H₂O₂, and ·OH (the hydroxyl radical), in the mechanism of ageing and in the development of cardiovascular disease, cancer,

Fig. 11.37 The molecular orbital energy level diagram for NO.

stroke, inflammatory disease, and other conditions. For this reason, much effort has been expended on studies of the biochemistry of *antioxidants*, substances that can either deactivate ROS directly (as glutathione does) or halt the progress of cellular damage through reactions with radicals formed by processes initiated by ROS. Important examples of antioxidants are vitamin C (ascorbic acid), vitamin E (α -tocopherol), and uric acid.

Nitric oxide (nitrogen monoxide, NO) is a small molecule that diffuses quickly between cells, carrying chemical messages that help initiate a variety of processes, such as regulation of blood pressure, inhibition of platelet aggregation, and defence against inflammation and attacks to the immune system. The molecule is synthesized from the amino acid arginine in a series of reactions catalysed by nitric oxide synthase and requiring O_2 and NADPH.

Figure 11.37 shows the bonding scheme in NO and illustrates a number of points we have made about heteronuclear diatomic molecules. The ground configuration is $1\sigma^2 2\sigma^2 3\sigma^2 1\pi^4 2\pi^1$. The 3σ and 1π orbitals are predominantly of O character as that is the more electronegative element. The highest-energy occupied orbital is 2π , contains one electron, and has more N character than O character. It follows that NO is a radical with an unpaired electron that can be regarded as localized more on the N atom than on the O atom. The lowest-energy occupied orbital is 4σ , which is also localized predominantly on N.

Because NO is a radical, we expect it to be reactive. Its half-life is estimated at approximately 1–5 s, so it needs to be synthesized often in the cell. As we saw above, there is a biochemical price to be paid for the reactivity of biological radicals. Like O_2 , NO participates in some reactions that are not beneficial to the cell. Indeed, the radicals O_2^- and NO combine to form the peroxynitrite ion:

where we have shown the unpaired electrons explicitly. The peroxynitrite ion is a reactive oxygen species that damages proteins, DNA, and lipids, possibly leading to heart disease, amyotrophic lateral sclerosis (Lou Gehrig's disease), Alzheimer's disease, and multiple sclerosis. Note that the structure of the ion is consistent with the bonding scheme in Fig. 11.37: because the unpaired electron in NO is slightly more localized on the N atom, we expect that atom to form a bond with an O atom from the O_2^- ion.

Molecular orbitals for polyatomic systems

The molecular orbitals of polyatomic molecules are built in the same way as in diatomic molecules, the only difference being that we use more atomic orbitals to construct them. As for diatomic molecules, polyatomic molecular orbitals spread over the entire molecule. A molecular orbital has the general form

$$\psi = \sum_i c_i \chi_i \quad (11.35)$$

where χ_i is an atomic orbital and the sum extends over all the valence orbitals of all the atoms in the molecule. To find the coefficients, we set up the secular equations and the secular determinant, just as for diatomic molecules, solve the latter for the energies, and then use these energies in the secular equations to find the coefficients of the atomic orbitals for each molecular orbital.

The principal difference between diatomic and polyatomic molecules lies in the greater range of shapes that are possible: a diatomic molecule is necessarily linear, but

a triatomic molecule, for instance, may be either linear or angular with a characteristic bond angle. The shape of a polyatomic molecule—the specification of its bond lengths and its bond angles—can be predicted by calculating the total energy of the molecule for a variety of nuclear positions, and then identifying the conformation that corresponds to the lowest energy.

11.6 The Hückel approximation

Molecular orbital theory takes large molecules and extended aggregates of atoms, such as solid materials, in its stride. First we shall consider conjugated molecules, in which there is an alternation of single and double bonds along a chain of carbon atoms. Although the classification of an orbital as σ or π is strictly valid only in linear molecules, as will be familiar from introductory chemistry courses, it is also used to denote the local symmetry with respect to a given A—B bond axis.

The π molecular orbital energy level diagrams of conjugated molecules can be constructed using a set of approximations suggested by Erich Hückel in 1931. In his approach, the π orbitals are treated separately from the σ orbitals, and the latter form a rigid framework that determines the general shape of the molecule. All the C atoms are treated identically, so all the Coulomb integrals α for the atomic orbitals that contribute to the π orbitals are set equal. For example, in ethene, we take the σ bonds as fixed, and concentrate on finding the energies of the single π bond and its companion antibond.

(a) Ethene and frontier orbitals

We express the π orbitals as LCAOs of the $C2p$ orbitals that lie perpendicular to the molecular plane. In ethene, for instance, we would write

$$\psi = c_A A + c_B B \quad (11.36)$$

where the A is a $C2p$ orbital on atom A, and so on. Next, the optimum coefficients and energies are found by the variation principle as explained in Section 11.5. That is, we have to solve the secular determinant, which in the case of ethene is eqn 11.29 with $\alpha_A = \alpha_B = \alpha$:

$$\begin{vmatrix} \alpha - E & \beta - ES \\ \beta - ES & \alpha - E \end{vmatrix} = 0 \quad (11.37)$$

The roots of this determinant can be found very easily (they are the same as those in *Illustration 11.2*). In a modern computation all the resonance integrals and overlap integrals would be included, but an indication of the molecular orbital energy level diagram can be obtained very readily if we make the following additional **Hückel approximations**:

- 1 All overlap integrals are set equal to zero.
- 2 All resonance integrals between non-neighbours are set equal to zero.
- 3 All remaining resonance integrals are set equal (to β).

These approximations are obviously very severe, but they let us calculate at least a general picture of the molecular orbital energy levels with very little work. The assumptions result in the following structure of the secular determinant:

- 1 All diagonal elements: $\alpha - E$.
- 2 Off-diagonal elements between neighbouring atoms: β .
- 3 All other elements: 0.

Fig. 11.38 The Hückel molecular orbital energy levels of ethene. Two electrons occupy the lower π orbital.

These approximations lead to

$$\begin{vmatrix} \alpha - E & \beta \\ \beta & \alpha - E \end{vmatrix} = (\alpha - E)^2 - \beta^2 = 0 \quad (11.38)$$

The roots of the equation are

$$E_{\pm} = \alpha \pm \beta \quad (11.39)$$

The + sign corresponds to the bonding combination (β is negative) and the – sign corresponds to the antibonding combination (Fig. 11.38). We see the effect of neglecting overlap by comparing this result with eqn 11.31.

The building-up principle leads to the configuration $1\pi^2$, because each carbon atom supplies one electron to the π system. The **highest occupied molecular orbital** in ethene, its HOMO, is the 1π orbital; the **lowest unoccupied molecular orbital**, its LUMO, is the 2π orbital (or, as it is sometimes denoted, the $2\pi^*$ orbital). These two orbitals jointly form the **frontier orbitals** of the molecule. The frontier orbitals are important because they are largely responsible for many of the chemical and spectroscopic properties of the molecule. For example, we can estimate that $2|\beta|$ is the $\pi^* \leftarrow \pi$ excitation energy of ethene, the energy required to excite an electron from the 1π to the 2π orbital. The constant β is often left as an adjustable parameter; an approximate value for π bonds formed from overlap of two C2p atomic orbitals is about -2.4 eV (-230 kJ mol $^{-1}$).

(b) The matrix formulation of the Hückel method

In preparation for making Hückel theory more sophisticated and readily applicable to bigger molecules, we need to reformulate it in terms of matrices and vectors (see *Appendix 2*). We have seen that the secular equations that we have to solve for a two-atom system have the form

$$(H_{AA} - E_i S_{AA})c_{i,A} + (H_{AB} - E_i S_{AB})c_{i,B} = 0 \quad (11.40a)$$

$$(H_{BA} - E_i S_{BA})c_{i,A} + (H_{BB} - E_i S_{BB})c_{i,B} = 0 \quad (11.40b)$$

where the eigenvalue E_i corresponds to a wavefunction of the form $\psi_i = c_{i,A}A + c_{i,B}B$. (These expressions generalize eqn 11.25). There are two atomic orbitals, two eigenvalues, and two wavefunctions, so there are two pairs of secular equations, with the first corresponding to E_1 and ψ_1 :

$$(H_{AA} - E_1 S_{AA})c_{1,A} + (H_{AB} - E_1 S_{AB})c_{1,B} = 0 \quad (11.41a)$$

$$(H_{BA} - E_1 S_{BA})c_{1,A} + (H_{BB} - E_1 S_{BB})c_{1,B} = 0 \quad (11.41b)$$

and another corresponding to E_2 and ψ_2 :

$$(H_{AA} - E_2 S_{AA})c_{2,A} + (H_{AB} - E_2 S_{AB})c_{2,B} = 0 \quad (11.41c)$$

$$(H_{BA} - E_2 S_{BA})c_{2,A} + (H_{BB} - E_2 S_{BB})c_{2,B} = 0 \quad (11.41d)$$

If we introduce the following matrices and column vectors

$$\mathbf{H} = \begin{pmatrix} H_{AA} & H_{AB} \\ H_{BA} & H_{BB} \end{pmatrix} \quad \mathbf{S} = \begin{pmatrix} S_{AA} & S_{AB} \\ S_{BA} & S_{BB} \end{pmatrix} \quad \mathbf{c}_i = \begin{pmatrix} c_{i,A} \\ c_{i,B} \end{pmatrix} \quad (11.42)$$

then each pair of equations may be written more succinctly as

$$(\mathbf{H} - E_i \mathbf{S})\mathbf{c}_i = 0 \quad \text{or} \quad \mathbf{H}\mathbf{c}_i = \mathbf{S}\mathbf{c}_i E_i \quad (11.43)$$

where $\mathbf{H}$ is the hamiltonian matrix and $\mathbf{S}$ is the overlap matrix. To proceed with the calculation of the eigenvalues and coefficients, we introduce the matrices

$$\mathbf{C} = (\mathbf{c}_1 \quad \mathbf{c}_2) = \begin{pmatrix} c_{1,A} & c_{2,A} \\ c_{1,B} & c_{2,B} \end{pmatrix} \quad \mathbf{E} = \begin{pmatrix} E_1 & 0 \\ 0 & E_2 \end{pmatrix} \quad [11.44]$$

for then the entire set of equations we have to solve can be expressed as

$$HC = SCE \quad (11.45)$$

Self-test 11.7 Show by carrying out the necessary matrix operations that eqn 11.45 is a representation of the system of equations consisting of eqns 11.41(a)–(d).

In the Hückel approximation, $H_{AA} = H_{BB} = \alpha$, $H_{AB} = H_{BA} = \beta$, and we neglect overlap, setting $S = \mathbf{1}$, the unit matrix (with 1 on the diagonal and 0 elsewhere). Then

$$HC = CE$$

At this point, we multiply from the left by the inverse matrix C^{-1} , and find

$$C^{-1}HC = E \quad (11.46)$$

where we have used $C^{-1}C = \mathbf{1}$. In other words, to find the eigenvalues E_i , we have to find a transformation of H that makes it diagonal. This procedure is called **matrix diagonalization**. The diagonal elements then correspond to the eigenvalues E_i and the columns of the matrix C that brings about this diagonalization are the coefficients of the members of the **basis set**, the set of atomic orbitals used in the calculation, and hence give us the composition of the molecular orbitals. If there are N orbitals in the basis set (there are only two in our example), then there are N eigenvalues E_i and N corresponding column vectors c_i . As a result, we have to solve N equations of the form $Hc_i = Sc_iE_i$ by diagonalization of the $N \times N$ matrix H , as directed by eqn 11.46.

Example 11.4 Finding the molecular orbitals by matrix diagonalization

Set up and solve the matrix equations within the Hückel approximation for the π -orbitals of butadiene (3).

Method The matrices will be four-dimensional for this four-atom system. Ignore overlap, and construct the matrix H by using the Hückel values α and β . Find the matrix C that diagonalizes H : for this step, use mathematical software. Full details are given in *Appendix 2*.

Solution

$$H = \begin{pmatrix} H_{11} & H_{12} & H_{13} & H_{14} \\ H_{21} & H_{22} & H_{23} & H_{24} \\ H_{31} & H_{32} & H_{33} & H_{34} \\ H_{41} & H_{42} & H_{43} & H_{44} \end{pmatrix} = \begin{pmatrix} \alpha & \beta & 0 & 0 \\ \beta & \alpha & \beta & 0 \\ 0 & \beta & \alpha & \beta \\ 0 & 0 & \beta & \alpha \end{pmatrix}$$

Mathematical software then diagonalizes this matrix to

$$E = \begin{pmatrix} \alpha + 1.62\beta & 0 & 0 & 0 \\ 0 & \alpha + 0.62\beta & 0 & 0 \\ 0 & 0 & \alpha - 0.62\beta & 0 \\ 0 & 0 & 0 & \alpha - 1.62\beta \end{pmatrix}$$

and the matrix that achieves the diagonalization is

$$C = \begin{pmatrix} 0.372 & 0.602 & 0.602 & -0.372 \\ 0.602 & 0.372 & -0.372 & 0.602 \\ 0.602 & -0.372 & -0.372 & -0.602 \\ 0.372 & -0.602 & 0.602 & 0.372 \end{pmatrix}$$

3

We can conclude that the energies and molecular orbitals are

$$\begin{aligned} E_1 &= \alpha + 1.62\beta & \psi_1 &= 0.372\chi_A + 0.602\chi_B + 0.602\chi_C + 0.372\chi_D \\ E_2 &= \alpha + 0.62\beta & \psi_2 &= 0.602\chi_A + 0.372\chi_B - 0.372\chi_C - 0.602\chi_D \\ E_3 &= \alpha - 0.62\beta & \psi_3 &= 0.602\chi_A - 0.372\chi_B - 0.372\chi_C + 0.602\chi_D \\ E_4 &= \alpha - 1.62\beta & \psi_4 &= -0.372\chi_A + 0.602\chi_B - 0.602\chi_C - 0.372\chi_D \end{aligned}$$

where the $C2p$ atomic orbitals are denoted by $\chi_A, \dots, \chi_D$. Note that the orbitals are mutually orthogonal and, with overlap neglected, normalized.

Self-test 11.8 Repeat the exercise for the allyl radical, $\cdot\text{CH}_2-\text{CH}=\text{CH}_2$.

$$\begin{aligned} [E = \alpha + 2^{1/2}\beta, \alpha, \alpha - 2^{1/2}\beta; \psi_1 = \tfrac{1}{2}\chi_A + (\tfrac{1}{2})^{1/2}\chi_B + \tfrac{1}{2}\chi_C, \\ \psi_2 = (\tfrac{1}{2})^{1/2}\chi_A - (\tfrac{1}{2})^{1/2}\chi_C, \psi_3 = \tfrac{1}{2}\chi_A - (\tfrac{1}{2})^{1/2}\chi_B + \tfrac{1}{2}\chi_C] \end{aligned}$$

Fig. 11.39 The Hückel molecular orbital energy levels of butadiene and the top view of the corresponding π orbitals. The four p electrons (one supplied by each C) occupy the two lower π orbitals. Note that the orbitals are delocalized.

(c) Butadiene and π -electron binding energy

As we saw in the preceding example, the energies of the four LCAO-MOs for butadiene are

$$E = \alpha \pm 1.62\beta, \quad \alpha \pm 0.62\beta \quad (11.47)$$

These orbitals and their energies are drawn in Fig. 11.39. Note that the greater the number of internuclear nodes, the higher the energy of the orbital. There are four electrons to accommodate, so the ground-state configuration is $1\pi^2 2\pi^2$. The frontier orbitals of butadiene are the 2π orbital (the HOMO, which is largely bonding) and the 3π orbital (the LUMO, which is largely antibonding). ‘Largely’ bonding means that an orbital has both bonding and antibonding interactions between various neighbours, but the bonding effects dominate. ‘Largely antibonding’ indicates that the antibonding effects dominate.

An important point emerges when we calculate the total **π -electron binding energy**, E_π , the sum of the energies of each π electron, and compare it with what we find in ethene. In ethene the total energy is

$$E_\pi = 2(\alpha + \beta) = 2\alpha + 2\beta$$

In butadiene it is

$$E_\pi = 2(\alpha + 1.62\beta) + 2(\alpha + 0.62\beta) = 4\alpha + 4.48\beta$$

Therefore, the energy of the butadiene molecule lies lower by 0.48β (about 110 kJ mol^{-1}) than the sum of two individual π bonds. This extra stabilization of a conjugated system is called the **delocalization energy**. A closely related quantity is the **π -bond formation energy**, the energy released when a π bond is formed. Because the contribution of α is the same in the molecule as in the atoms, we can find the π -bond formation energy from the π -electron binding energy by writing

$$E_{\text{bf}} = E_\pi - N\alpha \quad (11.48)$$

where N is the number of carbon atoms in the molecule. The π -bond formation energy in butadiene, for instance, is 4.48β .

Example 11.5 Estimating the delocalization energy

Use the Hückel approximation to find the energies of the π orbitals of cyclobutadiene, and estimate the delocalization energy.

Method Set up the secular determinant using the same basis as for butadiene, but note that atoms A and D are also now neighbours. Then solve for the roots of the secular equation and assess the total π -bond energy. For the delocalization energy, subtract from the total π -bond energy the energy of two π -bonds.

Answer The hamiltonian matrix is

$$H = \begin{pmatrix} \alpha & \beta & 0 & \beta \\ \beta & \alpha & \beta & 0 \\ 0 & \beta & \alpha & \beta \\ \beta & 0 & \beta & \alpha \end{pmatrix}$$

Diagonalization gives the energies of the orbitals as

$$E = \alpha + 2\beta, \quad \alpha, \quad \alpha, \quad \alpha - 2\beta$$

Four electrons must be accommodated. Two occupy the lowest orbital (of energy $\alpha + 2\beta$), and two occupy the doubly degenerate orbitals (of energy α). The total energy is therefore $4\alpha + 4\beta$. Two isolated π bonds would have an energy $4\alpha + 4\beta$; therefore, in this case, the delocalization energy is zero.

Self-test 11.9 Repeat the calculation for benzene.

[See next subsection]

Fig. 11.40 The σ framework of benzene is formed by the overlap of Csp^2 hybrids, which fit without strain into a hexagonal arrangement.

(d) Benzene and aromatic stability

The most notable example of delocalization conferring extra stability is benzene and the aromatic molecules based on its structure. Benzene is often expressed in a mixture of valence-bond and molecular orbital terms, with typically valence-bond language used for its σ framework and molecular orbital language used to describe its π electrons.

First, the valence-bond component. The six C atoms are regarded as sp^2 hybridized, with a single unhybridized perpendicular $2p$ orbital. One H atom is bonded by ($Csp^2, H1s$) overlap to each C carbon, and the remaining hybrids overlap to give a regular hexagon of atoms (Fig. 11.40). The internal angle of a regular hexagon is 120° , so sp^2 hybridization is ideally suited for forming σ bonds. We see that benzene's hexagonal shape permits strain-free σ bonding.

Now consider the molecular orbital component of the description. The six $C2p$ orbitals overlap to give six π orbitals that spread all round the ring. Their energies are calculated within the Hückel approximation by diagonalizing the hamiltonian matrix

$$H = \begin{pmatrix} \alpha & \beta & 0 & 0 & 0 & \beta \\ \beta & \alpha & \beta & 0 & 0 & 0 \\ 0 & \beta & \alpha & \beta & 0 & 0 \\ 0 & 0 & \beta & \alpha & \beta & 0 \\ 0 & 0 & 0 & \beta & \alpha & \beta \\ \beta & 0 & 0 & 0 & \beta & \alpha \end{pmatrix}$$

The MO energies, the eigenvalues of this matrix, are simply

$$E = \alpha \pm 2\beta, \alpha \pm \beta, \alpha \pm \beta \quad (11.49)$$

as shown in Fig. 11.41. The orbitals there have been given symmetry labels that we explain in Chapter 12. Note that the lowest energy orbital is bonding between all neighbouring atoms, the highest energy orbital is antibonding between each pair of neighbours, and the intermediate orbitals are a mixture of bonding, nonbonding, and antibonding character between adjacent atoms.

Fig. 11.41 The Hückel orbitals of benzene and the corresponding energy levels. The symmetry labels are explained in Chapter 12. The bonding and antibonding character of the delocalized orbitals reflects the numbers of nodes between the atoms. In the ground state, only the bonding orbitals are occupied.

We now apply the building-up principle to the π system. There are six electrons to accommodate (one from each C atom), so the three lowest orbitals (a_{2u} and the doubly-degenerate pair e_{1g}) are fully occupied, giving the ground-state configuration $a_{2u}^2 e_{1g}^4$. A significant point is that the only molecular orbitals occupied are those with net bonding character.

The π -electron energy of benzene is

$$E_{\pi} = 2(\alpha + 2\beta) + 4(\alpha + \beta) = 6\alpha + 8\beta$$

If we ignored delocalization and thought of the molecule as having three isolated π bonds, it would be ascribed a π -electron energy of only $3(2\alpha + 2\beta) = 6\alpha + 6\beta$. The delocalization energy is therefore $2\beta \approx -460 \text{ kJ mol}^{-1}$, which is considerably more than for butadiene. The π -bond formation energy in benzene is 8β .

This discussion suggests that aromatic stability can be traced to two main contributions. First, the shape of the regular hexagon is ideal for the formation of strong σ bonds: the σ framework is relaxed and without strain. Second, the π orbitals are such as to be able to accommodate all the electrons in bonding orbitals, and the delocalization energy is large.

11.7 Computational chemistry

The difficulties arising from the severe assumptions of Hückel method have been overcome by more sophisticated theories that not only calculate the shapes and energies of molecular orbitals but also predict with reasonable accuracy the structure and reactivity of molecules. The full treatment of molecular electronic structure is quite easy to formulate but difficult to implement. However, it has received an enormous amount of attention by chemists, and has become a keystone of modern chemical research. John Pople and Walter Kohn were awarded the Nobel Prize in Chemistry for 1998 for their contributions to the development of computational techniques for the elucidation of molecular structure and reactivity.

Comment 11.12

The web site contains links to sites where you may perform semi-empirical and *ab initio* calculations on simple molecules directly from your web browser.

(a) The Hartree–Fock equations

The starting point is to write down the many-electron wavefunction as a product of one-electron wavefunctions:

$$\Psi = \psi_{a,\alpha}(1) \psi_{a,\beta}(2) \dots \psi_{z,\beta}(N)$$

This is the wavefunction for an N -electron closed-shell molecule in which electron 1 occupies molecular orbital ψ_a with spin α , electron 2 occupies molecular orbital ψ_a with spin β , and so on. However, the wavefunction must satisfy the Pauli principle and change sign under the permutation of any pair of electrons. To achieve this behaviour, we write the wavefunction as a sum of all possible permutations with the appropriate sign:

$$\Psi = \psi_{a,\alpha}(1) \psi_{a,\beta}(2) \dots \psi_{z,\beta}(N) - \psi_{a,\alpha}(2) \psi_{a,\beta}(1) \dots \psi_{z,\beta}(N) + \dots$$

There are $N!$ terms in this sum, and the entire sum can be written as a determinant:

$$\Psi = \frac{1}{\sqrt{N!}} \begin{vmatrix} \psi_{a,\alpha}(1) & \psi_{a,\beta}(1) & \dots & \dots & \psi_{z,\beta}(1) \\ \psi_{a,\alpha}(2) & \psi_{a,\beta}(2) & \dots & \dots & \psi_{z,\beta}(2) \\ \vdots & \vdots & & & \vdots \\ \psi_{a,\alpha}(N) & \psi_{a,\beta}(N) & \dots & \dots & \psi_{z,\beta}(N) \end{vmatrix} \quad (11.50a)$$

The initial factor ensures that the wavefunction is normalized if the component molecular orbitals are normalized. To save the tedium of writing out large determinants, the wavefunction is normally written simply as

$$\Psi = (1/N!)^{1/2} \det |\psi_{a,\alpha}(1) \psi_{a,\beta}(2) \dots \psi_{z,\beta}(N)| \quad (11.50b)$$

When the determinantal wavefunction is combined with the variation principle (Section 11.5c), the optimum wavefunctions, in the sense of corresponding to the lowest total energy, must satisfy the **Hartree–Fock equations**:

$$f_1 \psi_{a,\sigma}(1) = \epsilon \psi_{a,\sigma}(1) \quad (11.51)$$

where σ is either α or β . The **Fock operator** f_1 is

$$f_1 = h_1 + \sum_j \{2J_j(1) - K_j(1)\} \quad (11.52)$$

The three terms in this expression are the **core hamiltonian**

$$h_1 = -\frac{\hbar^2}{2m_e} \nabla_1^2 - \sum_n \frac{Z_n e^2}{4\pi\epsilon_0 r_{n1}} \quad [11.53a]$$

the **Coulomb operator** J , where

$$J_j(1) \psi_a(1) = \int \psi_j^*(2) \psi_j(2) \left(\frac{e^2}{4\pi\epsilon_0 r_{12}} \right) \psi_a(1) d\tau_2 \quad [11.53b]$$

and the **exchange operator**, K , where

$$K_j(1) \psi_a(1) = \int \psi_j^*(2) \psi_a(2) \left(\frac{e^2}{4\pi\epsilon_0 r_{12}} \right) \psi_j(1) d\tau_2 \quad [11.53c]$$

Although the Hartree–Fock equations look deceptively simple, with the Fock operator looking like a hamiltonian, we see from these definitions that f actually depends on the wavefunctions of all the electrons. To proceed, we have to guess the initial form of the wavefunctions, use them in the definition of the Coulomb and exchange operators, and solve the Hartree–Fock equations. That process is then continued using the newly found wavefunctions until each cycle of calculation leaves the energies and wavefunctions unchanged to within a chosen criterion. This is the origin of the term **self-consistent field** (SCF) for this type of procedure.

The difficulty in this procedure is in the solution of the Hartree–Fock equations. To make progress, we have to express the wavefunctions as linear combinations of M atomic orbitals χ_i , and write

$$\psi_a = \sum_{i=1}^M c_{ia} \chi_i$$

As we show in the *Justification* below, the use of a linear combination like this leads to a set of equations that can be expressed in a matrix form known as the **Roothaan equations**:

$$FC = SC\epsilon \quad (11.54)$$

where F is the matrix formed from the Fock operator:

$$F_{ij} = \int \chi_i^*(1) f_1 \chi_j(1) d\tau \quad (11.55a)$$

and S is the matrix of overlap integrals

$$S_{ij} = \int \chi_i^*(1) \chi_j(1) d\tau \quad (11.55b)$$

Justification 11.5 *The Roothaan equations*

To construct the Roothaan equations we substitute the linear combination of atomic orbitals into eqn 11.51, which gives

$$f_1 \sum_{i=1}^M c_{i\alpha} \chi_i(1) = \epsilon_\alpha \sum_{i=1}^M c_{i\alpha} \chi_i(1)$$

Now multiply from the left by $\chi_j^*(1)$ and integrate over the coordinates of electron 1:

$$\sum_{i=1}^M c_{i\alpha} \overbrace{\int \chi_j(1)^* f(1) \chi_i(1) d\mathbf{r}_1}^{F_{ji}} = \epsilon_\alpha \sum_{i=1}^M c_{i\alpha} \overbrace{\int \chi_j(1)^* \chi_i(1) d\mathbf{r}_1}^{S_{ji}}$$

That is,

$$\sum_{i=1}^M F_{ji} c_{i\alpha} = \epsilon_\alpha \sum_{i=1}^M S_{ji} c_{i\alpha}$$

This expression has the form of the matrix equation in eqn 11.54.

(b) Semi-empirical and *ab initio* methods

There are two main strategies for continuing the calculation from this point. In the **semi-empirical methods**, many of the integrals are estimated by appealing to spectroscopic data or physical properties such as ionization energies, and using a series of rules to set certain integrals equal to zero. In the ***ab initio* methods**, an attempt is made to calculate all the integrals that appear in the Fock and overlap matrices. Both procedures employ a great deal of computational effort and, along with cryptanalysts and meteorologists, theoretical chemists are among the heaviest users of the fastest computers.

The Fock matrix has elements that consist of integrals of the form

$$(AB|CD) = \int A(1)B(1) \left(\frac{e^2}{4\pi\epsilon_0 r_{12}} \right) C(2)D(2) d\tau_1 d\tau_2 \quad (11.56)$$

where A , B , C , and D are atomic orbitals that in general may be centred on different nuclei. It can be appreciated that, if there are several dozen atomic orbitals used to build the molecular orbitals, then there will be tens of thousands of integrals of this form to evaluate (the number of integrals increases as the fourth power of the number of atomic orbitals in the basis). One severe approximation is called **complete neglect of differential overlap** (CNDO), in which all integrals are set to zero unless A and B are the same orbitals centred on the same nucleus, and likewise for C and D . The surviving integrals are then adjusted until the energy levels are in good agreement with experiment. The more recent semi-empirical methods make less draconian decisions about which integrals are to be ignored, but they are all descendants of the early CNDO technique. These procedures are now readily available in commercial software packages and can be used with very little detailed knowledge of their mode of calculation. The packages also have sophisticated graphical output procedures, which enable one to analyse the shapes of orbitals and the distribution of electric charge in molecules. The latter is important when assessing, for instance, the likelihood that a given molecule will bind to an active site in an enzyme.

Commercial packages are also available for *ab initio* calculations. Here the problem is to evaluate as efficiently as possible thousands of integrals. This task is greatly facilitated by expressing the atomic orbitals used in the LCAOs as linear combinations of

Gaussian orbitals. A **Gaussian type orbital** (GTO) is a function of the form $e^{-\zeta r^2}$. The advantage of GTOs over the correct orbitals (which for hydrogenic systems are proportional to $e^{-\zeta r}$) is that the product of two Gaussian functions is itself a Gaussian function that lies between the centres of the two contributing functions (Fig. 11.42). In this way, the four-centre integrals like that in eqn 11.56 become two-centre integrals of the form

$$(AB|CD) = \int X(1) \left(\frac{e^2}{4\pi\epsilon_0 r_{12}} \right) Y(2) d\tau_1 d\tau_2 \quad (11.57)$$

where X is the Gaussian corresponding to the product AB and Y is the corresponding Gaussian from CD . Integrals of this form are much easier and faster to evaluate numerically than the original four-centre integrals. Although more GTOs have to be used to simulate the atomic orbitals, there is an overall increase in speed of computation.

(c) Density functional theory

A technique that has gained considerable ground in recent years to become one of the most widely used techniques for the calculation of molecular structure is **density functional theory** (DFT). Its advantages include less demanding computational effort, less computer time, and—in some cases (particularly d -metal complexes)—better agreement with experimental values than is obtained from Hartree–Fock procedures.

The central focus of DFT is the electron density, ρ , rather than the wavefunction ψ . The ‘functional’ part of the name comes from the fact that the energy of the molecule is a function of the electron density, written $E[\rho]$, and the electron density is itself a function of position, $\rho(r)$, and in mathematics a function of a function is called a *functional*. The exact ground-state energy of an n -electron molecule is

$$E[\rho] = E_K + E_{P;e,N} + E_{P;e,e} + E_{XC}[\rho] \quad (11.58)$$

where E_K is the total electron kinetic energy, $E_{P;e,N}$ the electron–nucleus potential energy, $E_{P;e,e}$ the electron–electron potential energy, and $E_{XC}[\rho]$ the **exchange–correlation energy**, which takes into account all the effects due to spin. The orbitals used to construct the electron density from

$$\rho(r) = \sum_{i=1}^N |\psi_i(r)|^2 \quad (11.59)$$

are calculated from the **Kohn–Sham equations**, which are found by applying the variation principle to the electron energy, and are like the Hartree–Fock equations except for a term V_{XC} , which is called the **exchange–correlation potential**:

$$\left\{ \underbrace{\frac{\hbar^2}{2m_e} \nabla^2}_{\text{Kinetic energy}} - \underbrace{\sum_{j=1}^N \frac{Z_j e^2}{4\pi\epsilon_0 r_{j1}}}_{\text{Electron–nucleus attraction}} + \underbrace{\int \frac{\rho(r_2) e^2}{4\pi\epsilon_0 r_{12}} dr_2}_{\text{Electron–electron repulsion}} + \underbrace{V_{XC}(r_1)}_{\text{Exchange–correlation}} \right\} \psi_i(r_1) = \epsilon_i \psi_i(r_1) \quad (11.60)$$

The exchange–correlation potential is the ‘functional derivative’ of the exchange–correlation energy:

$$V_{XC}[\rho] = \frac{\delta E_{XC}[\rho]}{\delta \rho} \quad (11.61)$$

The Kohn–Sham equations are solved iteratively and self-consistently. First, we guess the electron density. For this step it is common to use a superposition of atomic

Fig. 11.42 The product of two Gaussian functions (the purple curves) is itself a Gaussian function located between the two contributing Gaussians.

Comment 11.13

Consider the functional $G[f]$ where f is a function of x . When x changes to $x + \delta x$, the function changes to $f + \delta f$ and the functional changes to $G[f + \delta f]$. By analogy with the derivative of a function, the functional derivative is then defined as

$$\frac{\delta G}{\delta f} = \lim_{\delta f \rightarrow 0} \frac{G[f + \delta f] - G[f]}{\delta f}$$

where the manner in which δf goes to zero must be specified explicitly. See *Appendix 2* for more details and examples.

electron densities. Then the exchange–correlation potential is calculated by assuming an approximate form of the dependence of the exchange–correlation energy on the electron density and evaluating the functional derivative in eqn 11.61. For this step, the simplest approximation is the **local-density approximation** and to write

$$E_{\text{XC}}[\rho] = \int \rho(\mathbf{r}) \epsilon_{\text{XC}}[\rho(\mathbf{r})] d\mathbf{r} \quad (11.62)$$

where ϵ_{XC} is the exchange–correlation energy per electron in a homogeneous gas of constant density. Next, the Kohn–Sham equations are solved to obtain an initial set of orbitals. This set of orbitals is used to obtain a better approximation to the electron density (from eqn 11.59) and the process is repeated until the density and the exchange–correlation energy are constant to within some tolerance.

11.8 The prediction of molecular properties

The results of molecular orbital calculations are only approximate, with deviations from experimental values increasing with the size of the molecule. Therefore, one goal of computational chemistry is to gain insight into trends in properties of molecules, without necessarily striving for ultimate accuracy. In the next sections we give a brief summary of strategies used by computational chemists for the prediction of molecular properties.

(a) Electron density and the electrostatic potential surfaces

One of the most significant developments in computational chemistry has been the introduction of graphical representations of molecular orbitals and electron densities. The raw output of a molecular structure calculation is a list of the coefficients of the atomic orbitals in each molecular orbital and the energies of these orbitals. The graphical representation of a molecular orbital uses stylized shapes to represent the basis set, and then scales their size to indicate the coefficient in the linear combination. Different signs of the wavefunctions are represented by different colours.

Once the coefficients are known, we can build up a representation of the electron density in the molecule by noting which orbitals are occupied and then forming the squares of those orbitals. The total electron density at any point is then the sum of the squares of the wavefunctions evaluated at that point. The outcome is commonly represented by a **isodensity surface**, a surface of constant total electron density (Fig. 11.43). As shown in the illustration, there are several styles of representing an isodensity surface, as a solid form, as a transparent form with a ball-and-stick representation of the molecule within, or as a mesh. A related representation is a **solvent-accessible surface** in which the shape represents the shape of the molecule by imagining a sphere representing a solvent molecule rolling across the surface and plotting the locations of the centre of that sphere.

One of the most important aspects of a molecule other than its geometrical shape is the distribution of charge over its surface. The net charge at each point on an isodensity surface can be calculated by subtracting the charge due to the electron density at that point from the charge due to the nuclei: the result is an **electrostatic potential surface** (an ‘elpot surface’) in which net positive charge is shown in one colour and net negative charge is shown in another, with intermediate gradations of colour (Fig. 11.44).

Representations such as those we have illustrated are of critical importance in a number of fields. For instance, they may be used to identify an electron-poor region of a molecule that is susceptible to association with or chemical attack by an electron-rich region of another molecule. Such considerations are important for assessing the pharmacological activity of potential drugs.

Fig. 11.43 Various representations of an isodensity surface of ethanol (a) solid surface, (b) transparent surface, and (c) mesh surface.

Fig. 11.44 An elpot diagram of ethanol.

(b) Thermodynamic and spectroscopic properties

We already saw in Section 2.8 that computational chemistry is becoming the technique of choice for estimating standard enthalpies of formation of molecules with complex three-dimensional structures. The computational approach also makes it possible to gain insight into the effect of solvation on the enthalpy of formation without conducting experiments. A calculation performed in the absence of solvent molecules estimates the properties of the molecule of interest in the gas phase. Computational methods are available that allow for the inclusion of several solvent molecules around a solute molecule, thereby taking into account the effect of molecular interactions with the solvent on the enthalpy of formation of the solute. Again, the numerical results are only estimates and the primary purpose of the calculation is to predict whether interactions with the solvent increase or decrease the enthalpy of formation. As an example, consider the amino acid glycine, which can exist in a neutral (**4**) or zwitterionic (**5**) form, in which the amino group is protonated and the carboxyl group is deprotonated. It is possible to show computationally that in the gas phase the neutral form has a lower enthalpy of formation than the zwitterionic form. However, in water the opposite is true because of strong interactions between the polar solvent and the charges in the zwitterion.

Molecular orbital calculations can also be used to predict trends in electrochemical properties, such as standard potentials (Chapter 7). Several experimental and computational studies of aromatic hydrocarbons indicate that decreasing the energy of the LUMO enhances the ability of a molecule to accept an electron into the LUMO, with an attendant increase in the value of the molecule's standard potential. The effect is also observed in quinones and flavins, co-factors involved in biological electron transfer reactions. For example, stepwise substitution of the hydrogen atoms in *p*-benzoquinone by methyl groups ($-\text{CH}_3$) results in a systematic increase in the energy of the LUMO and a decrease in the standard potential for formation of the semiquinone radical (**6**):

The standard potentials of naturally occurring quinones are also modified by the presence of different substituents, a strategy that imparts specific functions to specific quinones. For example, the substituents in coenzyme Q are largely responsible for poising its standard potential so that the molecule can function as an electron shuttle between specific electroactive proteins in the respiratory chain (*Impact* I17.2).

We remarked in Chapter 8 that a molecule can absorb or emit a photon of energy hc/λ , resulting in a transition between two quantized molecular energy levels. The transition of lowest energy (and longest wavelength) occurs between the HOMO and LUMO. We can use calculations based on semi-empirical, *ab initio*, and DFT methods to correlate the calculated HOMO–LUMO energy gap with the wavelength of absorption. For example, consider the linear polyenes shown in Table 11.5: ethene (C_2H_4), butadiene (C_4H_6), hexatriene (C_6H_8), and octatetraene (C_8H_{10}), all of which absorb in the ultraviolet region of the spectrum. The table also shows that, as expected, the wavelength of the lowest-energy electronic transition decreases as the energy separation between the HOMO and LUMO increases. We also see that the smallest HOMO–LUMO gap and longest transition wavelength correspond to octatetraene, the longest

Table 11.5 *Ab initio* calculations and spectroscopic data

Polyene	$\{E(\text{HOMO}) - E(\text{LUMO})\}/\text{eV}$	λ/nm
 (C ₂ H ₄)	18.1	163
	14.5	217
	12.7	252
	11.8	304

polyene in the group. It follows that the wavelength of the transition increases with increasing number of conjugated double bonds in linear polyenes. Extrapolation of the trend suggests that a sufficiently long linear polyene should absorb light in the visible region of the electromagnetic spectrum. This is indeed the case for β -carotene (7), which absorbs light with $\lambda \approx 450$ nm. The ability of β -carotene to absorb visible light is part of the strategy employed by plants to harvest solar energy for use in photosynthesis (Chapter 23).

Checklist of key ideas

- ☐ 1. In the Born–Oppenheimer approximation, nuclei are treated as stationary while electrons move around them.
- ☐ 2. In valence-bond theory (VB theory), a bond is regarded as forming when an electron in an atomic orbital on one atom pairs its spin with that of an electron in an atomic orbital on another atom.
- ☐ 3. A valence bond wavefunction with cylindrical symmetry around the internuclear axis is a σ bond. A π bond arises from the merging of two p orbitals that approach side-by-side and the pairing of electrons that they contain.
- ☐ 4. Hybrid orbitals are mixtures of atomic orbitals on the same atom and are invoked in VB theory to explain molecular geometries.
- ☐ 5. In molecular orbital theory (MO theory), electrons are treated as spreading throughout the entire molecule.
- ☐ 6. A bonding orbital is a molecular orbital that, if occupied, contributes to the strength of a bond between two atoms. An antibonding orbital is a molecular orbital that, if occupied, decreases the strength of a bond between two atoms.
- ☐ 7. A σ molecular orbital has zero orbital angular momentum about the internuclear axis. A π molecular orbital has one unit of angular momentum around the internuclear axis; in a nonlinear molecule, it has a nodal plane that includes the internuclear axis.
- ☐ 8. The electron configurations of homonuclear diatomic molecules are shown in Figs. 11.31 and 11.33.
- ☐ 9. When constructing molecular orbitals, we need to consider only combinations of atomic orbitals of similar energies and of the same symmetry around the internuclear axis.
- ☐ 10. The bond order of a diatomic molecule is $b = \frac{1}{2}(n - n^*)$, where n and n^* are the numbers of electrons in bonding and antibonding orbitals, respectively.
- ☐ 11. The electronegativity, χ , of an element is the power of its atoms to draw electrons to itself when it is part of a compound.
- ☐ 12. In a bond between dissimilar atoms, the atomic orbital belonging to the more electronegative atom makes the larger contribution to the molecular orbital with the lowest energy. For the molecular orbital with the highest energy, the principal contribution comes from the atomic orbital belonging to the less electronegative atom.

- 13. The hamiltonian matrix, H , is formed of all integrals $H_{ij} = \int \psi_i^* \hat{H} \psi_j d\tau$. The overlap matrix, S , is formed of all $S_{ij} = \int \psi_i^* \psi_j d\tau$.
- 14. The variation principle states that if an arbitrary wavefunction is used to calculate the energy, the value calculated is never less than the true energy.
- 15. In the Hückel method, all Coulomb integrals H_{ii} are set equal (to α), all overlap integrals are set equal to zero, all resonance integrals H_{ij} between non-neighbours are set equal to zero, and all remaining resonance integrals are set equal (to β).
- 16. The π -electron binding energy is the sum of the energies of each π electron. The π -bond formation energy is the energy released when a π bond is formed. The delocalization energy is the extra stabilization of a conjugated system.
- 17. In the self-consistent field procedure, an initial guess about the composition of the molecular orbitals is successively refined until the solution remains unchanged in a cycle of calculations.
- 18. In semi-empirical methods for the determination of electronic structure, the Schrödinger equation is written in terms of parameters chosen to agree with selected experimental quantities. In *ab initio* and density functional methods, the Schrödinger equation is solved numerically, without the need of parameters that appeal to experimental data.

Discussion questions

- 11.1** Compare the approximations built into valence-bond theory and molecular-orbital theory.
- 11.2** Discuss the steps involved in the construction of sp^3 , sp^2 , and sp hybrid orbitals.
- 11.3** Distinguish between the Pauling and Mulliken electronegativity scales.
- 11.4** Discuss the steps involved in the calculation of the energy of a system by using the variation principle.
- 11.5** Discuss the approximations built into the Hückel method.
- 11.6** Distinguish between delocalization energy, π -electron binding energy, and π -bond formation energy.
- 11.7** Use concepts of molecular orbital theory to describe the biochemical reactivity of O_2 , N_2 , and NO.
- 11.8** Distinguish between semi-empirical, *ab initio*, and density functional theory methods of electronic structure determination.

Exercises

- 11.1a** Give the ground-state electron configurations and bond orders of (a) Li_2 , (b) Be_2 , and (c) C_2 .
- 11.1b** Give the ground-state electron configurations of (a) H_2^+ , (b) N_2 , and (c) O_2^- .
- 11.2a** Give the ground-state electron configurations of (a) CO, (b) NO, and (c) CN^- .
- 11.2b** Give the ground-state electron configurations of (a) ClF, (b) CS, and (c) O_2^- .

11.3a From the ground-state electron configurations of B_2 and C_2 , predict which molecule should have the greater bond dissociation energy.

11.3b Which of the molecules N_2 , NO , O_2 , C_2 , F_2 , and CN would you expect to be stabilized by (a) the addition of an electron to form AB^- , (b) the removal of an electron to form AB^+ ?

11.4a Sketch the molecular orbital energy level diagram for XeF and deduce its ground-state electron configurations. Is XeF likely to have a shorter bond length than XeF^+ ?

11.4b Sketch the molecular orbital energy level diagrams for $BrCl$ and deduce its ground-state electron configurations. Is $BrCl$ likely to have a shorter bond length than $BrCl^-$?

11.5a Use the electron configurations of NO and N_2 to predict which is likely to have the shorter bond length.

11.5b Arrange the species O_2^+ , O_2 , O_2^- , O_2^{2-} in order of increasing bond length.

11.6a Show that the sp^2 hybrid orbital $(s + 2^{1/2}p)/3^{1/2}$ is normalized to 1 if the s and p orbitals are normalized to 1.

11.6b Normalize the molecular orbital $\psi_A + \lambda\psi_B$ in terms of the parameter λ and the overlap integral S .

11.7a Confirm that the bonding and antibonding combinations $\psi_A \pm \psi_B$ are mutually orthogonal in the sense that their mutual overlap is zero.

11.7b Suppose that a molecular orbital has the form $N(0.145A + 0.844B)$. Find a linear combination of the orbitals A and B that is orthogonal to this combination.

11.8a Can the function $\psi = x(L - x)$ be used as a trial wavefunction for the $n = 1$ state of a particle with mass m in a one-dimensional box of length L ? If the answer is yes, then express the energy of this trial wavefunction in terms of h , m , and L and compare it with the exact result (eqn 9.4). If the answer is no, explain why this is not a suitable trial wavefunction.

11.8b Can the function $\psi = x^2(L - 2x)$ be used as a trial wavefunction for the $n = 1$ state of a particle with mass m in a one-dimensional box of length L ? If the answer is yes, then express the energy of this trial wavefunction in terms of h , m , and L and compare it with the exact result (eqn 9.4). If the answer is no, explain why this is not a suitable trial wavefunction.

11.9a Suppose that the function $\psi = Ae^{-ar^2}$, with A being the normalization constant and a being an adjustable parameter, is used as a trial wavefunction for the $1s$ orbital of the hydrogen atom. Express the energy of this trial

wavefunction as a function of the h , a , e , the electron charge, and μ , the effective mass of the H atom.

11.9b Suppose that the function $\psi = Ae^{-ar^2}$, with A being the normalization constant and a being an adjustable parameter, is used as a trial wavefunction for the $1s$ orbital of the hydrogen atom. The energy of this trial wavefunction is

$$E = \frac{3a\hbar^2}{2\mu} - \frac{e^2}{\epsilon_0} \left(\frac{a}{2\pi^3} \right)^{1/2}$$

where e is the electron charge, and μ is the effective mass of the H atom. What is the minimum energy associated with this trial wavefunction?

11.10a What is the energy of an electron that has been ejected from an orbital of ionization energy 11.0 eV by a photon of radiation of wavelength 100 nm?

11.10b What is the energy of an electron that has been ejected from an orbital of ionization energy 4.69 eV by a photon of radiation of wavelength 584 pm?

11.11a Construct the molecular orbital energy level diagrams of ethene on the basis that the molecule is formed from the appropriately hybridized CH_2 or CH fragments.

11.11b Construct the molecular orbital energy level diagrams of ethyne (acetylene) on the basis that the molecule is formed from the appropriately hybridized CH_2 or CH fragments.

11.12a Write down the secular determinants for (a) linear H_3 , (b) cyclic H_3 within the Hückel approximation.

11.12b Predict the electronic configurations of (a) the benzene anion, (b) the benzene cation. Estimate the π -electron binding energy in each case.

11.13a Write down the secular determinants (a) anthracene (8), (b) phenanthrene (9) within the Hückel approximation and using the $C2p$ orbitals as the basis set.

8

9

11.13b Use mathematical software to estimate the π -electron binding energy of (a) anthracene (7), (b) phenanthrene (8) within the Hückel approximation.

Problems*

Numerical problems

11.1 Show that, if a wave $\cos kx$ centred on A (so that x is measured from A) interferes with a similar wave $\cos k'x$ centred on B (with x measured from B) a distance R away, then constructive interference occurs in the intermediate region when $k = k' = \pi/2R$ and destructive interference if $kR = \frac{1}{2}\pi$ and $k'R = \frac{3}{2}\pi$.

11.2 The overlap integral between two $H1s$ orbitals on nuclei separated by a distance R is $S = \{1 + (R/a_0) + \frac{1}{3}(R/a_0)^2\}e^{-R/a_0}$. Plot this function for $0 \leq R < \infty$.

11.3 Before doing the calculation below, sketch how the overlap between a $1s$ orbital and a $2p$ orbital can be expected to depend on their separation. The overlap integral between an $H1s$ orbital and an $H2p$ orbital on nuclei

separated by a distance R and forming a σ orbital is $S = (R/a_0)\{1 + (R/a_0) + \frac{1}{3}(R/a_0)^2\}e^{-R/a_0}$. Plot this function, and find the separation for which the overlap is a maximum.

11.4 Calculate the total amplitude of the normalized bonding and antibonding LCAO-MOs that may be formed from two $H1s$ orbitals at a separation of 106 pm. Plot the two amplitudes for positions along the molecular axis both inside and outside the internuclear region.

11.5 Repeat the calculation in Problem 11.4 but plot the probability densities of the two orbitals. Then form the difference density, the difference between ψ^2 and $\frac{1}{2}\{\psi_A^2 + \psi_B^2\}$.

* Problems denoted with the symbol ‡ were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

11.6† Use the $2p_x$ and $2p_z$ hydrogenic atomic orbitals to construct simple LCAO descriptions of $2p\sigma$ and $2p\pi$ molecular orbitals. (a) Make a probability density plot, and both surface and contour plots of the xz -plane amplitudes of the $2p_z\sigma$ and $2p_z\sigma^*$ molecular orbitals. (b) Make surface and contour plots of the xz -plane amplitudes of the $2p_x\pi$ and $2p_x\pi^*$ molecular orbitals. Include plots for both internuclear distances, R , of $10a_0$ and $3a_0$, where $a_0 = 52.9$ pm. Interpret the graphs, and describe why this graphical information is useful.

11.7 Imagine a small electron-sensitive probe of volume 1.00 pm^3 inserted into an H_2^+ molecule-ion in its ground state. Calculate the probability that it will register the presence of an electron at the following positions: (a) at nucleus A, (b) at nucleus B, (c) half-way between A and B, (c) at a point 20 pm along the bond from A and 10 pm perpendicularly. Do the same for the molecule-ion the instant after the electron has been excited into the antibonding LCAO-MO.

11.8 The energy of H_2^+ with internuclear separation R is given by the expression

$$E = E_{\text{H}} + \frac{e^2}{4\pi\epsilon_0 R} - \frac{V_1 + V_2}{1 + S}$$

where E_{H} is the energy of an isolated H atom, V_1 is the attractive potential energy between the electron centred on one nucleus and the charge of the other nucleus, V_2 is the attraction between the overlap density and one of the nuclei, S is the overlap integral. The values are given below. Plot the molecular potential energy curve and find the bond dissociation energy (in electronvolts) and the equilibrium bond length.

R/a_0	0	1	2	3	4
V_1/E_{H}	11.000	10.729	10.473	10.330	10.250
V_2/E_{H}	11.000	10.736	10.406	10.199	10.092
S	1.000	0.858	0.587	0.349	0.189

where $E_{\text{H}} = 27.3$ eV and $a_0 = 52.9$ pm and $E_{\text{H}} = -\frac{1}{2}E_{\text{H}}$.

11.9 The same data as in Problem 11.8 may be used to calculate the molecular potential energy curve for the antibonding orbital, which is given by

$$E = E_{\text{H}} + \frac{e^2}{4\pi\epsilon_0 R} - \frac{V_1 - V_2}{1 - S}$$

Plot the curve.

11.10† J.G. Dojahn, E.C.M. Chen, and W.E. Wentworth (*J. Phys. Chem.* **100**, 9649 (1996)) characterized the potential energy curves of homonuclear diatomic halogen molecules and molecular anions. Among the properties they report are the equilibrium internuclear distance R_e , the vibrational wavenumber, $\tilde{\nu}$, and the dissociation energy, D_e :

Species	R_e	$\tilde{\nu}/\text{cm}^{-1}$	D_e/eV
F_2	1.411	916.6	1.60
F_2^-	1.900	450.0	1.31

Rationalize these data in terms of molecular orbital configurations.

11.11† *Rydberg molecules* are molecules with an electron in an atomic orbital with principal quantum number n one higher than the valence shells of the constituent atoms. Speculate about the existence of 'hyper Rydberg' H_2 formed from two H atoms with 100s electrons. Make reasonable guesses about the binding energy, the equilibrium internuclear separation, the vibrational force constant, and the rotational constant. Is such a molecule likely to exist under any circumstances?

11.12 In a particular photoelectron spectrum using 21.21 eV photons, electrons were ejected with kinetic energies of 11.01 eV, 8.23 eV, and 5.22 eV. Sketch the molecular orbital energy level diagram for the species, showing the ionization energies of the three identifiable orbitals.

11.13† Set up and solve the Hückel secular equations for the π electrons of NO^+ . Express the energies in terms of the Coulomb integrals α_{O} and α_{N} and the resonance integral β . Determine the delocalization energy of the ion.

11.14 In the 'free electron molecular orbital' (FEMO) theory, the electrons in a conjugated molecule are treated as independent particles in a box of length L . Sketch the form of the two occupied orbitals in butadiene predicted by this model and predict the minimum excitation energy of the molecule. The tetraene $\text{CH}_2=\text{CHCH}=\text{CHCH}=\text{CH}_2$ can be treated as a box of length $8R$, where $R \approx 140$ pm (as in this case, an extra half bond-length is often added at each end of the box). Calculate the minimum excitation energy of the molecule and sketch the HOMO and LUMO. Estimate the colour a sample of the compound is likely to appear in white light.

11.15 The FEMO theory (Problem 11.14) of conjugated molecules is rather crude and better results are obtained with simple Hückel theory. (a) For a linear conjugated polyene with each of N carbon atoms contributing an electron in a $2p$ orbital, the energies E_k of the resulting π molecular orbitals are given by (see also Section 20.9):

$$E_k = \alpha + 2\beta \cos \frac{k\pi}{N+1} \quad k = 1, 2, 3, \dots, N$$

Use this expression to determine a reasonable empirical estimate of the resonance integral β for the homologous series consisting of ethene, butadiene, hexatriene, and octatetraene given that $\pi^* \leftarrow \pi$ ultraviolet absorptions from the HOMO to the LUMO occur at 61 500, 46 080, 39 750, and 32 900 cm^{-1} , respectively. (b) Calculate the π -electron delocalization energy, $E_{\text{deloc}} = E_{\pi} - n(\alpha + \beta)$, of octatetraene, where E_{π} is the total π -electron binding energy and n is the total number of π -electrons. (c) In the context of this Hückel model, the π molecular orbitals are written as linear combinations of the carbon $2p$ orbitals. The coefficient of the j th atomic orbital in the k th molecular orbital is given by:

$$c_{kj} = \left(\frac{2}{N+1} \right)^{1/2} \sin \frac{jk\pi}{N+1} \quad j = 1, 2, 3, \dots, N$$

Determine the values of the coefficients of each of the six $2p$ orbitals in each of the six π molecular orbitals of hexatriene. Match each set of coefficients (that is, each molecular orbital) with a value of the energy calculated with the expression given in part (a) of the molecular orbital. Comment on trends that relate the energy of a molecular orbital with its 'shape', which can be inferred from the magnitudes and signs of the coefficients in the linear combination that describes the molecular orbital.

11.16 For monocyclic conjugated polyenes (such as cyclobutadiene and benzene) with each of N carbon atoms contributing an electron in a $2p$ orbital, simple Hückel theory gives the following expression for the energies E_k of the resulting π molecular orbitals:

$$E_k = \alpha + 2\beta \cos \frac{2k\pi}{N} \quad k = 0, \pm 1, \pm 2, \dots, \pm N/2 \text{ (even } N)$$

$$k = 0, \pm 1, \pm 2, \dots, \pm (N-1)/2 \text{ (odd } N)$$

(a) Calculate the energies of the π molecular orbitals of benzene and cyclooctatetraene. Comment on the presence or absence of degenerate energy levels. (b) Calculate and compare the delocalization energies of benzene (using the expression above) and hexatriene (see Problem 11.15a). What do you conclude from your results? (c) Calculate and compare the delocalization energies of cyclooctaene and octatetraene. Are your conclusions for this pair of molecules the same as for the pair of molecules investigated in part (b)?

11.17 If you have access to mathematical software that can perform matrix diagonalization, use it to solve Problems 11.15 and 11.16, disregarding the expressions for the energies and coefficients given there.

11.18 Molecular orbital calculations based on semi-empirical, *ab initio*, and DFT methods describe the spectroscopic properties of conjugated molecules a

bit better than simple Hückel theory. (a) Using molecular modelling software² and the computational method of your choice (semi-empirical, *ab initio*, or density functional methods), calculate the energy separation between the HOMO and LUMO of ethene, butadiene, hexatriene, and octatetraene. (b) Plot the HOMO–LUMO energy separations against the experimental frequencies for $\pi^* \leftarrow \pi$ ultraviolet absorptions for these molecules (Problem 11.15). Use mathematical software to find the polynomial equation that best fits the data. (c) Use your polynomial fit from part (b) to estimate the frequency of the $\pi^* \leftarrow \pi$ ultraviolet absorption of decapentaene from the calculated HOMO–LUMO energy separation. (d) Discuss why the calibration procedure of part (b) is necessary.

11.19 Electronic excitation of a molecule may weaken or strengthen some bonds because bonding and antibonding characteristics differ between the HOMO and the LUMO. For example, a carbon–carbon bond in a linear polyene may have bonding character in the HOMO and antibonding character in the LUMO. Therefore, promotion of an electron from the HOMO to the LUMO weakens this carbon–carbon bond in the excited electronic state, relative to the ground electronic state. Display the HOMO and LUMO of each molecule in Problem 11.15 and discuss in detail any changes in bond order that accompany the $\pi^* \leftarrow \pi$ ultraviolet absorptions in these molecules.

11.20 As mentioned in Section 2.8, molecular electronic structure methods may be used to estimate the standard enthalpy of formation of molecules in the gas phase. (a) Using molecular modelling software and a semi-empirical method of your choice, calculate the standard enthalpy of formation of ethene, butadiene, hexatriene, and octatetraene in the gas phase. (b) Consult a database of thermochemical data, such as the online sources listed in this textbook's web site, and, for each molecule in part (a), calculate the relative error between the calculated and experimental values of the standard enthalpy of formation. (c) A good thermochemical database will also report the uncertainty in the experimental value of the standard enthalpy of formation. Compare experimental uncertainties with the relative errors calculated in part (b) and discuss the reliability of your chosen semi-empirical method for the estimation of thermochemical properties of linear polyenes.

Theoretical problems

11.21 An sp^2 hybrid orbital that lies in the xy -plane and makes an angle of 120° to the x -axis has the form

$$\psi = \frac{1}{3^{1/2}} \left(s - \frac{1}{2^{1/2}} p_x + \frac{3^{1/2}}{2^{1/2}} p_y \right)$$

Use hydrogenic atomic orbitals to write the explicit form of the hybrid orbital. Show that it has its maximum amplitude in the direction specified.

11.22 Use the expressions in Problems 11.8 and 11.9 to show that the antibonding orbital is more antibonding than the bonding orbital is bonding at most internuclear separations.

11.23 Derive eqns 11.11 and 11.14 by working with the normalized LCAO–MOs for the H_2^+ molecule-ion (Section 11.3a). Proceed by evaluating the expectation value of the hamiltonian for the ion. Make use of the fact that A and B each individually satisfy the Schrödinger equation for an isolated H atom.

11.24 Take as a trial function for the ground state of the hydrogen atom (a) e^{-kr} , (b) e^{-kr^2} and use the variation principle to find the optimum value of k in each case. Identify the better wavefunction. The only part of the laplacian that need be considered is the part that involves radial derivatives (eqn 9.5).

11.25 We saw in Section 11.5 that, to find the energies of the bonding and antibonding orbitals of a heteronuclear diatomic molecule, we need to solve the secular determinant

$$\begin{vmatrix} \alpha_A - E & B \\ \beta & \alpha_B - E \end{vmatrix} = 0$$

where $\alpha_A \neq \alpha_B$ and we have taken $S = 0$. Equations 11.34a and 11.34b give the general solution to this problem. Here, we shall develop the result for the case $(\alpha_B - \alpha_A)^2 \gg \beta^2$. (a) Begin by showing that

$$E_{\pm} = \frac{\alpha_A + \alpha_B}{2} \pm \frac{\alpha_A - \alpha_B}{2} \left[1 + \frac{4\beta^2}{(\alpha_A - \alpha_B)^2} \right]^{1/2}$$

where E_+ and E_- are the energies of the bonding and antibonding molecular orbitals, respectively. (b) Now use the expansion

$$(1+x)^{1/2} = 1 + \frac{x}{2} - \frac{x^2}{8} + \dots$$

to show that

$$E_- = \alpha_B + \frac{\beta^2}{\alpha_B - \alpha_A} \quad E_+ = \alpha_A - \frac{\beta^2}{\alpha_B - \alpha_A}$$

which is the limiting result used in *Justification 11.4*.

Applications: to astrophysics and biology

11.26† In Exercise 11.12a you were invited to set up the Hückel secular determinant for linear and cyclic H_3 . The same secular determinant applies to the molecular ions H_3^+ and D_3^+ . The molecular ion H_3^+ was discovered as long ago as 1912 by J.J. Thomson, but only more recently has the equivalent equilateral triangular structure been confirmed by M.J. Gaillard *et al.* (*Phys. Rev. A* **17**, 1797 (1978)). The molecular ion H_3^+ is the simplest polyatomic species with a confirmed existence and plays an important role in chemical reactions occurring in interstellar clouds that may lead to the formation of water, carbon monoxide, and ethyl alcohol. The H_3^+ ion has also been found in the atmospheres of Jupiter, Saturn, and Uranus. (a) Solve the Hückel secular equations for the energies of the H_3 system in terms of the parameters α and β , draw an energy level diagram for the orbitals, and determine the binding energies of H_3^+ , H_3 , and H_3^- . (b) Accurate quantum mechanical calculations by G.D. Carney and R.N. Porter (*J. Chem. Phys.* **65**, 3547 (1976)) give the dissociation energy for the process $\text{H}_3^+ \rightarrow \text{H} + \text{H} + \text{H}^+$ as 849 kJ mol^{-1} . From this information and data in Table 11.3, calculate the enthalpy of the reaction $\text{H}^+(\text{g}) + \text{H}_2(\text{g}) \rightarrow \text{H}_3^+(\text{g})$. (c) From your equations and the information given, calculate a value for the resonance integral β in H_3^+ . Then go on to calculate the binding energies of the other H_3 species in (a).

11.27† There is some indication that other hydrogen ring compounds and ions in addition to H_3 and D_3 species may play a role in interstellar chemistry. According to J.S. Wright and G.A. DiLabio (*J. Phys. Chem.* **96**, 10793 (1992)), H_5^- , H_6 , and H_7^+ are particularly stable whereas H_4 and H_5^+ are not. Confirm these statements by Hückel calculations.

11.28 Here we develop a molecular orbital theory treatment of the peptide group (10), which links amino acids in proteins. Specifically, we shall describe the factors that stabilize the planar conformation of the peptide group.

10

² The web site contains links to molecular modelling freeware and to other sites where you may perform molecular orbital calculations directly from your web browser.

(a) It will be familiar from introductory chemistry that valence bond theory explains the planar conformation of the peptide group by invoking delocalization of the π bond between the oxygen, carbon, and nitrogen atoms (11, 11):

It follows that we can model the peptide group with molecular orbital theory by making LCAO-MOs from $2p$ orbitals perpendicular to the plane defined by the O, C, and N atoms. The three combinations have the form:

$$\psi_1 = a\psi_O + b\psi_C + c\psi_N \quad \psi_2 = d\psi_O - e\psi_N \quad \psi_3 = f\psi_O - g\psi_C + h\psi_N$$

where the coefficients a through h are all positive. Sketch the orbitals ψ_1 , ψ_2 , and ψ_3 and characterize them as bonding, non-bonding, or antibonding molecular orbitals. In a non-bonding molecular orbital, a pair of electrons resides in an orbital confined largely to one atom and not appreciably involved in bond formation. (b) Show that this treatment is consistent only with a planar conformation of the peptide link. (c) Draw a diagram showing the relative energies of these molecular orbitals and determine the occupancy of the orbitals. *Hint.* Convince yourself that there are four electrons to be distributed among the molecular orbitals. (d) Now consider a non-planar conformation of the peptide link, in which the $O2p$ and $C2p$ orbitals are perpendicular to the plane defined by the O, C, and N atoms, but the $N2p$ orbital lies on that plane. The LCAO-MOs are given by

$$\psi_4 = a\psi_O + b\psi_C \quad \psi_5 = e\psi_N \quad \psi_6 = f\psi_O - g\psi_C$$

Just as before, sketch these molecular orbitals and characterize them as bonding, non-bonding, or antibonding. Also, draw an energy level diagram and determine the occupancy of the orbitals. (e) Why is this arrangement of atomic orbitals consistent with a non-planar conformation for the peptide link? (f) Does the bonding MO associated with the planar conformation have the same energy as the bonding MO associated with the non-planar conformation? If not, which bonding MO is lower in energy? Repeat the analysis for the non-bonding and anti-bonding molecular orbitals. (g) Use your results from parts (a)–(f) to construct arguments that support the planar model for the peptide link.

11.29 Molecular orbital calculations may be used to predict trends in the standard potentials of conjugated molecules, such as the quinones and flavins, that are involved in biological electron transfer reactions (*Impact I17.2*). It is

commonly assumed that decreasing the energy of the LUMO enhances the ability of a molecule to accept an electron into the LUMO, with an attendant increase in the value of the molecule's standard potential. Furthermore, a number of studies indicate that there is a linear correlation between the LUMO energy and the reduction potential of aromatic hydrocarbons (see, for example, J.P. Lowe, *Quantum chemistry*, Chapter 8, Academic Press (1993)).

(a) The standard potentials at pH = 7 for the one-electron reduction of methyl-substituted 1,4-benzoquinones (13) to their respective semiquinone radical anions are:

R_2	R_3	R_5	R_6	E°/V
H	H	H	H	0.078
CH_3	H	H	H	0.023
CH_3	H	CH_3	H	-0.067
CH_3	CH_3	CH_3	H	-0.165
CH_3	CH_3	CH_3	CH_3	-0.260

13

Using molecular modelling software and the computational method of your choice (semi-empirical, *ab initio*, or density functional theory methods), calculate E_{LUMO} , the energy of the LUMO of each substituted 1,4-benzoquinone, and plot E_{LUMO} against E° . Do your calculations support a linear relation between E_{LUMO} and E° ? (b) The 1,4-benzoquinone for which $R_2 = R_3 = \text{CH}_3$ and $R_5 = R_6 = \text{OCH}_3$ is a suitable model of ubiquinone, a component of the respiratory electron transport chain (*Impact I7.2*). Determine E_{LUMO} of this quinone and then use your results from part (a) to estimate its standard potential. (c) The 1,4-benzoquinone for which $R_2 = R_3 = R_5 = \text{CH}_3$ and $R_6 = \text{H}$ is a suitable model of plastoquinone, a component of the photosynthetic electron transport chain (*Impact I7.2*). Determine E_{LUMO} of this quinone and then use your results from part (a) to estimate its standard potential. Is plastoquinone expected to be a better or worse oxidizing agent than ubiquinone? (d) Based on your predictions and on basic concepts of biological electron transport (*Impact I7.2 and I23.2*), suggest a reason why ubiquinone is used in respiration and plastoquinone is used in photosynthesis.

Problems

In this chapter we sharpen the concept of ‘shape’ into a precise definition of ‘symmetry’, and show that symmetry may be discussed systematically. We see how to classify any molecule according to its symmetry and how to use this classification to discuss molecular properties. After describing the symmetry properties of molecules themselves, we turn to a consideration of the effect of symmetry transformations on orbitals and see that their transformation properties can be used to set up a labelling scheme. These symmetry labels are used to identify integrals that necessarily vanish. One important integral is the overlap integral between two orbitals. By knowing which atomic orbitals may have nonzero overlap, we can decide which ones can contribute to molecular orbitals. We also see how to select linear combinations of atomic orbitals that match the symmetry of the nuclear framework. Finally, by considering the symmetry properties of integrals, we see that it is possible to derive the selection rules that govern spectroscopic transitions.

The systematic discussion of symmetry is called **group theory**. Much of group theory is a summary of common sense about the symmetries of objects. However, because group theory is systematic, its rules can be applied in a straightforward, mechanical way. In most cases the theory gives a simple, direct method for arriving at useful conclusions with the minimum of calculation, and this is the aspect we stress here. In some cases, though, it leads to unexpected results.

The symmetry elements of objects

Some objects are ‘more symmetrical’ than others. A sphere is more symmetrical than a cube because it looks the same after it has been rotated through any angle about any diameter. A cube looks the same only if it is rotated through certain angles about specific axes, such as 90° , 180° , or 270° about an axis passing through the centres of any of its opposite faces (Fig. 12.1), or by 120° or 240° about an axis passing through any of its opposite corners. Similarly, an NH_3 molecule is ‘more symmetrical’ than an H_2O molecule because NH_3 looks the same after rotations of 120° or 240° about the axis shown in Fig. 12.2, whereas H_2O looks the same only after a rotation of 180° .

An action that leaves an object looking the same after it has been carried out is called a **symmetry operation**. Typical symmetry operations include rotations, reflections, and inversions. There is a corresponding **symmetry element** for each symmetry operation, which is the point, line, or plane with respect to which the symmetry operation is performed. For instance, a rotation (a symmetry operation) is carried out around an axis (the corresponding symmetry element). We shall see that we can classify molecules by identifying all their symmetry elements, and grouping together molecules that

Fig. 12.1 Some of the symmetry elements of a cube. The twofold, threefold, and fourfold axes are labelled with the conventional symbols.

Fig. 12.2 (a) An NH_3 molecule has a threefold (C_3) axis and (b) an H_2O molecule has a twofold (C_2) axis. Both have other symmetry elements too.

possess the same set of symmetry elements. This procedure, for example, puts the trigonal pyramidal species NH_3 and SO_3^{2-} into one group and the angular species H_2O and SO_2 into another group.

12.1 Operations and symmetry elements

The classification of objects according to symmetry elements corresponding to operations that leave at least one common point unchanged gives rise to the **point groups**. There are five kinds of symmetry operation (and five kinds of symmetry element) of this kind. When we consider crystals (Chapter 20), we shall meet symmetries arising from translation through space. These more extensive groups are called **space groups**.

The **identity**, E , consists of doing nothing; the corresponding symmetry element is the entire object. Because every molecule is indistinguishable from itself if nothing is done to it, every object possesses at least the identity element. One reason for including the identity is that some molecules have only this symmetry element (**1**); another reason is technical and connected with the detailed formulation of group theory.

An **n -fold rotation** (the operation) about an **n -fold axis of symmetry**, C_n (the corresponding element) is a rotation through $360^\circ/n$. The operation C_1 is a rotation through 360° , and is equivalent to the identity operation E . An H_2O molecule has one twofold axis, C_2 . An NH_3 molecule has one threefold axis, C_3 , with which is associated two symmetry operations, one being 120° rotation in a clockwise sense and the other 120° rotation in a counter-clockwise sense. A pentagon has a C_5 axis, with two (clockwise and counterclockwise) rotations through 72° associated with it. It also has an axis denoted C_5^2 , corresponding to two successive C_5 rotations; there are two such operations, one through 144° in a clockwise sense and the other through 144° in a counter-clockwise sense. A cube has three C_4 axes, four C_3 axes, and six C_2 axes. However, even this high symmetry is exceeded by a sphere, which possesses an infinite number of symmetry axes (along any diameter) of all possible integral values of n . If a molecule possesses several rotation axes, then the one (or more) with the greatest value of n is called the **principal axis**. The principal axis of a benzene molecule is the sixfold axis perpendicular to the hexagonal ring (**2**).

1 CBrClFI

2 Benzene, C_6H_6

Comment 12.1

There is only one twofold rotation associated with a C_2 axis because clockwise and counter-clockwise 180° rotations are identical.

Fig. 12.3 An H_2O molecule has two mirror planes. They are both vertical (i.e. contain the principal axis), so are denoted σ_v and σ'_v .

Fig. 12.4 Dihedral mirror planes (σ_d) bisect the C_2 axes perpendicular to the principal axis.

Fig. 12.5 A regular octahedron has a centre of inversion (i).

A **reflection** (the operation) in a **mirror plane**, σ (the element), may contain the principal axis of a molecule or be perpendicular to it. If the plane is parallel to the principal axis, it is called 'vertical' and denoted σ_v . An H_2O molecule has two vertical planes of symmetry (Fig. 12.3) and an NH_3 molecule has three. A vertical mirror plane that bisects the angle between two C_2 axes is called a 'dihedral plane' and is denoted σ_d (Fig. 12.4). When the plane of symmetry is perpendicular to the principal axis it is called 'horizontal' and denoted σ_h . A C_6H_6 molecule has a C_6 principal axis and a horizontal mirror plane (as well as several other symmetry elements).

In an **inversion** (the operation) through a **centre of symmetry**, i (the element), we imagine taking each point in a molecule, moving it to the centre of the molecule, and then moving it out the same distance on the other side; that is, the point (x, y, z) is taken into the point $(-x, -y, -z)$. Neither an H_2O molecule nor an NH_3 molecule has a centre of inversion, but a sphere and a cube do have one. A C_6H_6 molecule does have a centre of inversion, as does a regular octahedron (Fig. 12.5); a regular tetrahedron and a CH_4 molecule do not.

An **n -fold improper rotation** (the operation) about an **n -fold axis of improper rotation** or an **n -fold improper rotation axis**, S_n , (the symmetry element) is composed of two successive transformations. The first component is a rotation through $360^\circ/n$, and the second is a reflection through a plane perpendicular to the axis of that rotation; neither operation alone needs to be a symmetry operation. A CH_4 molecule has three S_4 axes (Fig. 12.6).

Fig. 12.6 (a) A CH_4 molecule has a fourfold improper rotation axis (S_4): the molecule is indistinguishable after a 90° rotation followed by a reflection across the horizontal plane, but neither operation alone is a symmetry operation. (b) The staggered form of ethane has an S_6 axis composed of a 60° rotation followed by a reflection.

12.2 The symmetry classification of molecules

To classify molecules according to their symmetries, we list their symmetry elements and collect together molecules with the same list of elements. This procedure puts CH_4 and CCl_4 , which both possess the same symmetry elements as a regular tetrahedron, into the same group, and H_2O into another group.

The name of the group to which a molecule belongs is determined by the symmetry elements it possesses. There are two systems of notation (Table 12.1). The **Schoenflies system** (in which a name looks like C_{4v}) is more common for the discussion of individual molecules, and the **Hermann–Mauguin system**, or **International system** (in which a name looks like $4mm$), is used almost exclusively in the discussion of crystal symmetry. The identification of a molecule's point group according to the Schoenflies system is simplified by referring to the flow diagram in Fig. 12.7 and the shapes shown in Fig. 12.8.

Select C_n with highest n ; then, are the nC_2 perpendicular to C_n ?

4 Quinoline, C9H7N

Fig. 12.7 A flow diagram for determining the point group of a molecule. Start at the top and answer the question posed in each diamond (Y = yes, N = no).

(a) The groups C_1 , C_i , and C_s

A molecule belongs to the group C_1 if it has no element other than the identity, as in (1). It belongs to C_i if it has the identity and the inversion alone (3), and to C_s if it has the identity and a mirror plane alone (4).

Table 12.1 The notation for point groups*

C_i	$\bar{1}$								
C_s	m								
C_1	1	C_2	2	C_3	3	C_4	4	C_6	6
		C_{2v}	$2mm$	C_{3v}	$3m$	C_{4v}	$4mm$	C_{6v}	$6mm$
		C_{2h}	$2m$	C_{3h}	$\bar{6}$	C_{4h}	$4/m$	C_{6h}	$6/m$
		D_2	222	D_3	32	D_4	422	D_6	622
		D_{2h}	mmm	D_{3h}	$\bar{6}2m$	D_{4h}	$4/mmm$	D_{6h}	$6/mmm$

T	23	T_d	$\bar{4}3m$	T_h	$m\bar{3}$				
O	432	O_h	$m\bar{3}m$						

* In the International system (or Hermann–Mauguin system) for point groups, a number n denotes the presence of an n -fold axis and m denotes a mirror plane. A slash (/) indicates that the mirror plane is perpendicular to the symmetry axis. It is important to distinguish symmetry elements of the same type but of different classes, as in $4/mmm$, in which there are three classes of mirror plane. A bar over a number indicates that the element is combined with an inversion. The only groups listed here are the so-called ‘crystallographic point groups’ (Section 20.1).

Fig. 12.8 A summary of the shapes corresponding to different point groups. The group to which a molecule belongs can often be identified from this diagram without going through the formal procedure in Fig. 12.7.

5 Hydrogen peroxide, H_2O_2 6 *trans*- $\text{CHCl}=\text{CHCl}$ 7 B(OH)_3 **(b) The groups C_n , C_{nv} , and C_{nh}**

A molecule belongs to the group C_n if it possesses an n -fold axis. Note that symbol C_n is now playing a triple role: as the label of a symmetry element, a symmetry operation, and a group. For example, an H_2O_2 molecule has the elements E and C_2 (5), so it belongs to the group C_2 .

If in addition to the identity and a C_n axis a molecule has n vertical mirror planes σ_v , then it belongs to the group C_{nv} . An H_2O molecule, for example, has the symmetry elements E , C_2 , and $2\sigma_v$, so it belongs to the group C_{2v} . An NH_3 molecule has the elements E , C_3 , and $3\sigma_v$, so it belongs to the group C_{3v} . A heteronuclear diatomic molecule such as HCl belongs to the group $C_{\infty v}$ because all rotations around the axis and reflections across the axis are symmetry operations. Other members of the group $C_{\infty v}$ include the linear OCS molecule and a cone.

Objects that in addition to the identity and an n -fold principal axis also have a horizontal mirror plane σ_h belong to the groups C_{nh} . An example is *trans*- $\text{CHCl}=\text{CHCl}$ (6), which has the elements E , C_2 , and σ_h , so belongs to the group C_{2h} ; the molecule B(OH)_3 in the conformation shown in (7) belongs to the group C_{3h} . The presence of certain symmetry elements may be implied by the presence of others: thus, in C_{2h} the operations C_2 and σ_h jointly imply the presence of a centre of inversion (Fig. 12.9).

Fig. 12.9 The presence of a twofold axis and a horizontal mirror plane jointly imply the presence of a centre of inversion in the molecule.

(c) The groups D_n , D_{nh} , and D_{nd}

We see from Fig. 12.7 that a molecule that has an n -fold principal axis and n twofold axes perpendicular to C_n belongs to the group D_n . A molecule belongs to D_{nh} if it also possesses a horizontal mirror plane. The planar trigonal BF_3 molecule has the elements E , C_3 , $3C_2$, and σ_h (with one C_2 axis along each $\text{B}-\text{F}$ bond), so belongs to D_{3h} (8). The C_6H_6 molecule has the elements E , C_6 , $3C_2$, $3C_2'$, and σ_h together with some others that these elements imply, so it belongs to D_{6h} . All homonuclear diatomic molecules, such as N_2 , belong to the group $D_{\infty h}$ because all rotations around the axis are symmetry operations, as are end-to-end rotation and end-to-end reflection; $D_{\infty h}$ is also the group of the linear OCO and HCCH molecules and of a uniform cylinder. Other examples of D_{nh} molecules are shown in (9), (10), and (11).

A molecule belongs to the group D_{nd} if in addition to the elements of D_n it possesses n dihedral mirror planes σ_d . The twisted, 90° allene (12) belongs to D_{2d} , and the staggered conformation of ethane (13) belongs to D_{3d} .

(d) The groups S_n

Molecules that have not been classified into one of the groups mentioned so far, but that possess one S_n axis, belong to the group S_n . An example is tetraphenylmethane, which belongs to the point group S_4 (14). Molecules belonging to S_n with $n > 4$ are rare. Note that the group S_2 is the same as C_i , so such a molecule will already have been classified as C_i .

Comment 12.2

The prime on $3C_2'$ indicates that the three C_2 axes are different from the other three C_2 axes. In benzene, three of the C_2 axes bisect $\text{C}-\text{C}$ bonds and the other three pass through vertices of the hexagon formed by the carbon framework of the molecule.

8 Boron trifluoride, BF_3

9 Ethene, $\text{CH}_2=\text{CH}_2$ (D_{2h})

10 Phosphorus pentachloride, PCl_5 (D_{3h})

11 Tetrachloroaurate(III) ion, $[\text{AuCl}_4]^-$ (D_{4h})

12 Allene, C_3H_4 (D_{2d})

13 Ethane, C_2H_6 (D_{3d})

14 Tetraphenylmethane, $\text{C}(\text{C}_6\text{H}_5)_4$ (S_4)

15 Buckminsterfullerene, C_{60} (I_h)

(e) The cubic groups

A number of very important molecules (e.g. CH_4 and SF_6) possess more than one principal axis. Most belong to the **cubic groups**, and in particular to the **tetrahedral groups** T , T_d , and T_h (Fig. 12.10a) or to the **octahedral groups** O and O_h (Fig. 12.10b). A few icosahedral (20-faced) molecules belonging to the **icosahedral group**, I (Fig. 12.10c), are also known: they include some of the boranes and buckminsterfullerene, C_{60} (15). The groups T_d and O_h are the groups of the regular tetrahedron (for instance, CH_4) and the regular octahedron (for instance, SF_6), respectively. If the object possesses the rotational symmetry of the tetrahedron or the octahedron, but none of their planes of reflection, then it belongs to the simpler groups T or O (Fig. 12.11). The group T_h is based on T but also contains a centre of inversion (Fig. 12.12).

Fig. 12.10 (a) Tetrahedral, (b) octahedral, and (c) icosahedral molecules are drawn in a way that shows their relation to a cube: they belong to the cubic groups T_d , O_h , and I_h , respectively.

Fig. 12.11 Shapes corresponding to the point groups (a) T and (b) O . The presence of the decorated slabs reduces the symmetry of the object from T_d and O_h , respectively.

Fig. 12.12 The shape of an object belonging to the group T_h .

(f) The full rotation group

The **full rotation group**, R_3 (the 3 refers to rotation in three dimensions), consists of an infinite number of rotation axes with all possible values of n . A sphere and an atom belong to R_3 , but no molecule does. Exploring the consequences of R_3 is a very important way of applying symmetry arguments to atoms, and is an alternative approach to the theory of orbital angular momentum.

Example 12.1 Identifying a point group of a molecule

Identify the point group to which a ruthenocene molecule (**16**) belongs.

Method Use the flow diagram in Fig. 12.7.

Answer The path to trace through the flow diagram in Fig. 12.7 is shown by a green line; it ends at D_{nh} . Because the molecule has a fivefold axis, it belongs to the group D_{5h} . If the rings were staggered, as they are in an excited state of ferrocene that lies 4 kJ mol^{-1} above the ground state (**17**), the horizontal reflection plane would be absent, but dihedral planes would be present.

Self-test 12.1 Classify the pentagonal antiprismatic excited state of ferrocene (**17**).
[D_{5d}]

16 Ruthenocene, $\text{Ru}(\text{cp})_2$

17 Ferrocene, $\text{Fe}(\text{cp})_2$

12.3 Some immediate consequences of symmetry

Some statements about the properties of a molecule can be made as soon as its point group has been identified.

(a) Polarity

A **polar molecule** is one with a permanent electric dipole moment (HCl , O_3 , and NH_3 are examples). If the molecule belongs to the group C_n with $n > 1$, it cannot possess a charge distribution with a dipole moment perpendicular to the symmetry axis because the symmetry of the molecule implies that any dipole that exists in one direction perpendicular to the axis is cancelled by an opposing dipole (Fig. 12.13a). For example, the perpendicular component of the dipole associated with one $\text{O}-\text{H}$ bond in H_2O is cancelled by an equal but opposite component of the dipole of the second $\text{O}-\text{H}$ bond, so any dipole that the molecule has must be parallel to the twofold symmetry axis.

Comment 12.3

The web site contains links to interactive tutorials, where you use your web browser to assign point groups of molecules.

Fig. 12.13 (a) A molecule with a C_n axis cannot have a dipole perpendicular to the axis, but (b) it may have one parallel to the axis. The arrows represent local contributions to the overall electric dipole, such as may arise from bonds between pairs of neighbouring atoms with different electronegativities.

Fig. 12.14 Some symmetry elements are implied by the other symmetry elements in a group. Any molecule containing an inversion also possesses at least an S_2 element because i and S_2 are equivalent.

18 L-Alanine, $\text{NH}_2\text{CH}(\text{CH}_3)\text{COOH}$

19 Glycine, $\text{NH}_2\text{CH}_2\text{COOH}$

20 $\text{N}(\text{CH}_2\text{CH}(\text{CH}_3)\text{CH}(\text{CH}_3)\text{CH}_2)_2^+$

However, as the group makes no reference to operations relating the two ends of the molecule, a charge distribution may exist that results in a dipole along the axis (Fig. 12.13b), and H₂O has a dipole moment parallel to its twofold symmetry axis. The same remarks apply generally to the group C_{nv} , so molecules belonging to any of the C_{nv} groups may be polar. In all the other groups, such as C_{3h} , D , etc., there are symmetry operations that take one end of the molecule into the other. Therefore, as well as having no dipole perpendicular to the axis, such molecules can have none along the axis, for otherwise these additional operations would not be symmetry operations. We can conclude that *only molecules belonging to the groups C_n , C_{nv} , and C_s may have a permanent electric dipole moment.*

For C_n and C_{nv} , that dipole moment must lie along the symmetry axis. Thus ozone, O₃, which is angular and belongs to the group C_{2v} , may be polar (and is), but carbon dioxide, CO₂, which is linear and belongs to the group $D_{\infty h}$, is not.

(b) Chirality

A **chiral molecule** (from the Greek word for 'hand') is a molecule that cannot be superimposed on its mirror image. An **achiral molecule** is a molecule that can be superimposed on its mirror image. Chiral molecules are **optically active** in the sense that they rotate the plane of polarized light (a property discussed in more detail in Appendix 3). A chiral molecule and its mirror-image partner constitute an **enantiomeric pair** of isomers and rotate the plane of polarization in equal but opposite directions.

A molecule may be chiral, and therefore optically active, only if it does not possess an axis of improper rotation, S_n . However, we need to be aware that such an axis may be present under a different name, and be implied by other symmetry elements that are present. For example, molecules belonging to the groups C_{nh} possess an S_n axis implicitly because they possess both C_n and σ_h , which are the two components of an improper rotation axis. Any molecule containing a centre of inversion, i , also possesses an S_2 axis, because i is equivalent to C_2 in conjunction with σ_h , and that combination of elements is S_2 (Fig. 12.14). It follows that all molecules with centres of inversion are achiral and hence optically inactive. Similarly, because $S_1 = \sigma$, it follows that any molecule with a mirror plane is achiral.

A molecule may be chiral if it does not have a centre of inversion or a mirror plane, which is the case with the amino acid alanine (18), but not with glycine (19). However, a molecule may be achiral even though it does not have a centre of inversion. For example, the S_4 species (20) is achiral and optically inactive: though it lacks i (that is, S_2) it does have an S_4 axis.

Applications to molecular orbital theory and spectroscopy

We shall now turn our attention away from the symmetries of molecules themselves and direct it towards the symmetry characteristics of orbitals that belong to the various atoms in a molecule. This material will enable us to discuss the formulation and labelling of molecular orbitals and selection rules in spectroscopy.

12.4 Character tables and symmetry labels

We saw in Chapter 11 that molecular orbitals of diatomic and linear polyatomic molecules are labelled σ , π , etc. These labels refer to the symmetries of the orbitals with respect to rotations around the principal symmetry axis of the molecule. Thus, a σ orbital does not change sign under a rotation through any angle, a π orbital changes sign when rotated by 180° , and so on (Fig. 12.15). The symmetry classifications σ and π can also be assigned to individual atomic orbitals in a linear molecule. For example, we can speak of an individual p_z orbital as having σ symmetry if the z -axis lies along the bond, because p_z is cylindrically symmetrical about the bond. This labelling of orbitals according to their behaviour under rotations can be generalized and extended to nonlinear polyatomic molecules, where there may be reflections and inversions to take into account as well as rotations.

(a) Representations and characters

Labels analogous to σ and π are used to denote the symmetries of orbitals in polyatomic molecules. These labels look like a , a_1 , e , e_g , and we first encountered them in Fig. 11.4 in connection with the molecular orbitals of benzene. As we shall see, these labels indicate the behaviour of the orbitals under the symmetry operations of the relevant point group of the molecule.

A label is assigned to an orbital by referring to the **character table** of the group, a table that characterizes the different symmetry types possible in the point group. Thus, to assign the labels σ and π , we use the table shown in the margin. This table is a fragment of the full character table for a linear molecule. The entry +1 shows that the orbital remains the same and the entry -1 shows that the orbital changes sign under the operation C_2 at the head of the column (as illustrated in Fig. 12.15). So, to assign the label σ or π to a particular orbital, we compare the orbital's behaviour with the information in the character table.

The entries in a complete character table are derived by using the formal techniques of group theory and are called **characters**, χ (chi). These numbers characterize the essential features of each symmetry type in a way that we can illustrate by considering the C_{2v} molecule SO_2 and the valence p_x orbitals on each atom, which we shall denote p_S , p_A , and p_B (Fig. 12.16).

Under σ_v , the change $(p_S, p_B, p_A) \leftarrow (p_S, p_A, p_B)$ takes place. We can express this transformation by using matrix multiplication:

$$(p_S, p_B, p_A) = (p_S, p_A, p_B) \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix} = (p_S, p_A, p_B) D(\sigma_v) \quad (12.1)$$

The matrix $D(\sigma_v)$ is called a **representative** of the operation σ_v . Representatives take different forms according to the **basis**, the set of orbitals, that has been adopted.

Fig. 12.15 A rotation through 180° about the internuclear axis (perpendicular to the page) leaves the sign of a σ orbital unchanged but the sign of a π orbital is changed. In the language introduced in this chapter, the characters of the C_2 rotation are +1 and -1 for the σ and π orbitals, respectively.

	C_2	(i.e. rotation by 180°)
σ	+1	(i.e. no change of sign)
π	-1	(i.e. change of sign)

Fig. 12.16 The three p_x orbitals that are used to illustrate the construction of a matrix representation in a C_{2v} molecule (SO_2).

Comment 12.4

See [Appendix 2](#) for a summary of the rules of matrix algebra.

We can use the same technique to find matrices that reproduce the other symmetry operations. For instance, C_2 has the effect $(-p_S, -p_B, -p_A) \leftarrow (p_S, p_A, p_B)$, and its representative is

$$D(C_2) = \begin{pmatrix} -1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & -1 & 0 \end{pmatrix} \quad (12.2)$$

The effect of σ'_v is $(-p_S, -p_A, -p_B) \leftarrow (p_S, p_A, p_B)$, and its representative is

$$D(\sigma'_v) = \begin{pmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & -1 \end{pmatrix} \quad (12.3)$$

The identity operation has no effect on the basis, so its representative is the 3×3 unit matrix:

$$D(E) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad (12.4)$$

The set of matrices that represents *all* the operations of the group is called a **matrix representation**, Γ (uppercase gamma), of the group for the particular basis we have chosen. We denote this three-dimensional representation by $\Gamma^{(3)}$. The discovery of a matrix representation of the group means that we have found a link between symbolic manipulations of operations and algebraic manipulations of numbers.

The character of an operation in a particular matrix representation is the sum of the diagonal elements of the representative of that operation. Thus, in the basis we are illustrating, the characters of the representatives are

$$\begin{array}{cccc} D(E) & D(C_2) & D(\sigma_v) & D(\sigma'_v) \\ 3 & -1 & 1 & -3 \end{array}$$

The character of an operation depends on the basis.

Inspection of the representatives shows that they are all of **block-diagonal form**:

$$D = \begin{pmatrix} [\blacksquare] & 0 & 0 \\ 0 & [\blacksquare] & [\blacksquare] \\ 0 & [\blacksquare] & [\blacksquare] \end{pmatrix}$$

The block-diagonal form of the representatives show us that the symmetry operations of C_{2v} never mix p_S with the other two functions. Consequently, the basis can be cut into two parts, one consisting of p_S alone and the other of (p_A, p_B) . It is readily verified that the p_S orbital itself is a basis for the one-dimensional representation

$$D(E) = 1 \quad D(C_2) = -1 \quad D(\sigma_v) = 1 \quad D(\sigma'_v) = -1$$

which we shall call $\Gamma^{(1)}$. The remaining two basis functions are a basis for the two-dimensional representation $\Gamma^{(2)}$:

$$D(E) = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \quad D(C_2) = \begin{pmatrix} 0 & -1 \\ -1 & 0 \end{pmatrix} \quad D(\sigma_v) = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \quad D(\sigma'_v) = \begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix}$$

These matrices are the same as those of the original three-dimensional representation, except for the loss of the first row and column. We say that the original three-dimensional representation has been **reduced** to the 'direct sum' of a one-dimensional representation 'spanned' by p_S , and a two-dimensional representation spanned by (p_A, p_B) . This reduction is consistent with the common sense view that the central

orbital plays a role different from the other two. We denote the reduction symbolically by writing

$$\Gamma^{(3)} = \Gamma^{(1)} + \Gamma^{(2)} \quad (12.5)$$

The one-dimensional representation $\Gamma^{(1)}$ cannot be reduced any further, and is called an **irreducible representation** of the group (an ‘irrep’). We can demonstrate that the two-dimensional representation $\Gamma^{(2)}$ is reducible (for this basis in this group) by switching attention to the linear combinations $p_1 = p_A + p_B$ and $p_2 = p_A - p_B$. These combinations are sketched in Fig. 12.17. The representatives in the new basis can be constructed from the old by noting, for example, that under σ_v , $(p_B, p_A) \leftarrow (p_A, p_B)$. In this way we find the following representation in the new basis:

$$D(E) = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \quad D(C_2) = \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix} \quad D(\sigma_v) = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \quad D(\sigma'_v) = \begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix}$$

The new representatives are all in block-diagonal form, and the two combinations are not mixed with each other by any operation of the group. We have therefore achieved the reduction of $\Gamma^{(2)}$ to the sum of two one-dimensional representations. Thus, p_1 spans

$$D(E) = 1 \quad D(C_2) = -1 \quad D(\sigma_v) = 1 \quad D(\sigma'_v) = -1$$

which is the same one-dimensional representation as that spanned by p_s , and p_2 spans

$$D(E) = 1 \quad D(C_2) = 1 \quad D(\sigma_v) = -1 \quad D(\sigma'_v) = -1$$

which is a different one-dimensional representation; we shall denote it $\Gamma^{(1)'}$.

At this point we have found two irreducible representations of the group C_{2v} (Table 12.2). The two irreducible representations are normally labelled B_1 and A_2 , respectively. An A or a B is used to denote a one-dimensional representation; A is used if the character under the principal rotation is +1, and B is used if the character is -1. Subscripts are used to distinguish the irreducible representations if there is more than one of the same type: A_1 is reserved for the representation with character 1 for all operations. When higher dimensional irreducible representations are permitted, E denotes a two-dimensional irreducible representation and T a three-dimensional irreducible representation; all the irreducible representations of C_{2v} are one-dimensional.

There are in fact only two more species of irreducible representations of this group, for a surprising theorem of group theory states that

$$\text{Number of symmetry species} = \text{number of classes} \quad (12.6)$$

Symmetry operations fall into the same **class** if they are of the same type (for example, rotations) and can be transformed into one another by a symmetry operation of the

Fig. 12.17 Two symmetry-adapted linear combinations of the basis orbitals shown in Fig. 12.16. The two combinations each span a one-dimensional irreducible representation, and their symmetry species are different.

Table 12.2* The C_{2v} character table

$C_{2v}, 2mm$	E	C_2	σ_v	σ'_v	$h=4$	
A_1	1	1	1	1	z	z^2, y^2, x^2
A_2	1	1	-1	-1		xy
B_1	1	-1	1	-1	x	zx
B_2	1	-1	-1	1	y	yz

* More character tables are given at the end of the *Data section*.

Table 12.3* The C_{3v} character table

$C_{3v}, 3m$	E	$2C_3$	$3\sigma_v$	$h=6$	
A_1	1	1	1	z	$z^2, x^2 + y^2$
A_2	1	1	-1		
E	2	-1	0	(x, y)	$(xy, x^2 - y^2), (yz, zx)$

* More character tables are given at the end of the *Data section*.

Fig. 12.18 Symmetry operations in the same class are related to one another by the symmetry operations of the group. Thus, the three mirror frames shown here are related by threefold rotations, and the two rotations shown here are related by reflection in σ_v .

Comment 12.5

Note that care must be taken to distinguish the identity element E (italic, a column heading) from the symmetry label E (roman, a row label).

group. In C_{2v} , for instance, there are four classes (four columns in the character table), so there are only four species of irreducible representation. The character table in Table 12.2 therefore shows the characters of all the irreducible representations of this group.

(b) The structure of character tables

In general, the columns in a character table are labelled with the symmetry operations of the group. For instance, for the group C_{3v} the columns are headed E , C_3 , and σ_v (Table 12.3). The numbers multiplying each operation are the numbers of members of each class. In the C_{3v} character table we see that the two threefold rotations (clockwise and counter-clockwise rotations by 120°) belong to the same class: they are related by a reflection (Fig. 12.18). The three reflections (one through each of the three vertical mirror planes) also lie in the same class: they are related by the threefold rotations. The two reflections of the group C_{2v} fall into different classes: although they are both reflections, one cannot be transformed into the other by any symmetry operation of the group.

The total number of operations in a group is called the **order**, h , of the group. The order of the group C_{3v} , for instance, is 6.

The rows under the labels for the operations summarize the symmetry properties of the orbitals. They are labelled with the **symmetry species** (the analogues of the labels σ and π). More formally, the symmetry species label the irreducible representations of the group, which are the basic types of behaviour that orbitals may show when subjected to the symmetry operations of the group, as we have illustrated for the group C_{2v} . By convention, irreducible representations are labelled with upper case Roman letters (such as A_1 and E) but the orbitals to which they apply are labelled with the lower case italic equivalents (so an orbital of symmetry species A_1 is called an a_1 orbital). Examples of each type of orbital are shown in Fig. 12.19.

(c) Character tables and orbital degeneracy

The character of the identity operation E tells us the degeneracy of the orbitals. Thus, in a C_{3v} molecule, any orbital with a symmetry label a_1 or a_2 is nondegenerate. Any doubly degenerate pair of orbitals in C_{3v} must be labelled e because, in this group, only E symmetry species have characters greater than 1.

Because there are no characters greater than 2 in the column headed E in C_{3v} , we know that there can be no triply degenerate orbitals in a C_{3v} molecule. This last point is a powerful result of group theory, for it means that, with a glance at the character table of a molecule, we can state the maximum possible degeneracy of its orbitals.

Example 12.2 Using a character table to judge degeneracy

Can a trigonal planar molecule such as BF_3 have triply degenerate orbitals? What is the minimum number of atoms from which a molecule can be built that does display triple degeneracy?

Method First, identify the point group, and then refer to the corresponding character table in the *Data section*. The maximum number in the column headed by the identity E is the maximum orbital degeneracy possible in a molecule of that point group. For the second part, consider the shapes that can be built from two, three, etc. atoms, and decide which number can be used to form a molecule that can have orbitals of symmetry species T .

Answer Trigonal planar molecules belong to the point group D_{3h} . Reference to the character table for this group shows that the maximum degeneracy is 2, as no character exceeds 2 in the column headed E . Therefore, the orbitals cannot be triply degenerate. A tetrahedral molecule (symmetry group T) has an irreducible representation with a T symmetry species. The minimum number of atoms needed to build such a molecule is four (as in P_4 , for instance).

Self-test 12.2 A buckminsterfullerene molecule, C_{60} (**15**), belongs to the icosahedral point group. What is the maximum possible degree of degeneracy of its orbitals?

[5]

(d) Characters and operations

The characters in the rows labelled A and B and in the columns headed by symmetry operations other than the identity E indicate the behaviour of an orbital under the corresponding operations: a +1 indicates that an orbital is unchanged, and a -1 indicates that it changes sign. It follows that we can identify the symmetry label of the orbital by comparing the changes that occur to an orbital under each operation, and then comparing the resulting +1 or -1 with the entries in a row of the character table for the point group concerned.

For the rows labelled E or T (which refer to the behaviour of sets of doubly and triply degenerate orbitals, respectively), the characters in a row of the table are the sums of the characters summarizing the behaviour of the individual orbitals in the basis. Thus, if one member of a doubly degenerate pair remains unchanged under a symmetry operation but the other changes sign (Fig. 12.20), then the entry is reported as $\chi = 1 - 1 = 0$. Care must be exercised with these characters because the transformations of orbitals can be quite complicated; nevertheless, the sums of the individual characters are integers.

As an example, consider the $\text{O}2p_x$ orbital in H_2O . Because H_2O belongs to the point group C_{2v} , we know by referring to the C_{2v} character table (Table 12.2) that the labels available for the orbitals are a_1 , a_2 , b_1 , and b_2 . We can decide the appropriate label for $\text{O}2p_x$ by noting that under a 180° rotation (C_2) the orbital changes sign (Fig. 12.21), so it must be either B_1 or B_2 , as only these two symmetry types have character -1 under C_2 . The $\text{O}2p_x$ orbital also changes sign under the reflection σ'_v , which identifies it as B_1 . As we shall see, any molecular orbital built from this atomic orbital will also be a b_1 orbital. Similarly, $\text{O}2p_y$ changes sign under C_2 but not under σ'_v ; therefore, it can contribute to b_2 orbitals.

The behaviour of s , p , and d orbitals on a central atom under the symmetry operations of the molecule is so important that the symmetry species of these orbitals

Fig. 12.19 Typical symmetry-adapted linear combinations of orbitals in a C_{3v} molecule.

Fig. 12.20 The two orbitals shown here have different properties under reflection through the mirror plane: one changes sign (character -1), the other does not (character +1).

Fig. 12.21 A p_x orbital on the central atom of a C_{2v} molecule and the symmetry elements of the group.

Fig. 12.22 The three $H1s$ orbitals used to construct symmetry-adapted linear combinations in a C_{3v} molecule such as NH_3 .

Fig. 12.23 One symmetry-adapted linear combination of $O2p_x$ orbitals in the C_{2v} NO_2^- ion.

are generally indicated in a character table. To make these allocations, we look at the symmetry species of x , y , and z , which appear on the right-hand side of the character table. Thus, the position of z in Table 12.3 shows that p_z (which is proportional to $zf(r)$), has symmetry species A_1 in C_{3v} , whereas p_x and p_y (which are proportional to $xf(r)$ and $yf(r)$, respectively) are jointly of E symmetry. In technical terms, we say that p_x and p_y jointly **span** an irreducible representation of symmetry species E . An s orbital on the central atom always spans the fully symmetrical irreducible representation (typically labelled A_1 but sometimes A_1') of a group as it is unchanged under all symmetry operations.

The five d orbitals of a shell are represented by xy for d_{xy} , etc, and are also listed on the right of the character table. We can see at a glance that in C_{3v} , d_{xy} and $d_{x^2-y^2}$ on a central atom jointly belong to E and hence form a doubly degenerate pair.

(e) The classification of linear combinations of orbitals

So far, we have dealt with the symmetry classification of individual orbitals. The same technique may be applied to linear combinations of orbitals on atoms that are related by symmetry transformations of the molecule, such as the combination $\psi_1 = \psi_A + \psi_B + \psi_C$ of the three $H1s$ orbitals in the C_{3v} molecule NH_3 (Fig. 12.22). This combination remains unchanged under a C_3 rotation and under any of the three vertical reflections of the group, so its characters are

$$\chi(E) = 1 \quad \chi(C_3) = 1 \quad \chi(\sigma_v) = 1$$

Comparison with the C_{3v} character table shows that ψ_1 is of symmetry species A_1 , and therefore that it contributes to a_1 molecular orbitals in NH_3 .

Example 12.3 Identifying the symmetry species of orbitals

Identify the symmetry species of the orbital $\psi = \psi_A - \psi_B$ in a C_{2v} NO_2 molecule, where ψ_A is an $O2p_x$ orbital on one O atom and ψ_B that on the other O atom.

Method The negative sign in ψ indicates that the sign of ψ_B is opposite to that of ψ_A . We need to consider how the combination changes under each operation of the group, and then write the character as +1, -1, or 0 as specified above. Then we compare the resulting characters with each row in the character table for the point group, and hence identify the symmetry species.

Answer The combination is shown in Fig. 12.23. Under C_2 , ψ changes into itself, implying a character of +1. Under the reflection σ_v , both orbitals change sign, so $\psi \rightarrow -\psi$, implying a character of -1. Under σ_v' , $\psi \rightarrow -\psi$, so the character for this operation is also -1. The characters are therefore

$$\chi(E) = 1 \quad \chi(C_2) = 1 \quad \chi(\sigma_v) = -1 \quad \chi(\sigma_v') = -1$$

These values match the characters of the A_2 symmetry species, so ψ can contribute to an a_2 orbital.

Self-test 12.3 Consider $PtCl_4^{2-}$, in which the Cl ligands form a square planar array of point group D_{4h} (21). Identify the symmetry type of the combination $\psi_A - \psi_B + \psi_C - \psi_D$. [B_{2g}]

12.5 Vanishing integrals and orbital overlap

Suppose we had to evaluate the integral

$$I = \int f_1 f_2 d\tau \quad (12.7)$$

where f_1 and f_2 are functions. For example, f_1 might be an atomic orbital A on one atom and f_2 an atomic orbital B on another atom, in which case I would be their overlap integral. If we knew that the integral is zero, we could say at once that a molecular orbital does not result from (A,B) overlap in that molecule. We shall now see that character tables provide a quick way of judging whether an integral is necessarily zero.

(a) The criteria for vanishing integrals

The key point in dealing with the integral I is that the value of any integral, and of an overlap integral in particular, is independent of the orientation of the molecule (Fig. 12.24). In group theory we express this point by saying that I is *invariant under any symmetry operation of the molecule*, and that each operation brings about the trivial transformation $I \rightarrow I$. Because the volume element $d\tau$ is invariant under any symmetry operation, it follows that the integral is nonzero only if the integrand itself, the product $f_1 f_2$, is unchanged by any symmetry operation of the molecular point group. If the integrand changed sign under a symmetry operation, the integral would be the sum of equal and opposite contributions, and hence would be zero. It follows that the only contribution to a nonzero integral comes from functions for which under any symmetry operation of the molecular point group $f_1 f_2 \rightarrow f_1 f_2$, and hence for which the characters of the operations are all equal to +1. Therefore, for I not to be zero, *the integrand $f_1 f_2$ must have symmetry species A_1 (or its equivalent in the specific molecular point group)*.

We use the following procedure to deduce the symmetry species spanned by the product $f_1 f_2$ and hence to see whether it does indeed span A_1 .

- 1 Decide on the symmetry species of the individual functions f_1 and f_2 by reference to the character table, and write their characters in two rows in the same order as in the table.
- 2 Multiply the numbers in each column, writing the results in the same order.
- 3 Inspect the row so produced, and see if it can be expressed as a sum of characters from each column of the group. The integral must be zero if this sum does not contain A_1 .

For example, if f_1 is the s_N orbital in NH_3 and f_2 is the linear combination $s_3 = s_B - s_C$ (Fig. 12.25), then, because s_N spans A_1 and s_3 is a member of the basis spanning E , we write

f_1 :	1	1	1
f_2 :	2	-1	0
$f_1 f_2$:	2	-1	0

The characters 2, -1, 0 are those of E alone, so the integrand does not span A_1 . It follows that the integral must be zero. Inspection of the form of the functions (see Fig. 12.25) shows why this is so: s_3 has a node running through s_N . Had we taken $f_1 = s_N$ and $f_2 = s_1$ instead, where $s_1 = s_A + s_B + s_C$, then because each spans A_1 with characters 1, 1, 1:

f_1 :	1	1	1
f_2 :	1	1	1
$f_1 f_2$:	1	1	1

(a)

(b)

Fig. 12.24 The value of an integral I (for example, an area) is independent of the coordinate system used to evaluate it. That is, I is a basis of a representation of symmetry species A_1 (or its equivalent).

Fig. 12.25 A symmetry-adapted linear combination that belongs to the symmetry species E in a C_{3v} molecule such as NH_3 . This combination can form a molecular orbital by overlapping with the p_x orbital on the central atom (the orbital with its axis parallel to the width of the page; see Fig. 12.28c).

Fig. 12.26 The integral of the function $f = xy$ over the tinted region is zero. In this case, the result is obvious by inspection, but group theory can be used to establish similar results in less obvious cases. The insert shows the shape of the function in three dimensions.

Fig. 12.27 The integration of a function over a pentagonal region. The insert shows the shape of the function in three dimensions.

The characters of the product are those of A_1 itself. Therefore, s_1 and s_N may have nonzero overlap. A shortcut that works when f_1 and f_2 are bases for irreducible representations of a group is to note their symmetry species: if they are different, then the integral of their product must vanish; if they are the same, then the integral may be nonzero.

It is important to note that group theory is specific about when an integral must be zero, but integrals that it allows to be nonzero may be zero for reasons unrelated to symmetry. For example, the N—H distance in ammonia may be so great that the (s_1, s_N) overlap integral is zero simply because the orbitals are so far apart.

Example 12.4 Deciding if an integral must be zero (1)

May the integral of the function $f = xy$ be nonzero when evaluated over a region the shape of an equilateral triangle centred on the origin (Fig. 12.26)?

Method First, note that an integral over a single function f is included in the previous discussion if we take $f_1 = f$ and $f_2 = 1$ in eqn 12.7. Therefore, we need to judge whether f alone belongs to the symmetry species A_1 (or its equivalent) in the point group of the system. To decide that, we identify the point group and then examine the character table to see whether f belongs to A_1 (or its equivalent).

Answer An equilateral triangle has the point-group symmetry D_{3h} . If we refer to the character table of the group, we see that xy is a member of a basis that spans the irreducible representation E' . Therefore, its integral must be zero, because the integrand has no component that spans A_1' .

Self-test 12.4 Can the function $x^2 + y^2$ have a nonzero integral when integrated over a regular pentagon centred on the origin? [Yes, Fig. 12.27]

In many cases, the product of functions f_1 and f_2 spans a sum of irreducible representations. For instance, in C_{2v} we may find the characters 2, 0, 0, -2 when we multiply the characters of f_1 and f_2 together. In this case, we note that these characters are the sum of the characters for A_2 and B_1 :

	E	C_{2v}	σ_v	σ_v'
A_2	1	1	-1	-1
B_1	1	-1	1	-1
$A_2 + B_1$	2	0	0	-2

To summarize this result we write the symbolic expression $A_2 \times B_1 = A_2 + B_1$, which is called the **decomposition of a direct product**. This expression is symbolic. The $\times$ and $+$ signs in this expression are not ordinary multiplication and addition signs: formally, they denote technical procedures with matrices called a 'direct product' and a 'direct sum'. Because the sum on the right does not include a component that is a basis for an irreducible representation of symmetry species A_1 , we can conclude that the integral of $f_1 f_2$ over all space is zero in a C_{2v} molecule.

Whereas the decomposition of the characters 2, 0, 0, -2 can be done by inspection in this simple case, in other cases and more complex groups the decomposition is often far from obvious. For example, if we found the characters 8, -2 , -6 , 4, it would not be obvious that the sum contains A_1 . Group theory, however, provides a systematic way of using the characters of the representation spanned by a product to find the symmetry species of the irreducible representations. The recipe is as follows:

1 Write down a table with columns headed by the symmetry operations of the group.

2 In the first row write down the characters of the symmetry species we want to analyse.

3 In the second row, write down the characters of the irreducible representation Γ we are interested in.

4 Multiply the two rows together, add the products together, and divide by the order of the group.

The resulting number is the number of times Γ occurs in the decomposition.

Illustration 12.1 To find whether A_1 occurs in a direct product

To find whether A_1 does indeed occur in the product with characters 8, -2, -6, 4 in C_{2v} , we draw up the following table:

	E	C_{2v}	σ_v	σ'_v	$h = 4$ (the order of the group)
$f_1 f_2$	8	-2	-6	4	(the characters of the product)
A_1	1	1	1	1	(the symmetry species we are interested in)
	8	-2	-6	4	(the product of the two sets of characters)

The sum of the numbers in the last line is 4; when that number is divided by the order of the group, we get 1, so A_1 occurs once in the decomposition. When the procedure is repeated for all four symmetry species, we find that $f_1 f_2$ spans $A_1 + 2A_2 + 5B_2$.

Self-test 12.5 Does A_2 occur among the symmetry species of the irreducible representations spanned by a product with characters 7, -3, -1, 5 in the group C_{2v} ?

[No]

(b) Orbitals with nonzero overlap

The rules just given let us decide which atomic orbitals may have nonzero overlap in a molecule. We have seen that s_N may have nonzero overlap with s_1 (the combination $s_A + s_B + s_C$), so bonding and antibonding molecular orbitals can form from (s_N , s_1) overlap (Fig. 12.28). The general rule is that *only orbitals of the same symmetry species may have nonzero overlap*, so only orbitals of the same symmetry species form bonding and antibonding combinations. It should be recalled from Chapter 11 that the selection of atomic orbitals that had mutual nonzero overlap is the central and initial step in the construction of molecular orbitals by the LCAO procedure. We are therefore at the point of contact between group theory and the material introduced in that chapter. The molecular orbitals formed from a particular set of atomic orbitals with nonzero overlap are labelled with the lowercase letter corresponding to the symmetry species. Thus, the (s_N , s_1)-overlap orbitals are called a_1 orbitals (or a_1^* , if we wish to emphasize that they are antibonding).

The linear combinations $s_2 = 2s_a - s_b - s_c$ and $s_3 = s_b - s_c$ have symmetry species E . Does the N atom have orbitals that have nonzero overlap with them (and give rise to e molecular orbitals)? Intuition (as supported by Figs. 12.28b and c) suggests that $N2p_x$ and $N2p_y$ should be suitable. We can confirm this conclusion by noting that the character table shows that, in C_{3v} , the functions x and y jointly belong to the symmetry species E . Therefore, $N2p_x$ and $N2p_y$ also belong to E , so may have nonzero overlap with s_2 and s_3 . This conclusion can be verified by multiplying the characters

Fig. 12.28 Orbitals of the same symmetry species may have non-vanishing overlap. This diagram illustrates the three bonding orbitals that may be constructed from ($N2s$, $H1s$) and ($N2p$, $H1s$) overlap in a C_{3v} molecule. (a) a_1 ; (b) and (c) the two components of the doubly degenerate e orbitals. (There are also three antibonding orbitals of the same species.)

and finding that the product of characters can be expressed as the decomposition $E \times E = A_1 + A_2 + E$. The two e orbitals that result are shown in Fig. 12.28 (there are also two antibonding e orbitals).

We can see the power of the method by exploring whether any d orbitals on the central atom can take part in bonding. As explained earlier, reference to the C_{3v} character table shows that d_{z^2} has A_1 symmetry and that the pairs $(d_{x^2-y^2}, d_{xy})$ and (d_{yz}, d_{zx}) each transform as E . It follows that molecular orbitals may be formed by (s_1, d_{z^2}) overlap and by overlap of the s_2, s_3 combinations with the E d orbitals. Whether or not the d orbitals are in fact important is a question group theory cannot answer because the extent of their involvement depends on energy considerations, not symmetry.

Example 12.5 *Determining which orbitals can contribute to bonding*

The four H1s orbitals of methane span $A_1 + T_2$. With which of the C atom orbitals can they overlap? What bonding pattern would be possible if the C atom had d orbitals available?

Method Refer to the T_d character table (in the *Data section*) and look for s , p , and d orbitals spanning A_1 or T_2 .

Answer An s orbital spans A_1 , so it may have nonzero overlap with the A_1 combination of H1s orbitals. The $C2p$ orbitals span T_2 , so they may have nonzero overlap with the T_2 combination. The d_{xy} , d_{yz} , and d_{zx} orbitals span T_2 , so they may overlap the same combination. Neither of the other two d orbitals span A_1 (they span E), so they remain nonbonding orbitals. It follows that in methane there are $(C2s, H1s)$ -overlap a_1 orbitals and $(C2p, H1s)$ -overlap t_2 orbitals. The $C3d$ orbitals might contribute to the latter. The lowest energy configuration is probably $a_1^2 t_2^6$, with all bonding orbitals occupied.

Self-test 12.6 Consider the octahedral SF_6 molecule, with the bonding arising from overlap of S orbitals and a $2p$ orbital on each F directed towards the central S atom. The latter span $A_{1g} + E_g + T_{1u}$. What s orbitals have nonzero overlap? Suggest what the ground-state configuration is likely to be.

$$[3s(A_{1g}), 3p(T_{1u}), 3d(E_g); a_{1g}^2 t_{1u}^6 e_g^4]$$

(c) Symmetry-adapted linear combinations

So far, we have only asserted the forms of the linear combinations (such as s_1 , etc.) that have a particular symmetry. Group theory also provides machinery that takes an arbitrary **basis**, or set of atomic orbitals (s_A , etc.), as input and generates combinations of the specified symmetry. Because these combinations are adapted to the symmetry of the molecule, they are called **symmetry-adapted linear combinations** (SALC). Symmetry-adapted linear combinations are the building blocks of LCAO molecular orbitals, for they include combinations such as those used to construct molecular orbitals in benzene. The construction of SALCs is the first step in any molecular orbital treatment of molecules.

The technique for building SALCs is derived by using the full power of group theory. We shall not show the derivation (see *Further reading*), which is very lengthy, but present the main conclusions as a set of rules:

- 1 Construct a table showing the effect of each operation on each orbital of the original basis.

2 To generate the combination of a specified symmetry species, take each column in turn and:

- (i) Multiply each member of the column by the character of the corresponding operation.
- (ii) Add together all the orbitals in each column with the factors as determined in (i).
- (iii) Divide the sum by the order of the group.

For example, from the (s_N, s_A, s_B, s_C) basis in NH_3 we form the table shown in the margin. To generate the A_1 combination, we take the characters for A_1 (1,1,1,1,1); then rules (i) and (ii) lead to

$$\psi \propto s_N + s_N + \dots = 6s_N$$

The order of the group (the number of elements) is 6, so the combination of A_1 symmetry that can be generated from s_N is s_N itself. Applying the same technique to the column under s_A gives

$$\psi = \frac{1}{6}(s_A + s_B + s_C + s_A + s_B + s_C) = \frac{1}{3}(s_A + s_B + s_C)$$

The same combination is built from the other two columns, so they give no further information. The combination we have just formed is the s_1 combination we used before (apart from the numerical factor).

We now form the overall molecular orbital by forming a linear combination of all the SALCs of the specified symmetry species. In this case, therefore, the a_1 molecular orbital is

$$\psi = c_N s_N + c_1 s_1$$

This is as far as group theory can take us. The coefficients are found by solving the Schrödinger equation; they do not come directly from the symmetry of the system.

We run into a problem when we try to generate an SALC of symmetry species E, because, for representations of dimension 2 or more, the rules generate sums of SALCs. This problem can be illustrated as follows. In C_{3v} , the E characters are 2, -1, -1, 0, 0, 0, so the column under s_N gives

$$\psi = \frac{1}{6}(2s_N - s_N - s_N + 0 + 0 + 0) = 0$$

The other columns give

$$\frac{1}{6}(2s_A - s_B - s_C) \quad \frac{1}{6}(2s_B - s_A - s_C) \quad \frac{1}{6}(2s_C - s_B - s_A)$$

However, any one of these three expressions can be expressed as a sum of the other two (they are not 'linearly independent'). The difference of the second and third gives $\frac{1}{2}(s_B - s_C)$, and this combination and the first, $\frac{1}{6}(2s_A - s_B - s_C)$ are the two (now linearly independent) SALCs we have used in the discussion of e orbitals.

	Original basis			
	s_N	s_A	s_B	s_C
Under E	s_N	s_A	s_B	s_C
C_3^+	s_N	s_B	s_C	s_A
C_3^-	s_N	s_C	s_A	s_B
σ_v	s_N	s_A	s_C	s_B
σ'_v	s_N	s_B	s_A	s_C
σ''_v	s_N	s_C	s_B	s_A

12.6 Vanishing integrals and selection rules

Integrals of the form

$$I = \int f_1 f_2 f_3 d\tau \quad (12.8)$$

are also common in quantum mechanics for they include matrix elements of operators (Section 8.5d), and it is important to know when they are necessarily zero. For the integral to be nonzero, *the product $f_1 f_2 f_3$ must span A_1 (or its equivalent) or contain a component that spans A_1* . To test whether this is so, the characters of all three functions are multiplied together in the same way as in the rules set out above.

Example 12.6 Deciding if an integral must be zero (2)

Does the integral $\int (3d_{z^2})x(3d_{xy})d\tau$ vanish in a C_{2v} molecule?

Method We must refer to the C_{2v} character table (Table 12.2) and the characters of the irreducible representations spanned by $3z^2 - r^2$ (the form of the d_{z^2} orbital), x , and xy ; then we can use the procedure set out above (with one more row of multiplication).

Answer We draw up the following table:

	E	C_2	σ_v	σ'_v	
$f_3 = d_{xy}$	1	1	-1	-1	A_2
$f_2 = x$	1	-1	1	-1	B_1
$f_1 = d_{z^2}$	1	1	1	1	A_1
$f_1 f_2 f_3$	1	-1	-1	1	

The characters are those of B_2 . Therefore, the integral is necessarily zero.

Self-test 12.7 Does the integral $\int (2p_x)(2p_y)(2p_z)d\tau$ necessarily vanish in an octahedral environment? [No]

We saw in Chapters 9 and 10, and will see in more detail in Chapters 13 and 14, that the intensity of a spectral line arising from a molecular transition between some initial state with wavefunction ψ_i and a final state with wavefunction ψ_f depends on the (electric) transition dipole moment, μ_{fi} . The z -component of this vector is defined through

$$\mu_{z,fi} = -e \int \psi_f^* z \psi_i d\tau \quad [12.9]$$

where $-e$ is the charge of the electron. The transition moment has the form of the integral in eqn 12.8, so, once we know the symmetry species of the states, we can use group theory to formulate the selection rules for the transitions.

As an example, we investigate whether an electron in an a_1 orbital in H_2O (which belongs to the group C_{2v}) can make an electric dipole transition to a b_1 orbital (Fig. 12.29). We must examine all three components of the transition dipole moment, and take f_2 in eqn 12.8 as x , y , and z in turn. Reference to the C_{2v} character table shows that these components transform as B_1 , B_2 , and A_1 , respectively. The three calculations run as follows:

Fig. 12.29 The polarizations of the allowed transitions in a C_{2v} molecule. The shading indicates the structure of the orbitals of the specified symmetry species. The perspective view of the molecule makes it look rather like a door stop; however, from the side, each 'door stop' is in fact an isosceles triangle.

	x -component				y -component				z -component			
	E	C_2	σ_v	σ'_v	E	C_2	σ_v	σ'_v	E	C_2	σ_v	σ'_v
f_3	1	-1	1	-1	1	-1	1	-1	1	-1	1	$-1B_1$
f_2	1	-1	1	-1	1	-1	-1	1	1	1	1	1
f_1	1	1	1	1	1	1	1	1	1	1	1	$1A_1$
$f_1 f_2 f_3$	1	1	1	1	1	1	-1	-1	1	-1	1	-1

Only the first product (with $f_2 = x$) spans A_1 , so only the x -component of the transition dipole moment may be nonzero. Therefore, we conclude that the electric dipole

transitions between a_1 and b_1 are allowed. We can go on to state that the radiation emitted (or absorbed) is x -polarized and has its electric field vector in the x -direction, because that form of radiation couples with the x -component of a transition dipole.

Example 12.7 *Deducing a selection rule*

Is $p_x \rightarrow p_y$ an allowed transition in a tetrahedral environment?

Method We must decide whether the product $p_y q p_x$, with $q = x, y$, or z , spans A_1 by using the T_d character table.

Answer The procedure works out as follows:

	E	$8C_3$	$3C_2$	$6\sigma_d$	$6S_4$	
$f_3(p_y)$	3	0	-1	-1	1	T_2
$f_2(q)$	3	0	-1	-1	1	T_2
$f_1(p_x)$	3	0	-1	-1	1	T_2
$f_1 f_2 f_3$	27	0	-1	-1	1	

We can use the decomposition procedure described in Section 12.5a to deduce that A_1 occurs (once) in this set of characters, so $p_x \rightarrow p_y$ is allowed.

A more detailed analysis (using the matrix representatives rather than the characters) shows that only $q = z$ gives an integral that may be nonzero, so the transition is z -polarized. That is, the electromagnetic radiation involved in the transition has its electric vector aligned in the z -direction.

Self-test 12.8 What are the allowed transitions, and their polarizations, of a b_1 electron in a C_{4v} molecule? $[b_1 \rightarrow b_1(z); b_1 \rightarrow e(x,y)]$

The following chapters will show many more examples of the systematic use of symmetry. We shall see that the techniques of group theory greatly simplify the analysis of molecular structure and spectra.

Checklist of key ideas

☐ 1. A symmetry operation is an action that leaves an object looking the same after it has been carried out. ☐ 2. A symmetry element is a point, line, or plane with respect to which a symmetry operation is performed. ☐ 3. A point group is a group of symmetry operations that leaves at least one common point unchanged. A space group, a group of symmetry operations that includes translation through space. ☐ 4. The notation for point groups commonly used for molecules and solids is summarized in Table 12.1. ☐ 5. To be polar, a molecule must belong to C_n, C_{nv}, or C_s (and have no higher symmetry). ☐ 6. A molecule may be chiral only if it does not possess an axis of improper rotation, S_n.	☐ 7. A representative $D(X)$ is a matrix that brings about the transformation of the basis under the operation X. The basis is the set of functions on which the representative acts. ☐ 8. A character, χ, is the sum of the diagonal elements of a matrix representative. ☐ 9. A character table characterizes the different symmetry types possible in the point group. ☐ 10. In a reduced representation all the matrices have block-diagonal form. An irreducible representation cannot be reduced further. ☐ 11. Symmetry species are the labels for the irreducible representations of a group. ☐ 12. Decomposition of the direct product is the reduction of a product of symmetry species to a sum of symmetry species, $\Gamma \times \Gamma' = \Gamma^{(1)} + \Gamma^{(2)} + \dots$

- 13. For an integral $\int f_1 f_2 d\tau$ to be nonzero, the integrand $f_1 f_2$ must have the symmetry species A_1 (or its equivalent in the specific molecular point group).
- 14. A symmetry-adapted linear combination (SALC) is a combination of atomic orbitals adapted to the symmetry of the molecule and used as the building blocks for LCAO molecular orbitals.
- 15. Allowed and forbidden spectroscopic transitions can be identified by considering the symmetry criteria for the non-vanishing of the transition moment between the initial and final states.

Discussion questions

- 12.1** Explain how a molecule is assigned to a point group.
- 12.2** List the symmetry operations and the corresponding symmetry elements of the point groups.
- 12.3** Explain the symmetry criteria that allow a molecule to be polar.
- 12.4** Explain the symmetry criteria that allow a molecule to be optically active.
- 12.5** Explain what is meant by (a) a representative and (b) a representation in the context of group theory.
- 12.6** Explain the construction and content of a character table.
- 12.7** Explain how spectroscopic selection rules arise and how they are formulated by using group theory.
- 12.8** Outline how a direct product is expressed as a direct sum and how to decide whether the totally symmetric irreducible representation is present in the direct product.

Exercises

- 12.1a** The CH_3Cl molecule belongs to the point group C_{3v} . List the symmetry elements of the group and locate them in the molecule.
- 12.1b** The CCl_4 molecule belongs to the point group T_d . List the symmetry elements of the group and locate them in the molecule.
- 12.2a** Which of the following molecules may be polar? (a) pyridine (C_{2v}), (b) nitroethane (C_s), (c) gas-phase HgBr_2 ($D_{\infty h}$), (d) $\text{B}_3\text{N}_3\text{N}_6$ (D_{3h}).
- 12.2b** Which of the following molecules may be polar? (a) CH_3Cl (C_{3v}), (b) $\text{HW}_2(\text{CO})_{10}$ (D_{4h}), (c) SnCl_4 (T_d).
- 12.3a** Use symmetry properties to determine whether or not the integral $\int p_x z p_z d\tau$ is necessarily zero in a molecule with symmetry C_{4v} .
- 12.3b** Use symmetry properties to determine whether or not the integral $\int p_x z p_z d\tau$ is necessarily zero in a molecule with symmetry D_{6h} .
- 12.4a** Show that the transition $A_1 \rightarrow A_2$ is forbidden for electric dipole transitions in a C_{3v} molecule.
- 12.4b** Is the transition $A_{1g} \rightarrow E_{2u}$ forbidden for electric dipole transitions in a D_{6h} molecule?
- 12.5a** Show that the function xy has symmetry species B_2 in the group C_{4v} .
- 12.5b** Show that the function xyz has symmetry species A_1 in the group D_2 .
- 12.6a** Molecules belonging to the point groups D_{2h} or C_{3h} cannot be chiral. Which elements of these groups rule out chirality?
- 12.6b** Molecules belonging to the point groups T_h or T_d cannot be chiral. Which elements of these groups rule out chirality?
- 12.7a** The group D_2 consists of the elements E , C_2 , C_2' , and C_2'' , where the three twofold rotations are around mutually perpendicular axes. Construct the group multiplication table.

12.7b The group C_{4v} consists of the elements E , $2C_4$, C_2 , and $2\sigma_v$, $2\sigma_d$. Construct the group multiplication table.

12.8a Identify the point groups to which the following objects belong: (a) a sphere, (b) an isosceles triangle, (c) an equilateral triangle, (d) an unsharpened cylindrical pencil.

12.8b Identify the point groups to which the following objects belong: (a) a sharpened cylindrical pencil, (b) a three-bladed propeller, (c) a four-legged table, (d) yourself (approximately).

12.9a List the symmetry elements of the following molecules and name the point groups to which they belong: (a) NO_2 , (b) N_2O , (c) CHCl_3 , (d) $\text{CH}_2=\text{CH}_2$, (e) *cis*- $\text{CHBr}=\text{CHBr}$, (f) *trans*- $\text{CHCl}=\text{CHCl}$.

12.9b List the symmetry elements of the following molecules and name the point groups to which they belong: (a) naphthalene, (b) anthracene, (c) the three dichlorobenzenes.

12.10a Assign (a) *cis*-dichloroethene and (b) *trans*-dichloroethene to point groups.

12.10b Assign the following molecules to point groups: (a) HF , (b) IF_7 (pentagonal bipyramid), (c) XeO_2F_2 (see-saw), (d) $\text{Fe}_2(\text{CO})_9$ (**22**), (e) cubane, C_8H_8 , (f) tetrafluorocubane, $\text{C}_8\text{H}_4\text{F}_4$ (**23**).

12.11a Which of the molecules in Exercises 12.9a and 12.10a can be (a) polar, (b) chiral?

12.11b Which of the molecules in Exercises 12.9b and 12.10b can be (a) polar, (b) chiral?

Problems*

12.1 List the symmetry elements of the following molecules and name the point groups to which they belong: (a) staggered CH_3CH_3 , (b) chair and boat cyclohexane, (c) B_2H_6 , (d) $[\text{Co}(\text{en})_3]^{3+}$, where en is ethylenediamine (ignore its detailed structure), (e) crown-shaped S_8 . Which of these molecules can be (i) polar, (ii) chiral?

12.2 The group C_{2h} consists of the elements E , C_2 , σ_h , i . Construct the group multiplication table and find an example of a molecule that belongs to the group.

12.3 The group D_{2h} has a C_2 axis perpendicular to the principal axis and a horizontal mirror plane. Show that the group must therefore have a centre of inversion.

12.4 Consider the H_2O molecule, which belongs to the group C_{2v} . Take as a basis the two $1s$ orbitals and the four valence orbitals of the O atom and set

12.12a Consider the C_{2v} molecule NO_2 . The combination $p_x(\text{A}) - p_x(\text{B})$ of the two O atoms (with x perpendicular to the plane) spans A_2 . Is there any orbital of the central N atom that can have a nonzero overlap with that combination of O orbitals? What would be the case in SO_2 , where $3d$ orbitals might be available?

12.12b Consider the C_{3v} ion NO_3^- . Is there any orbital of the central N atom that can have a nonzero overlap with the combination $2p_z(\text{A}) - p_z(\text{B}) - p_z(\text{C})$ of the three O atoms (with z perpendicular to the plane). What would be the case in SO_3 , where $3d$ orbitals might be available?

12.13a The ground state of NO_2 is A_1 in the group C_{2v} . To what excited states may it be excited by electric dipole transitions, and what polarization of light is it necessary to use?

12.13b The ClO_2 molecule (which belongs to the group C_{2v}) was trapped in a solid. Its ground state is known to be B_1 . Light polarized parallel to the y -axis (parallel to the OO separation) excited the molecule to an upper state. What is the symmetry of that state?

12.14a What states of (a) benzene, (b) naphthalene may be reached by electric dipole transitions from their (totally symmetrical) ground states?

12.14b What states of (a) anthracene, (b) coronene (**24**) may be reached by electric dipole transitions from their (totally symmetrical) ground states?

24 Coronene

12.15a Write $f_1 = \sin \theta$ and $f_2 = \cos \theta$, and show by symmetry arguments using the group C_s that the integral of their product over a symmetrical range around $\theta = 0$ is zero.

12.15b Determine whether the integral over f_1 and f_2 in Exercise 12.15a is zero over a symmetrical range about $\theta = 0$ in the group C_{3v} .

up the 6×6 matrices that represent the group in this basis. Confirm by explicit matrix multiplication that the group multiplications (a) $C_2\sigma_v = \sigma'_v$ and (b) $\sigma_v\sigma'_v = C_2$. Confirm, by calculating the traces of the matrices: (a) that symmetry elements in the same class have the same character, (b) that the representation is reducible, and (c) that the basis spans $3A_1 + B_1 + 2B_2$.

12.5 Confirm that the z -component of orbital angular momentum is a basis for an irreducible representation of A_2 symmetry in C_{3v} .

12.6 The (one-dimensional) matrices $D(C_3) = 1$ and $D(C_2) = 1$, and $D(C_3) = 1$ and $D(C_2) = -1$ both represent the group multiplication $C_3C_2 = C_6$ in the group C_{6v} with $D(C_6) = +1$ and -1 , respectively. Use the character table to confirm these remarks. What are the representatives of σ_v and σ_d in each case?

12.7 Construct the multiplication table of the Pauli spin matrices, σ , and the 2×2 unit matrix:

* Problems denoted with the symbol ‡ were supplied by Charles Trapp and Carmen Giunta.

$$\sigma_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \quad \sigma_y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} \quad \sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \quad \sigma_0 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$$

Do the four matrices form a group under multiplication?

12.8 What irreducible representations do the four H1s orbitals of CH₄ span? Are there *s* and *p* orbitals of the central C atom that may form molecular orbitals with them? Could *d* orbitals, even if they were present on the C atom, play a role in orbital formation in CH₄?

12.9 Suppose that a methane molecule became distorted to (a) C_{3v} symmetry by the lengthening of one bond, (b) C_{2v} symmetry, by a kind of scissors action in which one bond angle opened and another closed slightly. Would more *d* orbitals become available for bonding?

12.10† B.A. Bovenzi and G.A. Pearce, Jr. (*J. Chem. Soc. Dalton Trans.*, 2763 (1997)) synthesized coordination compounds of the tridentate ligand pyridine-2,6-diamidoxime (C₇H₉N₅O₂, **25**). Reaction with NiSO₄ produced a complex in which two of the essentially planar ligands are bonded at right angles to a single Ni atom. Name the point group and the symmetry operations of the resulting [Ni(C₇H₉N₅O₂)₂]²⁺ complex cation.

25

12.11† R. Eujen, B. Hoge, and D.J. Brauer (*Inorg. Chem.* **36**, 1464 (1997)) prepared and characterized several square-planar Ag(III) complex anions. In the complex anion [*trans*-Ag(CF₃)₂(CN)₂]⁻, the Ag—CN groups are collinear. (a) Assuming free rotation of the CF₃ groups (that is, disregarding the AgCF and AgCH angles), name the point group of this complex anion. (b) Now suppose the CF₃ groups cannot rotate freely (because the ion was in a solid, for example). Structure (**26**) shows a plane that bisects the NC—Ag—CN axis and is perpendicular to it. Name the point group of the complex if each CF₃ group has a CF bond in that plane (so the CF₃ groups do not point to either CN group preferentially) and the CF₃ groups are (i) staggered, (ii) eclipsed.

26

12.12† A computational study by C.J. Marsden (*Chem. Phys. Lett.* **245**, 475 (1995)) of AM_x compounds, where A is in Group 14 of the periodic table and M is an alkali metal, shows several deviations from the most symmetric structures for each formula. For example, most of the AM₄ structures were not tetrahedral but had two distinct values for MAM bond angles. They could be

27

28

derived from a tetrahedron by a distortion shown in (27). (a) What is the point group of the distorted tetrahedron? (b) What is the symmetry species of the distortion considered as a vibration in the new, less symmetric group? Some AM₆ structures are not octahedral, but could be derived from an octahedron by translating a C—M—C axis as in (28). (c) What is the point group of the distorted octahedron? (d) What is the symmetry species of the distortion considered as a vibration in the new, less symmetric group?

12.13 The algebraic forms of the *f* orbitals are a radial function multiplied by one of the factors (a) $z(5z^2 - 3r^2)$, (b) $y(5y^2 - 3r^2)$, (c) $x(5x^2 - 3r^2)$, (d) $z(x^2 - y^2)$, (e) $y(x^2 - z^2)$, (f) $x(z^2 - y^2)$, (g) xyz . Identify the irreducible representations spanned by these orbitals in (a) C_{2v}, (b) C_{3v}, (c) T_d, (d) O_h. Consider a lanthanide ion at the centre of (a) a tetrahedral complex, (b) an octahedral complex. What sets of orbitals do the seven *f* orbitals split into?

12.14 Does the product xyz necessarily vanish when integrated over (a) a cube, (b) a tetrahedron, (c) a hexagonal prism, each centred on the origin?

12.15 The NO₂ molecule belongs to the group C_{2v}, with the C₂ axis bisecting the ONO angle. Taking as a basis the N2s, N2p, and O2p orbitals, identify the irreducible representations they span, and construct the symmetry-adapted linear combinations.

12.16 Construct the symmetry-adapted linear combinations of C2p_z orbitals for benzene, and use them to calculate the Hückel secular determinant. This procedure leads to equations that are much easier to solve than using the original orbitals, and show that the Hückel orbitals are those specified in Section 11.6d.

12.17 The phenanthrene molecule (**29**) belongs to the group C_{2v} with the C₂ axis perpendicular to the molecular plane. (a) Classify the irreducible representations spanned by the carbon 2p_z orbitals and find their symmetry-adapted linear combinations. (b) Use your results from part (a) to calculate the Hückel secular determinant. (c) What states of phenanthrene may be reached by electric dipole transitions from its (totally symmetrical) ground state?

29 Phenanthrene

12.18† In a spectroscopic study of C₆₀, F. Negri, G. Orlandi, and F. Zerbetto (*J. Phys. Chem.* **100**, 10849 (1996)) assigned peaks in the fluorescence spectrum. The molecule has icosahedral symmetry (I_h). The ground electronic state is A_{1g}, and the lowest-lying excited states are T_{1g} and G_g. (a) Are photon-induced transitions allowed from the ground state to either of these excited states? Explain your answer. (b) What if the transition is accompanied by a vibration that breaks the parity?

Applications: to astrophysics and biology

12.19† The H_3^+ molecular ion, which plays an important role in chemical reactions occurring in interstellar clouds, is known to be equilateral triangular. (a) Identify the symmetry elements and determine the point group of this molecule. (b) Take as a basis for a representation of this molecule the three $1s$ orbitals and set up the matrices that group in this basis. (c) Obtain the group multiplication table by explicit multiplication of the matrices. (d) Determine if the representation is reducible and, if so, give the irreducible representations obtained.

12.20† The H_3^+ molecular ion has recently been found in the interstellar medium and in the atmospheres of Jupiter, Saturn, and Uranus. The H_4 analogues have not yet been found, and the square planar structure is thought to be unstable with respect to vibration. Take as a basis for a representation of the point group of this molecule the four $1s$ orbitals and determine if this representation is reducible.

12.21 Some linear polyenes, of which β -carotene is an example, are important biological co-factors that participate in processes as diverse as the absorption of solar energy in photosynthesis (*Impact I23.2*) and protection against harmful biological oxidations. Use as a model of β -carotene a linear polyene containing 22 conjugated C atoms. (a) To what point group does this model of β -carotene belong? (b) Classify the irreducible representations spanned by

the carbon $2p_z$ orbitals and find their symmetry-adapted linear combinations. (c) Use your results from part (b) to calculate the Hückel secular determinant. (d) What states of this model of β -carotene may be reached by electric dipole transitions from its (totally symmetrical) ground state?

12.22 The chlorophylls that participate in photosynthesis (*Impact I24.2*) and the haem groups of cytochromes (*Impact I7.2*) are derived from the porphine dianion group (**30**), which belongs to the D_{4h} point group. The ground electronic state is A_{1g} and the lowest-lying excited state is E_u . Is a photon-induced transition allowed from the ground state to the excited state? Explain your answer.

Problems

The general strategy we adopt in the chapter is to set up expressions for the energy levels of molecules and then apply selection rules and considerations of populations to infer the form of spectra. Rotational energy levels are considered first, and we see how to derive expressions for their values and how to interpret rotational spectra in terms of molecular dimensions. Not all molecules can occupy all rotational states: we see the experimental evidence for this restriction and its explanation in terms of nuclear spin and the Pauli principle. Next, we consider the vibrational energy levels of diatomic molecules, and see that we can use the properties of harmonic oscillators developed in Chapter 9. Then we consider polyatomic molecules and find that their vibrations may be discussed as though they consisted of a set of independent harmonic oscillators, so the same approach as employed for diatomic molecules may be used. We also see that the symmetry properties of the vibrations of polyatomic molecules are helpful for deciding which modes of vibration can be studied spectroscopically.

The origin of spectral lines in molecular spectroscopy is the absorption, emission, or scattering of a photon when the energy of a molecule changes. The difference from atomic spectroscopy is that the energy of a molecule can change not only as a result of electronic transitions but also because it can undergo changes of rotational and vibrational state. Molecular spectra are therefore more complex than atomic spectra. However, they also contain information relating to more properties, and their analysis leads to values of bond strengths, lengths, and angles. They also provide a way of determining a variety of molecular properties, particularly molecular dimensions, shapes, and dipole moments. Molecular spectroscopy is also useful to astrophysicists and environmental scientists, for the chemical composition of interstellar space and of planetary atmospheres can be inferred from their rotational, vibrational, and electronic spectra.

Pure rotational spectra, in which only the rotational state of a molecule changes, can be observed in the gas phase. Vibrational spectra of gaseous samples show features that arise from rotational transitions that accompany the excitation of vibration. Electronic spectra, which are described in Chapter 14, show features arising from simultaneous vibrational and rotational transitions. The simplest way of dealing with these complexities is to tackle each type of transition in turn, and then to see how simultaneous changes affect the appearance of spectra.

General features of spectroscopy

All types of spectra have some features in common, and we examine these first. In **emission spectroscopy**, a molecule undergoes a transition from a state of high energy E_1 to a state of lower energy E_2 and emits the excess energy as a photon. In **absorption spectroscopy**, the net absorption of nearly monochromatic (single frequency) incident radiation is monitored as the radiation is swept over a range of frequencies. We say *net* absorption, because it will become clear that, when a sample is irradiated, both absorption and emission at a given frequency are stimulated, and the detector measures the difference, the net absorption.

The energy, $h\nu$, of the photon emitted or absorbed, and therefore the frequency ν of the radiation emitted or absorbed, is given by the Bohr frequency condition, $h\nu = |E_1 - E_2|$ (eqn 8.10). Emission and absorption spectroscopy give the same information about energy level separations, but practical considerations generally determine which technique is employed. We shall discuss emission spectroscopy in Chapter 14; here we focus on absorption spectroscopy, which is widely employed in studies of electronic transitions, molecular rotations, and molecular vibrations.

In Chapter 9 we saw that transitions between electronic energy levels are stimulated by or emit ultraviolet, visible, or near-infrared radiation. Vibrational and rotational transitions, the focus of the discussion in this chapter, can be induced in two ways. First, the direct absorption or emission of infrared radiation can cause changes in vibrational energy levels, whereas absorption or emission of microwave radiation gives information about rotational energy levels. Second, vibrational and rotational energy levels can be explored by examining the frequencies present in the radiation scattered by molecules in **Raman spectroscopy**. About 1 in 10^7 of the incident photons collide with the molecules, give up some of their energy, and emerge with a lower energy. These scattered photons constitute the lower-frequency **Stokes radiation** from the sample (Fig. 13.1). Other incident photons may collect energy from the molecules (if they are already excited), and emerge as higher-frequency **anti-Stokes radiation**. The component of radiation scattered without change of frequency is called **Rayleigh radiation**.

13.1 Experimental techniques

A **spectrometer** is an instrument that detects the characteristics of light scattered, emitted, or absorbed by atoms and molecules. Figure 13.2 shows the general layouts of absorption and emission spectrometers operating in the ultraviolet and visible ranges. Radiation from an appropriate source is directed toward a sample. In most

Fig. 13.1 In Raman spectroscopy, an incident photon is scattered from a molecule with either an increase in frequency (if the radiation collects energy from the molecule) or—as shown here for the case of scattered Stokes radiation—with a lower frequency if it loses energy to the molecule. The process can be regarded as taking place by an excitation of the molecule to a wide range of states (represented by the shaded band), and the subsequent return of the molecule to a lower state; the net energy change is then carried away by the photon.

Fig. 13.2 Two examples of spectrometers: (a) the layout of an absorption spectrometer, used primarily for studies in the ultraviolet and visible ranges, in which the exciting beams of radiation pass alternately through a sample and a reference cell, and the detector is synchronized with them so that the relative absorption can be determined, and (b) a simple emission spectrometer, where light emitted or scattered by the sample is detected at right angles to the direction of propagation of an incident beam of radiation.

Comment 13.1

The principles of operation of radiation sources, dispersing elements, Fourier transform spectrometers, and detectors are described in *Further information 13.1*.

Fig. 13.3 A common arrangement adopted in Raman spectroscopy. A laser beam first passes through a lens and then through a small hole in a mirror with a curved reflecting surface. The focused beam strikes the sample and scattered light is both deflected and focused by the mirror. The spectrum is analysed by a monochromator or an interferometer.

spectrometers, light transmitted, emitted, or scattered by the sample is collected by mirrors or lenses and strikes a **dispersing element** that separates radiation into different frequencies. The intensity of light at each frequency is then analysed by a suitable detector. In a typical Raman spectroscopy experiment, a monochromatic incident laser beam is passed through the sample and the radiation scattered from the front face of the sample is monitored (Fig. 13.3). This detection geometry allows for the study of gases, pure liquids, solutions, suspensions, and solids.

Modern spectrometers, particularly those operating in the infrared and near-infrared, now almost always use **Fourier transform techniques** of spectral detection and analysis. The heart of a Fourier transform spectrometer is a *Michelson interferometer*, a device for analysing the frequencies present in a composite signal. The total signal from a sample is like a chord played on a piano, and the Fourier transform of the signal is equivalent to the separation of the chord into its individual notes, its spectrum.

13.2 The intensities of spectral lines

The ratio of the transmitted intensity, I , to the incident intensity, I_0 , at a given frequency is called the **transmittance**, T , of the sample at that frequency:

$$T = \frac{I}{I_0} \quad [13.1]$$

It is found empirically that the transmitted intensity varies with the length, l , of the sample and the molar concentration, $[J]$, of the absorbing species J in accord with the **Beer–Lambert law**:

$$I = I_0 10^{-\epsilon[J]l} \quad (13.2)$$

The quantity ϵ is called the **molar absorption coefficient** (formerly, and still widely, the ‘extinction coefficient’). The molar absorption coefficient depends on the frequency of the incident radiation and is greatest where the absorption is most intense. Its dimensions are $1/(\text{concentration} \times \text{length})$, and it is normally convenient to express it in cubic decimetres per mole per centimetre ($\text{dm}^3 \text{mol}^{-1} \text{cm}^{-1}$). Alternative units are square centimetres per mole ($\text{cm}^2 \text{mol}^{-1}$). This change of units demonstrates that ϵ may be regarded as a molar cross-section for absorption and, the greater the cross-sectional area of the molecule for absorption, the greater its ability to block the passage of the incident radiation.

To simplify eqn 13.2, we introduce the **absorbance**, A , of the sample at a given wavenumber as

$$A = \log \frac{I_0}{I} \quad \text{or} \quad A = -\log T \quad [13.3]$$

Then the Beer–Lambert law becomes

$$A = \epsilon[J]l \quad (13.4)$$

The product $\epsilon[J]l$ was known formerly as the *optical density* of the sample. Equation 13.4 suggests that, to achieve sufficient absorption, path lengths through gaseous samples must be very long, of the order of metres, because concentrations are low. Long path lengths are achieved by multiple passage of the beam between parallel mirrors at each end of the sample cavity. Conversely, path lengths through liquid samples can be significantly shorter, of the order of millimetres or centimetres.

Justification 13.1 *The Beer–Lambert law*

The Beer–Lambert law is an empirical result. However, it is simple to account for its form. The reduction in intensity, dI , that occurs when light passes through a layer of thickness dl containing an absorbing species J at a molar concentration $[J]$ is proportional to the thickness of the layer, the concentration of J , and the intensity, I , incident on the layer (because the rate of absorption is proportional to the intensity, see below). We can therefore write

$$dI = -\kappa[J]I dl$$

where κ (kappa) is the proportionality coefficient, or equivalently

$$\frac{dI}{I} = -\kappa[J] dl$$

This expression applies to each successive layer into which the sample can be regarded as being divided. Therefore, to obtain the intensity that emerges from a sample of thickness l when the intensity incident on one face of the sample is I_0 , we sum all the successive changes:

$$\int_{I_0}^I \frac{dI}{I} = -\kappa \int_0^l [J] dl$$

If the concentration is uniform, $[J]$ is independent of location, and the expression integrates to

$$\ln \frac{I}{I_0} = -\kappa[J]l$$

This expression gives the Beer–Lambert law when the logarithm is converted to base 10 by using $\ln x = (\ln 10) \log x$ and replacing κ by $\epsilon \ln 10$.

Illustration 13.1 *Using the Beer–Lambert law*

The Beer–Lambert law implies that the intensity of electromagnetic radiation transmitted through a sample at a given wavenumber decreases exponentially with the sample thickness and the molar concentration. If the transmittance is 0.1 for a path length of 1 cm (corresponding to a 90 per cent reduction in intensity), then it would be $(0.1)^2 = 0.01$ for a path of double the length (corresponding to a 99 per cent reduction in intensity overall).

The maximum value of the molar absorption coefficient, $\epsilon_{\max}$, is an indication of the intensity of a transition. However, as absorption bands generally spread over a range of wavenumbers, quoting the absorption coefficient at a single wavenumber might not give a true indication of the intensity of a transition. The **integrated absorption coefficient**, $\mathcal{A}$, is the sum of the absorption coefficients over the entire band (Fig. 13.4), and corresponds to the area under the plot of the molar absorption coefficient against wavenumber:

$$\mathcal{A} = \int_{\text{band}} \epsilon(\tilde{\nu}) d\tilde{\nu} \quad [13.5]$$

For lines of similar widths, the integrated absorption coefficients are proportional to the heights of the lines.

Fig. 13.4 The integrated absorption coefficient of a transition is the area under a plot of the molar absorption coefficient against the wavenumber of the incident radiation.

Fig. 13.5 The processes that account for absorption and emission of radiation and the attainment of thermal equilibrium. The excited state can return to the lower state spontaneously as well as by a process stimulated by radiation already present at the transition frequency.

Comment 13.2

The slight difference between the forms of the Planck distribution shown in eqns 8.5 and 13.7 stems from the fact that it is written here as $\rho d\nu$, and $d\lambda = (c/\nu^2)d\nu$.

(a) Absorption intensities

Einstein identified three contributions to the transitions between states. **Stimulated absorption** is the transition from a low energy state to one of higher energy that is driven by the electromagnetic field oscillating at the transition frequency. We saw in Section 9.10 that the transition rate, w , is the rate of change of probability of the molecule being found in the upper state. We also saw that the more intense the electromagnetic field (the more intense the incident radiation), the greater the rate at which transitions are induced and hence the stronger the absorption by the sample (Fig. 13.5). Einstein wrote the transition rate as

$$w = B\rho \quad (13.6)$$

The constant B is the **Einstein coefficient of stimulated absorption** and $\rho d\nu$ is the energy density of radiation in the frequency range ν to $\nu + d\nu$, where ν is the frequency of the transition. When the molecule is exposed to black-body radiation from a source of temperature T , ρ is given by the Planck distribution (eqn 8.5):

$$\rho = \frac{8\pi h \nu^3 / c^3}{e^{h\nu/kT} - 1} \quad (13.7)$$

For the time being, we can treat B as an empirical parameter that characterizes the transition: if B is large, then a given intensity of incident radiation will induce transitions strongly and the sample will be strongly absorbing. The **total rate of absorption**, W , the number of molecules excited during an interval divided by the duration of the interval, is the transition rate of a single molecule multiplied by the number of molecules N in the lower state: $W = Nw$.

Einstein considered that the radiation was also able to induce the molecule in the upper state to undergo a transition to the lower state, and hence to generate a photon of frequency ν . Thus, he wrote the rate of this stimulated emission as

$$w' = B'\rho \quad (13.8)$$

where B' is the **Einstein coefficient of stimulated emission**. Note that only radiation of the same frequency as the transition can stimulate an excited state to fall to a lower state. However, he realized that stimulated emission was not the only means by which the excited state could generate radiation and return to the lower state, and suggested that an excited state could undergo **spontaneous emission** at a rate that was independent of the intensity of the radiation (of any frequency) that is already present. Einstein therefore wrote the total rate of transition from the upper to the lower state as

$$w' = A + B'\rho \quad (13.9)$$

The constant A is the **Einstein coefficient of spontaneous emission**. The overall rate of emission is

$$W' = N'(A + B'\rho) \quad (13.10)$$

where N' is the population of the upper state.

As demonstrated in the *Justification* below, Einstein was able to show that the two coefficients of stimulated absorption and emission are equal, and that the coefficient of spontaneous emission is related to them by

$$A = \left(\frac{8\pi h \nu^3}{c^3} \right) B \quad (13.11)$$

Justification 13.2 *The relation between the Einstein coefficients*

At thermal equilibrium, the total rates of emission and absorption are equal, so

$$NB\rho = N'(A + B'\rho)$$

This expression rearranges into

$$\rho = \frac{N'A}{NB - N'B'} = \frac{A/B}{N/N' - B'/B} = \frac{A/B}{e^{h\nu/kT} - B'/B}$$

We have used the Boltzmann expression (*Molecular interpretation* 3.1) for the ratio of populations of states of energies E and E' in the last step:

$$\frac{N'}{N} = e^{-h\nu/kT} \quad h\nu = E' - E$$

This result has the same form as the Planck distribution (eqn 13.7), which describes the radiation density at thermal equilibrium. Indeed, when we compare the two expressions for ρ , we can conclude that $B' = B$ and that A is related to B by eqn 13.11.

The growth of the importance of spontaneous emission with increasing frequency is a very important conclusion, as we shall see when we consider the operation of lasers (Section 14.5). The equality of the coefficients of stimulated emission and absorption implies that, if two states happen to have equal populations, then the rate of stimulated emission is equal to the rate of stimulated absorption, and there is then no net absorption.

Spontaneous emission can be largely ignored at the relatively low frequencies of rotational and vibrational transitions, and the intensities of these transitions can be discussed in terms of stimulated emission and absorption. Then the net rate of absorption is given by

$$W_{\text{net}} = NB\rho - N'B'\rho = (N - N')B\rho \quad (13.12)$$

and is proportional to the population difference of the two states involved in the transition.

(b) Selection rules and transition moments

We met the concept of a 'selection rule' in Sections 10.3 and 12.6 as a statement about whether a transition is forbidden or allowed. Selection rules also apply to molecular spectra, and the form they take depends on the type of transition. The underlying classical idea is that, for the molecule to be able to interact with the electromagnetic field and absorb or create a photon of frequency ν , it must possess, at least transiently, a dipole oscillating at that frequency. We saw in Section 9.10 that this transient dipole is expressed quantum mechanically in terms of the transition dipole moment, μ_{fi} , between states ψ_i and ψ_f :

$$\mu_{fi} = \int \psi_f^* \hat{\mu} \psi_i d\tau \quad [13.13]$$

where $\hat{\mu}$ is the electric dipole moment operator. The size of the transition dipole can be regarded as a measure of the charge redistribution that accompanies a transition: a transition will be active (and generate or absorb photons) only if the accompanying charge redistribution is dipolar (Fig. 13.6).

We know from time-dependent perturbation theory (Section 9.10) that the transition rate is proportional to $|\mu_{fi}|^2$. It follows that the coefficient of stimulated absorption

Fig. 13.6 (a) When a $1s$ electron becomes a $2s$ electron, there is a spherical migration of charge; there is no dipole moment associated with this migration of charge; this transition is electric-dipole forbidden. (b) In contrast, when a $1s$ electron becomes a $2p$ electron, there is a dipole associated with the charge migration; this transition is allowed. (There are subtle effects arising from the sign of the wavefunction that give the charge migration a dipolar character, which this diagram does not attempt to convey.)

(and emission), and therefore the intensity of the transition, is also proportional to $|\mu_{fi}|^2$. A detailed analysis gives

$$B = \frac{|\mu_{fi}|^2}{6\epsilon_0\hbar^2} \quad (13.14)$$

Only if the transition moment is nonzero does the transition contribute to the spectrum. It follows that, to identify the selection rules, we must establish the conditions for which $\mu_{fi} \neq 0$.

A **gross selection rule** specifies the general features a molecule must have if it is to have a spectrum of a given kind. For instance, we shall see that a molecule gives a rotational spectrum only if it has a permanent electric dipole moment. This rule, and others like it for other types of transition, will be explained in the relevant sections of the chapter. A detailed study of the transition moment leads to the **specific selection rules** that express the allowed transitions in terms of the changes in quantum numbers. We have already encountered examples of specific selection rules when discussing atomic spectra (Section 10.3), such as the rule $\Delta l = \pm 1$ for the angular momentum quantum number.

13.3 Linewidths

A number of effects contribute to the widths of spectroscopic lines. Some contributions to linewidths can be modified by changing the conditions, and to achieve high resolutions we need to know how to minimize these contributions. Other contributions cannot be changed, and represent an inherent limitation on resolution.

Fig. 13.7 The Gaussian shape of a Doppler-broadened spectral line reflects the Maxwell distribution of speeds in the sample at the temperature of the experiment. Notice that the line broadens as the temperature is increased.

Exploration In a spectrometer that makes use of *phase-sensitive detection* the output signal is proportional to the first derivative of the signal intensity, $dI/d\nu$. Plot the resulting line shape for various temperatures. How is the separation of the peaks related to the temperature?

(a) Doppler broadening

The study of gaseous samples is very important, as it can inform our understanding of atmospheric chemistry. In some cases, meaningful spectroscopic data can be obtained only from gaseous samples. For example, they are essential for rotational spectroscopy, for only in gases can molecules rotate freely.

One important broadening process in gaseous samples is the **Doppler effect**, in which radiation is shifted in frequency when the source is moving towards or away from the observer. When a source emitting electromagnetic radiation of frequency ν moves with a speed s relative to an observer, the observer detects radiation of frequency

$$\nu_{\text{receding}} = \nu \left(\frac{1 - s/c}{1 + s/c} \right)^{1/2} \quad \nu_{\text{approaching}} = \nu \left(\frac{1 + s/c}{1 - s/c} \right)^{1/2} \quad (13.15)$$

where c is the speed of light (see *Further reading* for derivations). For nonrelativistic speeds ($s \ll c$), these expressions simplify to

$$\nu_{\text{receding}} \approx \frac{\nu}{1 + s/c} \quad \nu_{\text{approaching}} \approx \frac{\nu}{1 - s/c} \quad (13.16)$$

Molecules reach high speeds in all directions in a gas, and a stationary observer detects the corresponding Doppler-shifted range of frequencies. Some molecules approach the observer, some move away; some move quickly, others slowly. The detected spectral 'line' is the absorption or emission profile arising from all the resulting Doppler shifts. As shown in the following *Justification*, the profile reflects the distribution of molecular velocities parallel to the line of sight, which is a bell-shaped Gaussian curve. The Doppler line shape is therefore also a Gaussian (Fig. 13.7), and we show in the

Justification that, when the temperature is T and the mass of the molecule is m , then the observed width of the line at half-height (in terms of frequency or wavelength) is

$$\delta\nu_{\text{obs}} = \frac{2\nu}{c} \left(\frac{2kT \ln 2}{m} \right)^{1/2} \quad \delta\lambda_{\text{obs}} = \frac{2\lambda}{c} \left(\frac{2kT \ln 2}{m} \right)^{1/2} \quad (13.17)$$

For a molecule like N_2 at room temperature ($T \approx 300 \text{ K}$), $\delta\nu/\nu \approx 2.3 \times 10^{-6}$. For a typical rotational transition wavenumber of 1 cm^{-1} (corresponding to a frequency of 30 GHz), the linewidth is about 70 kHz. Doppler broadening increases with temperature because the molecules acquire a wider range of speeds. Therefore, to obtain spectra of maximum sharpness, it is best to work with cold samples.

Comment 13.3

A Gaussian function of the general form $y(x) = ae^{-(x-b)^2/2\sigma^2}$, where a , b , and σ are constants, has a maximum $y(b) = a$ and a width at half-height $\delta x = 2\sigma(2 \ln 2)^{1/2}$.

A note on good practice You will often hear people speak of ‘a frequency as so many wavenumbers’. This usage is doubly wrong. First, *frequency* and *wavenumber* are two distinct physical observables with different units, and should be distinguished. Second, ‘wavenumber’ is not a unit, it is an observable with the dimensions of 1/length and commonly reported in reciprocal centimetres (cm^{-1}).

Justification 13.3 Doppler broadening

We know from the Boltzmann distribution (*Molecular interpretation 3.1*) that the probability that a gas molecule of mass m and speed s in a sample with temperature T has kinetic energy $E_K = \frac{1}{2}ms^2$ is proportional to $e^{-ms^2/2kT}$. The observed frequencies, ν_{obs} , emitted or absorbed by the molecule are related to its speed by eqn 13.16:

$$\nu_{\text{obs}} = \nu \left(\frac{1}{1 \pm s/c} \right)$$

where ν is the unshifted frequency. When $s \ll c$, the Doppler shift in the frequency is

$$\nu_{\text{obs}} - \nu \approx \pm \nu s/c$$

which implies a symmetrical distribution of observed frequencies with respect to molecular speeds. More specifically, the intensity I of a transition at ν_{obs} is proportional to the probability of finding the molecule that emits or absorbs at ν_{obs} , so it follows from the Boltzmann distribution and the expression for the Doppler shift that

$$I(\nu_{\text{obs}}) \propto e^{-mc^2(\nu_{\text{obs}} - \nu)^2/2\nu^2kT}$$

which has the form of a Gaussian function. The width at half-height can be calculated directly from the exponent (see *Comment 13.3*) to give eqn 13.17.

(b) Lifetime broadening

It is found that spectroscopic lines from gas-phase samples are not infinitely sharp even when Doppler broadening has been largely eliminated by working at low temperatures. The same is true of the spectra of samples in condensed phases and solution. This residual broadening is due to quantum mechanical effects. Specifically, when the Schrödinger equation is solved for a system that is changing with time, it is found that it is impossible to specify the energy levels exactly. If on average a system survives in a state for a time τ (tau), the **lifetime** of the state, then its energy levels are blurred to an extent of order δE , where

$$\delta E \approx \frac{\hbar}{\tau} \quad (13.18)$$

This expression is reminiscent of the Heisenberg uncertainty principle (eqn 8.40), and consequently this **lifetime broadening** is often called ‘uncertainty broadening’. When the energy spread is expressed as a wavenumber through $\delta E = hc\delta\tilde{\nu}$, and the values of the fundamental constants introduced, this relation becomes

$$\delta\tilde{\nu} \approx \frac{5.3 \text{ cm}^{-1}}{\tau/\text{ps}} \quad (13.19)$$

No excited state has an infinite lifetime; therefore, all states are subject to some lifetime broadening and, the shorter the lifetimes of the states involved in a transition, the broader the corresponding spectral lines.

Two processes are responsible for the finite lifetimes of excited states. The dominant one for low frequency transitions is **collisional deactivation**, which arises from collisions between molecules or with the walls of the container. If the **collisional lifetime**, the mean time between collisions, is τ_{col} , the resulting collisional linewidth is $\delta E_{\text{col}} \approx \hbar/\tau_{\text{col}}$. Because $\tau_{\text{col}} = 1/z$, where z is the collision frequency, and from the kinetic model of gases (Section 1.3) we know that z is proportional to the pressure, we see that the collisional linewidth is proportional to the pressure. The collisional linewidth can therefore be minimized by working at low pressures.

The rate of spontaneous emission cannot be changed. Hence it is a natural limit to the lifetime of an excited state, and the resulting lifetime broadening is the **natural linewidth** of the transition. The natural linewidth is an intrinsic property of the transition, and cannot be changed by modifying the conditions. Natural linewidths depend strongly on the transition frequency (they increase with the coefficient of spontaneous emission A and therefore as ν^3), so low frequency transitions (such as the microwave transitions of rotational spectroscopy) have very small natural linewidths, and collisional and Doppler line-broadening processes are dominant. The natural lifetimes of electronic transitions are very much shorter than for vibrational and rotational transitions, so the natural linewidths of electronic transitions are much greater than those of vibrational and rotational transitions. For example, a typical electronic excited state natural lifetime is about 10^{-8} s (10 ns), corresponding to a natural width of about $5 \times 10^{-4} \text{ cm}^{-1}$ (15 MHz). A typical rotational state natural lifetime is about 10^3 s, corresponding to a natural linewidth of only $5 \times 10^{-15} \text{ cm}^{-1}$ (of the order of 10^{-4} Hz).

IMPACT ON ASTROPHYSICS

I13.1 Rotational and vibrational spectroscopy of interstellar space

Observations by the Cosmic Background Explorer (COBE) satellite support the long-held hypothesis that the distribution of energy in the current Universe can be modelled by a Planck distribution (eqn. 8.5) with $T = 2.726 \pm 0.001$ K, the bulk of the radiation spanning the microwave region of the spectrum. This *cosmic microwave background radiation* is the residue of energy released during the Big Bang, the event that brought the Universe into existence. Very small fluctuations in the background temperature are believed to account for the large-scale structure of the Universe.

The interstellar space in our galaxy is a little warmer than the cosmic background and consists largely of dust grains and gas clouds. The dust grains are carbon-based compounds and silicates of aluminium, magnesium, and iron, in which are embedded trace amounts of methane, water, and ammonia. Interstellar clouds are significant because it is from them that new stars, and consequently new planets, are formed. The hottest clouds are plasmas with temperatures of up to 10^6 K and densities of only about $3 \times 10^3 \text{ particles m}^{-3}$. Colder clouds range from 0.1 to 1000 solar masses (1 solar

Fig. 13.8 Rotational spectrum of the Orion nebula, showing spectral fingerprints of diatomic and polyatomic molecules present in the interstellar cloud. Adapted from G.A. Blake *et al.*, *Astrophys. J.* **315**, 621 (1987).

mass = 2×10^{30} kg), have a density of about 5×10^5 particles m^{-3} , consist largely of hydrogen atoms, and have a temperature of about 80 K. There are also colder and denser clouds, some with masses greater than 500 000 solar masses, densities greater than 10^9 particles m^{-3} , and temperatures that can be lower than 10 K. They are also called *molecular clouds*, because they are composed primarily of H_2 and CO gas in a proportion of about 10^5 to 1. There are also trace amounts of larger molecules. To place the densities in context, the density of liquid water at 298 K and 1 bar is about 3×10^{28} particles m^{-3} .

It follows from the Boltzmann distribution and the low temperature of a molecular cloud that the vast majority of a cloud's molecules are in their vibrational and electronic ground states. However, rotational excited states are populated at 10–100 K and decay by spontaneous emission. As a result, the spectrum of the cloud in the radiofrequency and microwave regions consists of sharp lines corresponding to rotational transitions (Fig. 13.8). The emitted light is collected by Earth-bound or spaceborne radiotelescopes, telescopes with antennas and detectors optimized for the collection and analysis of radiation in the microwave–radiowave range of the spectrum. Earth-bound radiotelescopes are often located at the tops of high mountains, as atmospheric water vapour can reabsorb microwave radiation from space and hence interfere with the measurement.

Over 100 interstellar molecules have been identified by their rotational spectra, often by comparing radiotelescope data with spectra obtained in the laboratory or calculated by computational methods. The experiments have revealed the presence of trace amounts (with abundances of less than 10^{-8} relative to hydrogen) of neutral molecules, ions, and radicals. Examples of neutral molecules include hydrides, oxides (including water), sulfides, halogenated compounds, nitriles, hydrocarbons, aldehydes, alcohols, ethers, ketones, and amides. The largest molecule detected by rotational spectroscopy is the nitrile HC_{11}N .

Interstellar space can also be investigated with vibrational spectroscopy by using a combination of telescopes and infrared detectors. The experiments are conducted

Table 13.1 Moments of inertia*

1. Diatomic molecules

$$I = \mu R^2 \quad \mu = \frac{m_A m_B}{m}$$

2. Triatomic linear rotors

$$I = m_A R^2 + m_C R'^2 - \frac{(m_A R - m_C R')^2}{m}$$

$$I = 2m_A R^2$$

3. Symmetric rotors

$$I_{\parallel} = 2m_A (1 - \cos \theta) R^2$$

$$I_{\perp} = m_A (1 - \cos \theta) R^2 + \frac{m_A}{m} (m_B + m_C) (1 + 2 \cos \theta) R^2 + \frac{m_C}{m} \{ (3m_A + m_B) R' + 6m_A R [\frac{1}{3} (1 + 2 \cos \theta)]^{1/2} \} R'$$

$$I_{\parallel} = 2m_A (1 - \cos \theta) R^2$$

$$I_{\perp} = m_A (1 - \cos \theta) R^2 + \frac{m_A m_B}{m} (1 + 2 \cos \theta) R^2$$

$$I_{\parallel} = 4m_A R^2$$

$$I_{\perp} = 2m_A R^2 + 2m_C R'^2$$

4. Spherical rotors

$$I = \frac{8}{3} m_A R^2$$

$$I = 4m_A R^2$$

* In each case, m is the total mass of the molecule.

primarily in space-borne telescopes because the Earth's atmosphere absorbs a great deal of infrared radiation (see *Impact I13.2*). In most cases, absorption by an interstellar species is detected against the background of infrared radiation emitted by a nearby star. The data can detect the presence of gas and solid water, CO, and CO₂ in molecular clouds. In certain cases, infrared emission can be detected, but these events are rare because interstellar space is too cold and does not provide enough energy to promote a significant number of molecules to vibrational excited states. However, infrared emissions can be observed if molecules are occasionally excited by high-energy photons emitted by hot stars in the vicinity of the cloud. For example, the polycyclic aromatic hydrocarbons hexabenzocoronene (C₄₈H₂₄) and circumcoronene (C₅₄H₁₈) have been identified from characteristic infrared emissions.

Pure rotation spectra

The general strategy we adopt for discussing molecular spectra and the information they contain is to find expressions for the energy levels of molecules and then to calculate the transition frequencies by applying the selection rules. We then predict the appearance of the spectrum by taking into account the transition moments and the populations of the states. In this section we illustrate the strategy by considering the rotational states of molecules.

13.4 Moments of inertia

The key molecular parameter we shall need is the **moment of inertia**, I , of the molecule (Section 9.6). The moment of inertia of a molecule is defined as the mass of each atom multiplied by the square of its distance from the rotational axis through the centre of mass of the molecule (Fig. 13.9):

$$I = \sum_i m_i r_i^2 \quad [13.20]$$

where r_i is the perpendicular distance of the atom i from the axis of rotation. The moment of inertia depends on the masses of the atoms present and the molecular geometry, so we can suspect (and later shall see explicitly) that rotational spectroscopy will give information about bond lengths and bond angles.

In general, the rotational properties of any molecule can be expressed in terms of the moments of inertia about three perpendicular axes set in the molecule (Fig. 13.10). The convention is to label the moments of inertia I_a , I_b , and I_c , with the axes chosen so that $I_c \geq I_b \geq I_a$. For linear molecules, the moment of inertia around the internuclear axis is zero. The explicit expressions for the moments of inertia of some symmetrical molecules are given in Table 13.1.

Example 13.1 Calculating the moment of inertia of a molecule

Calculate the moment of inertia of an H₂O molecule around the axis defined by the bisector of the HOH angle (1). The HOH bond angle is 104.5° and the bond length is 95.7 pm.

Method According to eqn 13.20, the moment of inertia is the sum of the masses multiplied by the squares of their distances from the axis of rotation. The latter can be expressed by using trigonometry and the bond angle and bond length.

Fig. 13.9 The definition of moment of inertia. In this molecule there are three identical atoms attached to the B atom and three different but mutually identical atoms attached to the C atom. In this example, the centre of mass lies on an axis passing through the B and C atom, and the perpendicular distances are measured from this axis.

Fig. 13.10 An asymmetric rotor has three different moments of inertia; all three rotation axes coincide at the centre of mass of the molecule.

Answer From eqn 13.20,

$$I = \sum_i m_i r_i^2 = m_{\text{H}} r_{\text{H}}^2 + 0 + m_{\text{H}} r_{\text{H}}^2 = 2m_{\text{H}} r_{\text{H}}^2$$

If the bond angle of the molecule is denoted 2ϕ and the bond length is R , trigonometry gives $r_{\text{H}} = R \sin \phi$. It follows that

$$I = 2m_{\text{H}} R^2 \sin^2 \phi$$

Substitution of the data gives

$$I = 2 \times (1.67 \times 10^{-27} \text{ kg}) \times (9.57 \times 10^{-11} \text{ m})^2 \times \sin^2 52.3^\circ = 1.91 \times 10^{-47} \text{ kg m}^2$$

Note that the mass of the O atom makes no contribution to the moment of inertia for this mode of rotation as the atom is immobile while the H atoms circulate around it.

A note on good practice The mass to use in the calculation of the moment of inertia is the actual atomic mass, not the element's molar mass; don't forget to convert from atomic mass units (u, formerly amu) to kilograms.

Self-test 13.1 Calculate the moment of inertia of a $\text{CH}^{35}\text{Cl}_3$ molecule around a rotational axis that contains the C—H bond. The C—Cl bond length is 177 pm and the HCCl angle is 107° ; $m(^{35}\text{Cl}) = 34.97 \text{ u}$. $[4.99 \times 10^{-45} \text{ kg m}^2]$

We shall suppose initially that molecules are **rigid rotors**, bodies that do not distort under the stress of rotation. Rigid rotors can be classified into four types (Fig. 13.11):

Spherical rotors have three equal moments of inertia (examples: CH_4 , SiH_4 , and SF_6).

Symmetric rotors have two equal moments of inertia (examples: NH_3 , CH_3Cl , and CH_3CN).

Linear rotors have one moment of inertia (the one about the molecular axis) equal to zero (examples: CO_2 , HCl , OCS , and $\text{HC}\equiv\text{CH}$).

Asymmetric rotors have three different moments of inertia (examples: H_2O , H_2CO , and CH_3OH).

Fig. 13.11 A schematic illustration of the classification of rigid rotors.

13.5 The rotational energy levels

The rotational energy levels of a rigid rotor may be obtained by solving the appropriate Schrödinger equation. Fortunately, however, there is a much less onerous short cut to the exact expressions that depends on noting the classical expression for the energy of a rotating body, expressing it in terms of the angular momentum, and then importing the quantum mechanical properties of angular momentum into the equations.

The classical expression for the energy of a body rotating about an axis a is

$$E_a = \frac{1}{2} I_a \omega_a^2 \quad (13.21)$$

where ω_a is the angular velocity (in radians per second, rad s^{-1}) about that axis and I_a is the corresponding moment of inertia. A body free to rotate about three axes has an energy

$$E = \frac{1}{2} I_a \omega_a^2 + \frac{1}{2} I_b \omega_b^2 + \frac{1}{2} I_c \omega_c^2$$

Because the classical angular momentum about the axis a is $J_a = I_a \omega_a$, with similar expressions for the other axes, it follows that

$$E = \frac{J_a^2}{2I_a} + \frac{J_b^2}{2I_b} + \frac{J_c^2}{2I_c} \quad (13.22)$$

This is the key equation. We described the quantum mechanical properties of angular momentum in Section 9.7b, and can now make use of them in conjunction with this equation to obtain the rotational energy levels.

(a) Spherical rotors

When all three moments of inertia are equal to some value I , as in CH_4 and SF_6 , the classical expression for the energy is

$$E = \frac{J_a^2 + J_b^2 + J_c^2}{2I} = \frac{J^2}{2I}$$

where $J^2 = J_a^2 + J_b^2 + J_c^2$ is the square of the magnitude of the angular momentum. We can immediately find the quantum expression by making the replacement

$$J^2 \rightarrow J(J+1)\hbar^2 \quad J = 0, 1, 2, \dots$$

Therefore, the energy of a spherical rotor is confined to the values

$$E_J = J(J+1) \frac{\hbar^2}{2I} \quad J = 0, 1, 2, \dots \quad (13.23)$$

The resulting ladder of energy levels is illustrated in Fig. 13.12. The energy is normally expressed in terms of the **rotational constant**, B , of the molecule, where

$$hcB = \frac{\hbar^2}{2I} \quad \text{so} \quad B = \frac{\hbar}{4\pi cI} \quad [13.24]$$

The expression for the energy is then

$$E_J = hcBJ(J+1) \quad J = 0, 1, 2, \dots \quad (13.25)$$

The rotational constant as defined by eqn 13.25 is a wavenumber. The energy of a rotational state is normally reported as the **rotational term**, $F(J)$, a wavenumber, by division by hc :

$$F(J) = BJ(J+1) \quad (13.26)$$

Fig. 13.12 The rotational energy levels of a linear or spherical rotor. Note that the energy separation between neighbouring levels increases as J increases.

Comment 13.4

The definition of B as a wavenumber is convenient when we come to vibration–rotation spectra. However, for pure rotational spectroscopy it is more common to define B as a frequency. Then $B = \hbar/4\pi cI$ and the energy is $E = hBJ(J+1)$.

The separation of adjacent levels is

$$F(J) - F(J-1) = 2BJ \quad (13.27)$$

Because the rotational constant decreases as I increases, we see that large molecules have closely spaced rotational energy levels. We can estimate the magnitude of the separation by considering CCl_4 : from the bond lengths and masses of the atoms we find $I = 4.85 \times 10^{-45} \text{ kg m}^2$, and hence $B = 0.0577 \text{ cm}^{-1}$.

(b) Symmetric rotors

In symmetric rotors, two moments of inertia are equal but different from the third (as in CH_3Cl , NH_3 , and C_6H_6); the unique axis of the molecule is its **principal axis** (or *figure axis*). We shall write the unique moment of inertia (that about the principal axis) as $I_{\parallel}$ and the other two as $I_{\perp}$. If $I_{\parallel} > I_{\perp}$, the rotor is classified as **oblate** (like a pancake, and C_6H_6); if $I_{\parallel} < I_{\perp}$ it is classified as **prolate** (like a cigar, and CH_3Cl). The classical expression for the energy, eqn 13.22, becomes

$$E = \frac{J_b^2 + J_c^2}{2I_{\perp}} + \frac{J_a^2}{2I_{\parallel}}$$

Again, this expression can be written in terms of $J^2 = J_a^2 + J_b^2 + J_c^2$:

$$E = \frac{J^2 - J_a^2}{2I_{\perp}} + \frac{J_a^2}{2I_{\parallel}} = \frac{J^2}{2I} + \left(\frac{1}{2I_{\parallel}} - \frac{1}{2I_{\perp}} \right) J_a^2 \quad (13.28)$$

Now we generate the quantum expression by replacing J^2 by $J(J+1)\hbar^2$, where J is the angular momentum quantum number. We also know from the quantum theory of angular momentum (Section 9.7b) that the component of angular momentum about any axis is restricted to the values $K\hbar$, with $K = 0, \pm 1, \dots, \pm J$. (K is the quantum number used to signify a component on the principal axis; M_J is reserved for a component on an externally defined axis.) Therefore, we also replace J_a^2 by $K^2\hbar^2$. It follows that the rotational terms are

$$F(J, K) = BJ(J+1) + (A - B)K^2 \quad J = 0, 1, 2, \dots \quad K = 0, \pm 1, \dots, \pm J \quad (13.29)$$

with

$$A = \frac{\hbar}{4\pi c I_{\parallel}} \quad B = \frac{\hbar}{4\pi c I_{\perp}} \quad [13.30]$$

Fig. 13.13 The significance of the quantum number K . (a) When $|K|$ is close to its maximum value, J , most of the molecular rotation is around the figure axis. (b) When $K = 0$ the molecule has no angular momentum about its principal axis: it is undergoing end-over-end rotation.

Equation 13.29 matches what we should expect for the dependence of the energy levels on the two distinct moments of inertia of the molecule. When $K = 0$, there is no component of angular momentum about the principal axis, and the energy levels depend only on $I_{\perp}$ (Fig. 13.13). When $K = \pm J$, almost all the angular momentum arises from rotation around the principal axis, and the energy levels are determined largely by $I_{\parallel}$. The sign of K does not affect the energy because opposite values of K correspond to opposite senses of rotation, and the energy does not depend on the sense of rotation.

Example 13.2 Calculating the rotational energy levels of a molecule

A $^{14}\text{NH}_3$ molecule is a symmetric rotor with bond length 101.2 pm and HNH bond angle 106.7° . Calculate its rotational terms.

A note on good practice To calculate moments of inertia precisely, we need to specify the nuclide.

Method Begin by calculating the rotational constants A and B by using the expressions for moments of inertia given in Table 13.1. Then use eqn 13.29 to find the rotational terms.

Answer Substitution of $m_A = 1.0078$ u, $m_B = 14.0031$ u, $R = 101.2$ pm, and $\theta = 106.7^\circ$ into the second of the symmetric rotor expressions in Table 13.1 gives $I_{\parallel} = 4.4128 \times 10^{-47}$ kg m² and $I_{\perp} = 2.8059 \times 10^{-47}$ kg m². Hence, $A = 6.344$ cm⁻¹ and $B = 9.977$ cm⁻¹. It follows from eqn 13.29 that

$$F(J, K)/\text{cm}^{-1} = 9.977J(J+1) - 3.633K^2$$

Upon multiplication by c , $F(J, K)$ acquires units of frequency:

$$F(J, K)/\text{GHz} = 299.1J(J+1) - 108.9K^2$$

For $J = 1$, the energy needed for the molecule to rotate mainly about its figure axis ($K = \pm J$) is equivalent to 16.32 cm⁻¹ (489.3 GHz), but end-over-end rotation ($K = 0$) corresponds to 19.95 cm⁻¹ (598.1 GHz).

Self-test 13.2 A $\text{CH}_3^{35}\text{Cl}$ molecule has a C–Cl bond length of 178 pm, a C–H bond length of 111 pm, and an HCH angle of 110.5° . Calculate its rotational energy terms.

$$[F(J, K)/\text{cm}^{-1} = 0.444J(J+1) + 4.58K^2; \text{ also } F(J, K)/\text{GHz} = 13.3J(J+1) + 137K^2]$$

(c) Linear rotors

For a linear rotor (such as CO_2 , HCl , and C_2H_2), in which the nuclei are regarded as mass points, the rotation occurs only about an axis perpendicular to the line of atoms and there is zero angular momentum around the line. Therefore, the component of angular momentum around the figure axis of a linear rotor is identically zero, and $K \equiv 0$ in eqn 13.29. The rotational terms of a linear molecule are therefore

$$F(J) = BJ(J+1) \quad J = 0, 1, 2, \dots \quad (13.31)$$

This expression is the same as eqn 13.26 but we have arrived at it in a significantly different way: here $K \equiv 0$ but for a spherical rotor $A = B$.

(d) Degeneracies and the Stark effect

The energy of a symmetric rotor depends on J and K , and each level except those with $K = 0$ is doubly degenerate: the states with K and $-K$ have the same energy. However, we must not forget that the angular momentum of the molecule has a component on an external, laboratory-fixed axis. This component is quantized, and its permitted values are $M_J\hbar$, with $M_J = 0, \pm 1, \dots, \pm J$, giving $2J + 1$ values in all (Fig. 13.14). The quantum number M_J does not appear in the expression for the energy, but it is necessary for a complete specification of the state of the rotor. Consequently, all $2J + 1$ orientations of the rotating molecule have the same energy. It follows that a symmetric rotor level is $2(2J + 1)$ -fold degenerate for $K \neq 0$ and $(2J + 1)$ -fold degenerate for $K = 0$. A linear rotor has K fixed at 0, but the angular momentum may still have $2J + 1$ components on the laboratory axis, so its degeneracy is $2J + 1$.

A spherical rotor can be regarded as a version of a symmetric rotor in which A is equal to B : The quantum number K may still take any one of $2J + 1$ values, but the energy is independent of which value it takes. Therefore, as well as having a $(2J + 1)$ -fold degeneracy arising from its orientation in space, the rotor also has a $(2J + 1)$ -fold degeneracy arising from its orientation with respect to an arbitrary axis in the

Fig. 13.14 The significance of the quantum number M_J . (a) When M_J is close to its maximum value, J , most of the molecular rotation is around the laboratory z -axis. (b) An intermediate value of M_J . (c) When $M_J = 0$ the molecule has no angular momentum about the z -axis. All three diagrams correspond to a state with $K = 0$; there are corresponding diagrams for different values of K , in which the angular momentum makes a different angle to the molecule's principal axis.

Fig. 13.15 The effect of an electric field on the energy levels of a polar linear rotor. All levels are doubly degenerate except that with $M_J = 0$.

Fig. 13.16 The effect of rotation on a molecule. The centrifugal force arising from rotation distorts the molecule, opening out bond angles and stretching bonds slightly. The effect is to increase the moment of inertia of the molecule and hence to decrease its rotational constant.

molecule. The overall degeneracy of a symmetric rotor with quantum number J is therefore $(2J + 1)^2$. This degeneracy increases very rapidly: when $J = 10$, for instance, there are 441 states of the same energy.

The degeneracy associated with the quantum number M_J (the orientation of the rotation in space) is partly removed when an electric field is applied to a polar molecule (e.g. HCl or NH_3), as illustrated in Fig. 13.15. The splitting of states by an electric field is called the **Stark effect**. For a linear rotor in an electric field $\mathcal{E}$, the energy of the state with quantum numbers J and M_J is given by

$$E(J, M_J) = hcBJ(J + 1) + a(J, M_J)\mu^2\mathcal{E}^2 \quad (13.32a)$$

where (see *Further reading* for a derivation)

$$a(J, M_J) = \frac{J(J + 1) - 3M_J^2}{2hcBJ(J + 1)(2J - 1)(2J + 3)} \quad (13.32b)$$

Note that the energy of a state with quantum number M_J depends on the square of the permanent electric dipole moment, μ . The observation of the Stark effect can therefore be used to measure this property, but the technique is limited to molecules that are sufficiently volatile to be studied by rotational spectroscopy. However, as spectra can be recorded for samples at pressures of only about 1 Pa and special techniques (such as using an intense laser beam or an electrical discharge) can be used to vaporize even some quite nonvolatile substances, a wide variety of samples may be studied. Sodium chloride, for example, can be studied as diatomic NaCl molecules at high temperatures.

(e) Centrifugal distortion

We have treated molecules as rigid rotors. However, the atoms of rotating molecules are subject to centrifugal forces that tend to distort the molecular geometry and change the moments of inertia (Fig. 13.16). The effect of centrifugal distortion on a diatomic molecule is to stretch the bond and hence to increase the moment of inertia. As a result, centrifugal distortion reduces the rotational constant and consequently the energy levels are slightly closer than the rigid-rotor expressions predict. The effect is usually taken into account largely empirically by subtracting a term from the energy and writing

$$F(J) = BJ(J + 1) - D_J J^2(J + 1)^2 \quad (13.33)$$

The parameter D_J is the **centrifugal distortion constant**. It is large when the bond is easily stretched. The centrifugal distortion constant of a diatomic molecule is related to the vibrational wavenumber of the bond, $\tilde{\nu}$ (which, as we shall see later, is a measure of its stiffness), through the approximate relation (see Problem 13.22)

$$D_J = \frac{4B^3}{\tilde{\nu}^2} \quad (13.34)$$

Hence the observation of the convergence of the rotational levels as J increases can be interpreted in terms of the rigidity of the bond.

13.6 Rotational transitions

Typical values of B for small molecules are in the region of 0.1 to 10 cm^{-1} (for example, 0.356 cm^{-1} for NF_3 and 10.59 cm^{-1} for HCl), so rotational transitions lie in the microwave region of the spectrum. The transitions are detected by monitoring the net absorption of microwave radiation. Modulation of the transmitted intensity can be achieved by varying the energy levels with an oscillating electric field. In this **Stark**

modulation, an electric field of about 10^5 V m^{-1} and a frequency of between 10 and 100 kHz is applied to the sample.

(a) Rotational selection rules

We have already remarked (Section 13.2) that the gross selection rule for the observation of a pure rotational spectrum is that a molecule must have a permanent electric dipole moment. That is, *for a molecule to give a pure rotational spectrum, it must be polar*. The classical basis of this rule is that a polar molecule appears to possess a fluctuating dipole when rotating, but a nonpolar molecule does not (Fig.13.17). The permanent dipole can be regarded as a handle with which the molecule stirs the electromagnetic field into oscillation (and vice versa for absorption). Homonuclear diatomic molecules and symmetrical linear molecules such as CO_2 are rotationally inactive. Spherical rotors cannot have electric dipole moments unless they become distorted by rotation, so they are also inactive except in special cases. An example of a spherical rotor that does become sufficiently distorted for it to acquire a dipole moment is SiH_4 , which has a dipole moment of about $8.3 \mu\text{D}$ by virtue of its rotation when $J \approx 10$ (for comparison, HCl has a permanent dipole moment of 1.1 D ; molecular dipole moments and their units are discussed in Section 18.1). The pure rotational spectrum of SiH_4 has been detected by using long path lengths (10 m) through high-pressure (4 atm) samples.

Illustration 13.2 Identifying rotationally active molecules

Of the molecules N_2 , CO_2 , OCS , H_2O , $\text{CH}_2=\text{CH}_2$, C_6H_6 , only OCS and H_2O are polar, so only these two molecules have microwave spectra.

Self-test 13.3 Which of the molecules H_2 , NO , N_2O , CH_4 can have a pure rotational spectrum? [NO, N_2O]

The specific rotational selection rules are found by evaluating the transition dipole moment between rotational states. We show in *Further information 13.2* that, for a linear molecule, the transition moment vanishes unless the following conditions are fulfilled:

$$\Delta J = \pm 1 \quad \Delta M_J = 0, \pm 1 \quad (13.35)$$

The transition $\Delta J = +1$ corresponds to absorption and the transition $\Delta J = -1$ corresponds to emission. The allowed change in J in each case arises from the conservation of angular momentum when a photon, a spin-1 particle, is emitted or absorbed (Fig. 13.18).

When the transition moment is evaluated for all possible relative orientations of the molecule to the line of flight of the photon, it is found that the total $J + 1 \leftrightarrow J$ transition intensity is proportional to

$$|\mu_{J+1,J}|^2 = \left(\frac{J+1}{2J+1} \right) \mu_0^2 \rightarrow \frac{1}{2} \mu_0^2 \quad \text{for } J \gg 1 \quad (13.36)$$

where μ_0 is the permanent electric dipole moment of the molecule. The intensity is proportional to the square of the permanent electric dipole moment, so strongly polar molecules give rise to much more intense rotational lines than less polar molecules.

For symmetric rotors, an additional selection rule states that $\Delta K = 0$. To understand this rule, consider the symmetric rotor NH_3 , where the electric dipole moment lies

Fig. 13.17 To a stationary observer, a rotating polar molecule looks like an oscillating dipole that can stir the electromagnetic field into oscillation (and vice versa for absorption). This picture is the classical origin of the gross selection rule for rotational transitions.

Fig. 13.18 When a photon is absorbed by a molecule, the angular momentum of the combined system is conserved. If the molecule is rotating in the same sense as the spin of the incoming photon, then J increases by 1.

parallel to the figure axis. Such a molecule cannot be accelerated into different states of rotation around the figure axis by the absorption of radiation, so $\Delta K = 0$.

(b) The appearance of rotational spectra

When these selection rules are applied to the expressions for the energy levels of a rigid symmetric or linear rotor, it follows that the wavenumbers of the allowed $J + 1 \leftarrow J$ absorptions are

$$\tilde{\nu}(J + 1 \leftarrow J) = 2B(J + 1) \quad J = 0, 1, 2, \dots \quad (13.37)$$

When centrifugal distortion is taken into account, the corresponding expression is

$$\tilde{\nu}(J + 1 \leftarrow J) = 2B(J + 1) - 4D_J(J + 1)^3 \quad (13.38)$$

However, because the second term is typically very small compared with the first, the appearance of the spectrum closely resembles that predicted from eqn 13.37.

Example 13.3 Predicting the appearance of a rotational spectrum

Predict the form of the rotational spectrum of $^{14}\text{NH}_3$.

Method We calculated the energy levels in Example 13.2. The $^{14}\text{NH}_3$ molecule is a polar symmetric rotor, so the selection rules $\Delta J = \pm 1$ and $\Delta K = 0$ apply. For absorption, $\Delta J = +1$ and we can use eqn 13.37. Because $B = 9.977 \text{ cm}^{-1}$, we can draw up the following table for the $J + 1 \leftarrow J$ transitions.

J	0	1	2	3	...
$\tilde{\nu}/\text{cm}^{-1}$	19.95	39.91	59.86	79.82	...
ν/GHz	598.1	1197	1795	2393	...

The line spacing is 19.95 cm^{-1} (598.1 GHz).

Self-test 13.4 Repeat the problem for $\text{C}^{35}\text{ClH}_3$ (see Self-test 13.2 for details).
[Lines of separation 0.888 cm^{-1} (26.6 GHz)]

Fig. 13.19 The rotational energy levels of a linear rotor, the transitions allowed by the selection rule $\Delta J = \pm 1$, and a typical pure rotational absorption spectrum (displayed here in terms of the radiation transmitted through the sample). The intensities reflect the populations of the initial level in each case and the strengths of the transition dipole moments.

The form of the spectrum predicted by eqn 13.37 is shown in Fig. 13.19. The most significant feature is that it consists of a series of lines with wavenumbers $2B, 4B, 6B, \dots$ and of separation $2B$. The measurement of the line spacing gives B , and hence the moment of inertia perpendicular to the principal axis of the molecule. Because the masses of the atoms are known, it is a simple matter to deduce the bond length of a diatomic molecule. However, in the case of a polyatomic molecule such as OCS or NH_3 , the analysis gives only a single quantity, $I_{\perp}$, and it is not possible to infer both bond lengths (in OCS) or the bond length and bond angle (in NH_3). This difficulty can be overcome by using isotopically substituted molecules, such as ABC and $A'BC$; then, by assuming that $R(A-B) = R(A'-B)$, both A—B and B—C bond lengths can be extracted from the two moments of inertia. A famous example of this procedure is the study of OCS; the actual calculation is worked through in Problem 13.10. The assumption that bond lengths are unchanged by isotopic substitution is only an approximation, but it is a good approximation in most cases.

The intensities of spectral lines increase with increasing J and pass through a maximum before tailing off as J becomes large. The most important reason for the maximum in intensity is the existence of a maximum in the population of rotational levels. The Boltzmann distribution (*Molecular interpretation 3.1*) implies that the population of each state decays exponentially with increasing J , but the degeneracy of the levels

increases. Specifically, the population of a rotational energy level J is given by the Boltzmann expression

$$N_J \propto N g_J e^{-E_J/kT}$$

where N is the total number of molecules and g_J is the degeneracy of the level J . The value of J corresponding to a maximum of this expression is found by treating J as a continuous variable, differentiating with respect to J , and then setting the result equal to zero. The result is (see Problem 13.24)

$$J_{\max} \approx \left(\frac{kT}{2hcB} \right)^{1/2} - \frac{1}{2} \quad (13.39)$$

For a typical molecule (for example, OCS, with $B = 0.2 \text{ cm}^{-1}$) at room temperature, $kT \approx 1000hcB$, so $J_{\max} \approx 30$. However, it must be recalled that the intensity of each transition also depends on the value of J (eqn 13.36) and on the population difference between the two states involved in the transition (see Section 13.2). Hence the value of J corresponding to the most intense line is not quite the same as the value of J for the most highly populated level.

13.7 Rotational Raman spectra

The gross selection rule for rotational Raman transitions is *that the molecule must be anisotropically polarizable*. We begin by explaining what this means. A formal derivation of this rule is given in *Further information 13.2*.

The distortion of a molecule in an electric field is determined by its polarizability, α (Section 18.2). More precisely, if the strength of the field is $\mathcal{E}$, then the molecule acquires an induced dipole moment of magnitude

$$\mu = \alpha \mathcal{E} \quad (13.40)$$

in addition to any permanent dipole moment it may have. An atom is isotropically polarizable. That is, the same distortion is induced whatever the direction of the applied field. The polarizability of a spherical rotor is also isotropic. However, non-spherical rotors have polarizabilities that do depend on the direction of the field relative to the molecule, so these molecules are anisotropically polarizable (Fig. 13.20). The electron distribution in H_2 , for example, is more distorted when the field is applied parallel to the bond than when it is applied perpendicular to it, and we write $\alpha_{\parallel} > \alpha_{\perp}$.

All linear molecules and diatomics (whether homonuclear or heteronuclear) have anisotropic polarizabilities, and so are rotationally Raman active. This activity is one reason for the importance of rotational Raman spectroscopy, for the technique can be used to study many of the molecules that are inaccessible to microwave spectroscopy. Spherical rotors such as CH_4 and SF_6 , however, are rotationally Raman inactive as well as microwave inactive. This inactivity does not mean that such molecules are never found in rotationally excited states. Molecular collisions do not have to obey such restrictive selection rules, and hence collisions between molecules can result in the population of any rotational state.

We show in *Further information 13.2* that the specific rotational Raman selection rules are

$$\text{Linear rotors:} \quad \Delta J = 0, \pm 2 \quad (13.41)$$

$$\text{Symmetric rotors:} \quad \Delta J = 0, \pm 1, \pm 2; \quad \Delta K = 0$$

The $\Delta J = 0$ transitions do not lead to a shift of the scattered photon's frequency in pure rotational Raman spectroscopy, and contribute to the unshifted Rayleigh radiation.

Fig. 13.20 An electric field applied to a molecule results in its distortion, and the distorted molecule acquires a contribution to its dipole moment (even if it is nonpolar initially). The polarizability may be different when the field is applied (a) parallel or (b) perpendicular to the molecular axis (or, in general, in different directions relative to the molecule); if that is so, then the molecule has an anisotropic polarizability.

Fig. 13.21 The rotational energy levels of a linear rotor and the transitions allowed by the $\Delta J = \pm 2$ Raman selection rules. The form of a typical rotational Raman spectrum is also shown. The Rayleigh line is much stronger than depicted in the figure; it is shown as a weaker line to improve visualization of the Raman lines.

We can predict the form of the Raman spectrum of a linear rotor by applying the selection rule $\Delta J = \pm 2$ to the rotational energy levels (Fig. 13.21). When the molecule makes a transition with $\Delta J = +2$, the scattered radiation leaves the molecule in a higher rotational state, so the wavenumber of the incident radiation, initially $\tilde{\nu}_i$, is decreased. These transitions account for the Stokes lines in the spectrum:

$$\tilde{\nu}(J+2 \leftarrow J) = \tilde{\nu}_i - \{F(J+2) - F(J)\} = \tilde{\nu}_i - 2B(2J+3) \quad (13.42a)$$

The Stokes lines appear to low frequency of the incident radiation and at displacements $6B, 10B, 14B, \dots$ from $\tilde{\nu}_i$ for $J = 0, 1, 2, \dots$. When the molecule makes a transition with $\Delta J = -2$, the scattered photon emerges with increased energy. These transitions account for the anti-Stokes lines of the spectrum:

$$\tilde{\nu}(J-2 \leftarrow J) = \tilde{\nu}_i + \{F(J) - F(J-2)\} = \tilde{\nu}_i + 2B(2J-1) \quad (13.42b)$$

The anti-Stokes lines occur at displacements of $6B, 10B, 14B, \dots$ (for $J = 2, 3, 4, \dots$; $J = 2$ is the lowest state that can contribute under the selection rule $\Delta J = -2$) to high frequency of the incident radiation. The separation of adjacent lines in both the Stokes and the anti-Stokes regions is $4B$, so from its measurement $I_\perp$ can be determined and then used to find the bond lengths exactly as in the case of microwave spectroscopy.

Example 13.4 Predicting the form of a Raman spectrum

Predict the form of the rotational Raman spectrum of $^{14}\text{N}_2$, for which $B = 1.99 \text{ cm}^{-1}$, when it is exposed to monochromatic 336.732 nm laser radiation.

Method The molecule is rotationally Raman active because end-over-end rotation modulates its polarizability as viewed by a stationary observer. The Stokes and anti-Stokes lines are given by eqn 13.42.

Answer Because $\lambda_i = 336.732 \text{ nm}$ corresponds to $\tilde{\nu}_i = 29\,697.2 \text{ cm}^{-1}$, eqns 13.42a and 13.42b give the following line positions:

J	0	1	2	3
Stokes lines				
$\tilde{\nu}/\text{cm}^{-1}$	29 685.3	29 677.3	29 669.3	29 661.4
λ/nm	336.868	336.958	337.048	337.139
Anti-Stokes lines				
$\tilde{\nu}/\text{cm}^{-1}$			29 709.1	29 717.1
λ/nm			336.597	336.507

There will be a strong central line at 336.732 nm accompanied on either side by lines of increasing and then decreasing intensity (as a result of transition moment and population effects). The spread of the entire spectrum is very small, so the incident light must be highly monochromatic.

Self-test 13.5 Repeat the calculation for the rotational Raman spectrum of NH_3 ($B = 9.977 \text{ cm}^{-1}$).

[Stokes lines at $29\,637.3, 29\,597.4, 29\,557.5, 29\,517.6 \text{ cm}^{-1}$,
anti-Stokes lines at $29\,757.1, 29\,797.0 \text{ cm}^{-1}$.]

13.8 Nuclear statistics and rotational states

If eqn 13.42 is used in conjunction with the rotational Raman spectrum of CO_2 , the rotational constant is inconsistent with other measurements of C—O bond lengths.

The results are consistent only if it is supposed that the molecule can exist in states with even values of J , so the Stokes lines are $2 \leftarrow 0, 4 \leftarrow 2, \dots$ and not $2 \leftarrow 0, 3 \leftarrow 1, \dots$

The explanation of the missing lines is the Pauli principle and the fact that O nuclei are spin-0 bosons: just as the Pauli principle excludes certain electronic states, so too does it exclude certain molecular rotational states. The form of the Pauli principle given in *Justification Section 10.4* states that, when two identical bosons are exchanged, the overall wavefunction must remain unchanged in every respect, including sign. In particular, when a CO_2 molecule rotates through 180° , two identical O nuclei are interchanged, so the overall wavefunction of the molecule must remain unchanged. However, inspection of the form of the rotational wavefunctions (which have the same form as the s, p , etc. orbitals of atoms) shows that they change sign by $(-1)^J$ under such a rotation (Fig. 13.22). Therefore, only even values of J are permissible for CO_2 , and hence the Raman spectrum shows only alternate lines.

The selective occupation of rotational states that stems from the Pauli principle is termed **nuclear statistics**. Nuclear statistics must be taken into account whenever a rotation interchanges equivalent nuclei. However, the consequences are not always as simple as for CO_2 because there are complicating features when the nuclei have nonzero spin: there may be several different relative nuclear spin orientations consistent with even values of J and a different number of spin orientations consistent with odd values of J . For molecular hydrogen and fluorine, for instance, with their two identical spin- $\frac{1}{2}$ nuclei, we show in the *Justification* below that there are three times as many ways of achieving a state with odd J than with even J , and there is a corresponding 3:1 alternation in intensity in their rotational Raman spectra (Fig. 13.23). In general, for a homonuclear diatomic molecule with nuclei of spin I , the numbers of ways of achieving states of odd and even J are in the ratio

$$\frac{\text{Number of ways of achieving odd } J}{\text{Number of ways of achieving even } J} = \begin{cases} (I+1)/I & \text{for half-integral spin nuclei} \\ I/(I+1) & \text{for integral spin nuclei} \end{cases} \quad (13.43)$$

For hydrogen, $I = \frac{1}{2}$, and the ratio is 3:1. For N_2 , with $I = 1$, the ratio is 1:2.

Justification 13.4 The effect of nuclear statistics on rotational spectra

Hydrogen nuclei are fermions, so the Pauli principle requires the overall wavefunction to change sign under particle interchange. However, the rotation of an H_2 molecule through 180° has a more complicated effect than merely relabelling the nuclei, because it interchanges their spin states too if the nuclear spins are paired ($\uparrow\downarrow$) but not if they are parallel ($\uparrow\uparrow$).

For the overall wavefunction of the molecule to change sign when the spins are parallel, the rotational wavefunction must change sign. Hence, only odd values of J are allowed. In contrast, if the nuclear spins are paired, their wavefunction is $\alpha(A)\beta(B) - \alpha(B)\beta(A)$, which changes sign when α and β are exchanged in order to bring about a simple $A \leftrightarrow B$ interchange overall (Fig. 13.24). Therefore, for the overall wavefunction to change sign in this case requires the rotational wavefunction *not* to change sign. Hence, only even values of J are allowed if the nuclear spins are paired.

As there are three nuclear spin states with parallel spins (just like the triplet state of two parallel electrons, as in Fig. 10.24), but only one state with paired spins (the analogue of the singlet state of two electrons, see Fig. 10.18), it follows that the populations of the odd J and even J states should be in the ratio of 3:1, and hence the intensities of transitions originating in these levels will be in the same ratio.

Different relative nuclear spin orientations change into one another only very slowly, so an H_2 molecule with parallel nuclear spins remains distinct from one with

Fig. 13.22 The symmetries of rotational wavefunctions (shown here, for simplicity as a two-dimensional rotor) under a rotation through 180° . Wavefunctions with J even do not change sign; those with J odd do change sign.

Fig. 13.23 The rotational Raman spectrum of a diatomic molecule with two identical spin- $\frac{1}{2}$ nuclei shows an alternation in intensity as a result of nuclear statistics. The Rayleigh line is much stronger than depicted in the figure; it is shown as a weaker line to improve visualization of the Raman lines.

Fig. 13.24 The interchange of two identical fermion nuclei results in the change in sign of the overall wavefunction. The relabelling can be thought of as occurring in two steps: the first is a rotation of the molecule; the second is the interchange of unlike spins (represented by the different colours of the nuclei). The wavefunction changes sign in the second step if the nuclei have antiparallel spins.

Fig. 13.25 When hydrogen is cooled, the molecules with parallel nuclear spins accumulate in their lowest available rotational state, the one with $J=0$. They can enter the lowest rotational state ($J=0$) only if the spins change their relative orientation and become antiparallel. This is a slow process under normal circumstances, so energy is slowly released.

paired nuclear spins for long periods. The two forms of hydrogen can be separated by physical techniques, and stored. The form with parallel nuclear spins is called **ortho-hydrogen** and the form with paired nuclear spins is called **para-hydrogen**. Because *ortho*-hydrogen cannot exist in a state with $J=0$, it continues to rotate at very low temperatures and has an effective rotational zero-point energy (Fig. 13.25). This energy is of some concern to manufacturers of liquid hydrogen, for the slow conversion of *ortho*-hydrogen into *para*-hydrogen (which can exist with $J=0$) as nuclear spins slowly realign releases rotational energy, which vaporizes the liquid. Techniques are used to accelerate the conversion of *ortho*-hydrogen to *para*-hydrogen to avoid this problem. One such technique is to pass hydrogen over a metal surface: the molecules adsorb on the surface as atoms, which then recombine in the lower energy *para*-hydrogen form.

The vibrations of diatomic molecules

In this section, we adopt the same strategy of finding expressions for the energy levels, establishing the selection rules, and then discussing the form of the spectrum. We shall also see how the simultaneous excitation of rotation modifies the appearance of a vibrational spectrum.

13.9 Molecular vibrations

We base our discussion on Fig. 13.26, which shows a typical potential energy curve (as in Fig. 11.1) of a diatomic molecule. In regions close to R_e (at the minimum of the curve) the potential energy can be approximated by a parabola, so we can write

$$V = \frac{1}{2}kx^2 \quad x = R - R_e \quad (13.44)$$

where k is the **force constant** of the bond. The steeper the walls of the potential (the stiffer the bond), the greater the force constant.

To see the connection between the shape of the molecular potential energy curve and the value of k , note that we can expand the potential energy around its minimum by using a Taylor series:

$$V(x) = V(0) + \left(\frac{dV}{dx}\right)_0 x + \frac{1}{2}\left(\frac{d^2V}{dx^2}\right)_0 x^2 + \dots \quad (13.45)$$

The term $V(0)$ can be set arbitrarily to zero. The first derivative of V is 0 at the minimum. Therefore, the first surviving term is proportional to the square of the displacement. For small displacements we can ignore all the higher terms, and so write

$$V(x) \approx \frac{1}{2}\left(\frac{d^2V}{dx^2}\right)_0 x^2 \quad (13.46)$$

Therefore, the first approximation to a molecular potential energy curve is a parabolic potential, and we can identify the force constant as

$$k = \left(\frac{d^2V}{dx^2}\right)_0 \quad [13.47]$$

We see that if the potential energy curve is sharply curved close to its minimum, then k will be large. Conversely, if the potential energy curve is wide and shallow, then k will be small (Fig. 13.27).

Fig. 13.26 A molecular potential energy curve can be approximated by a parabola near the bottom of the well. The parabolic potential leads to harmonic oscillations. At high excitation energies the parabolic approximation is poor (the true potential is less confining), and it is totally wrong near the dissociation limit.

Fig. 13.27 The force constant is a measure of the curvature of the potential energy close to the equilibrium extension of the bond. A strongly confining well (one with steep sides, a stiff bond) corresponds to high values of k .

Comment 13.5

It is often useful to express a function $f(x)$ in the vicinity of $x = a$ as an infinite Taylor series of the form:

$$f(x) = f(a) + \left(\frac{df}{dx}\right)_a (x-a) + \frac{1}{2!} \left(\frac{d^2f}{dx^2}\right)_a (x-a)^2 + \dots + \frac{1}{n!} \left(\frac{d^n f}{dx^n}\right)_a (x-a)^n + \dots$$

where $n = 0, 1, 2, \dots$

The Schrödinger equation for the relative motion of two atoms of masses m_1 and m_2 with a parabolic potential energy is

$$-\frac{\hbar^2}{2m_{\text{eff}}} \frac{d^2\psi}{dx^2} + \frac{1}{2}kx^2\psi = E\psi \quad (13.48)$$

where m_{eff} is the **effective mass**:

$$m_{\text{eff}} = \frac{m_1 m_2}{m_1 + m_2} \quad [13.49]$$

These equations are derived in the same way as in *Further information 10.1*, but here the separation of variables procedure is used to separate the relative motion of the atoms from the motion of the molecule as a whole. In that context, the effective mass is called the ‘reduced mass’, and the name is widely used in this context too.

The Schrödinger equation in eqn 13.48 is the same as eqn 9.24 for a particle of mass m undergoing harmonic motion. Therefore, we can use the results of Section 9.4 to write down the permitted vibrational energy levels:

$$E_v = \left(v + \frac{1}{2}\right)\hbar\omega \quad \omega = \left(\frac{k}{m_{\text{eff}}}\right)^{1/2} \quad v = 0, 1, 2, \dots \quad (13.50)$$

The **vibrational terms** of a molecule, the energies of its vibrational states expressed in wavenumbers, are denoted $G(v)$, with $E_v = hcG(v)$, so

$$G(v) = \left(v + \frac{1}{2}\right)\tilde{\nu} \quad \tilde{\nu} = \frac{1}{2\pi c} \left(\frac{k}{m_{\text{eff}}}\right)^{1/2} \quad (13.51)$$

The vibrational wavefunctions are the same as those discussed in Section 9.5.

It is important to note that the vibrational terms depend on the effective mass of the molecule, not directly on its total mass. This dependence is physically reasonable, for if atom 1 were as heavy as a brick wall, then we would find $m_{\text{eff}} \approx m_2$, the mass of the

lighter atom. The vibration would then be that of a light atom relative to that of a stationary wall (this is approximately the case in HI, for example, where the I atom barely moves and $m_{\text{eff}} \approx m_{\text{H}}$). For a homonuclear diatomic molecule $m_1 = m_2$, and the effective mass is half the total mass: $m_{\text{eff}} = \frac{1}{2}m$.

Illustration 13.3 Calculating a vibrational wavenumber

An HCl molecule has a force constant of 516 N m^{-1} , a reasonably typical value for a single bond. The effective mass of $^1\text{H}^{35}\text{Cl}$ is $1.63 \times 10^{-27} \text{ kg}$ (note that this mass is very close to the mass of the hydrogen atom, $1.67 \times 10^{-27} \text{ kg}$, so the Cl atom is acting like a brick wall). These values imply $\omega = 5.63 \times 10^{14} \text{ s}^{-1}$, $\nu = 89.5 \text{ THz}$ ($1 \text{ THz} = 10^{12} \text{ Hz}$), $\tilde{\nu} = 2990 \text{ cm}^{-1}$, $\lambda = 3.35 \text{ }\mu\text{m}$. These characteristics correspond to electromagnetic radiation in the infrared region.

Fig. 13.28 The oscillation of a molecule, even if it is nonpolar, may result in an oscillating dipole that can interact with the electromagnetic field.

13.10 Selection rules

The gross selection rule for a change in vibrational state brought about by absorption or emission of radiation is that *the electric dipole moment of the molecule must change when the atoms are displaced relative to one another*. Such vibrations are said to be **infrared active**. The classical basis of this rule is that the molecule can shake the electromagnetic field into oscillation if its dipole changes as it vibrates, and vice versa (Fig. 13.28); its formal basis is given in *Further information 13.2*. Note that the molecule need not have a permanent dipole: the rule requires only a change in dipole moment, possibly from zero. Some vibrations do not affect the molecule's dipole moment (e.g. the stretching motion of a homonuclear diatomic molecule), so they neither absorb nor generate radiation: such vibrations are said to be **infrared inactive**. Homonuclear diatomic molecules are infrared inactive because their dipole moments remain zero however long the bond; heteronuclear diatomic molecules are infrared active.

Illustration 13.4 Identifying infrared active molecules

Of the molecules N_2 , CO_2 , OCS , H_2O , $\text{CH}_2=\text{CH}_2$, and C_6H_6 , all except N_2 possess at least one vibrational mode that results in a change of dipole moment, so all except N_2 can show a vibrational absorption spectrum. Not all the modes of complex molecules are vibrationally active. For example, the symmetric stretch of CO_2 , in which the $\text{O}-\text{C}-\text{O}$ bonds stretch and contract symmetrically is inactive because it leaves the dipole moment unchanged (at zero).

Self-test 13.6 Which of the molecules H_2 , NO , N_2O , and CH_4 have infrared active vibrations? [NO , N_2O , CH_4]

The specific selection rule, which is obtained from an analysis of the expression for the transition moment and the properties of integrals over harmonic oscillator wavefunctions (as shown in *Further information 13.2*), is

$$\Delta v = \pm 1 \quad (13.52)$$

Transitions for which $\Delta v = +1$ correspond to absorption and those with $\Delta v = -1$ correspond to emission.

It follows from the specific selection rules that the wavenumbers of allowed vibrational transitions, which are denoted $\Delta G_{v+\frac{1}{2}}$ for the transition $v+1 \leftarrow v$, are

$$\Delta G_{v+\frac{1}{2}} = G(v+1) - G(v) = \tilde{\nu} \quad (13.53)$$

As we have seen, $\tilde{\nu}$ lies in the infrared region of the electromagnetic spectrum, so vibrational transitions absorb and generate infrared radiation.

At room temperature $kT/hc \approx 200 \text{ cm}^{-1}$, and most vibrational wavenumbers are significantly greater than 200 cm^{-1} . It follows from the Boltzmann distribution that almost all the molecules will be in their vibrational ground states initially. Hence, the dominant spectral transition will be the **fundamental transition**, $1 \leftarrow 0$. As a result, the spectrum is expected to consist of a single absorption line. If the molecules are formed in a vibrationally excited state, such as when vibrationally excited HF molecules are formed in the reaction $\text{H}_2 + \text{F}_2 \rightarrow 2 \text{HF}^*$, the transitions $5 \rightarrow 4, 4 \rightarrow 3, \dots$ may also appear (in emission). In the harmonic approximation, all these lines lie at the same frequency, and the spectrum is also a single line. However, as we shall now show, the breakdown of the harmonic approximation causes the transitions to lie at slightly different frequencies, so several lines are observed.

13.11 Anharmonicity

The vibrational terms in eqn 13.53 are only approximate because they are based on a parabolic approximation to the actual potential energy curve. A parabola cannot be correct at all extensions because it does not allow a bond to dissociate. At high vibrational excitations the swing of the atoms (more precisely, the spread of the vibrational wavefunction) allows the molecule to explore regions of the potential energy curve where the parabolic approximation is poor and additional terms in the Taylor expansion of V (eqn 13.45) must be retained. The motion then becomes **anharmonic**, in the sense that the restoring force is no longer proportional to the displacement. Because the actual curve is less confining than a parabola, we can anticipate that the energy levels become less widely spaced at high excitations.

(a) The convergence of energy levels

One approach to the calculation of the energy levels in the presence of anharmonicity is to use a function that resembles the true potential energy more closely. The **Morse potential energy** is

$$V = hcD_e \{1 - e^{-a(R-R_e)}\}^2 \quad a = \left(\frac{m_{\text{eff}} \omega^2}{2hcD_e} \right)^{1/2} \quad (13.54)$$

where D_e is the depth of the potential minimum (Fig. 13.29). Near the well minimum the variation of V with displacement resembles a parabola (as can be checked by expanding the exponential as far as the first term) but, unlike a parabola, eqn 13.54 allows for dissociation at large displacements. The Schrödinger equation can be solved for the Morse potential and the permitted energy levels are

$$G(v) = (v + \frac{1}{2})\tilde{\nu} - (v + \frac{1}{2})^2 x_e \tilde{\nu} \quad x_e = \frac{a^2 \hbar}{2m_{\text{eff}} \omega} = \frac{\tilde{\nu}}{4D_e} \quad (13.55)$$

The parameter x_e is called the **anharmonicity constant**. The number of vibrational levels of a Morse oscillator is finite, and $v = 0, 1, 2, \dots, v_{\text{max}}$ as shown in Fig. 13.30 (see also Problem 13.26). The second term in the expression for G subtracts from the first with increasing effect as v increases, and hence gives rise to the convergence of the levels at high quantum numbers.

Fig. 13.29 The dissociation energy of a molecule, D_0 , differs from the depth of the potential well, D_e , on account of the zero-point energy of the vibrations of the bond.

Fig. 13.30 The Morse potential energy curve reproduces the general shape of a molecular potential energy curve. The corresponding Schrödinger equation can be solved, and the values of the energies obtained. The number of bound levels is finite.

Fig. 13.31 The dissociation energy is the sum of the separations of the vibrational energy levels up to the dissociation limit just as the length of a ladder is the sum of the separations of its rungs.

Fig. 13.32 The area under a plot of transition wavenumber against vibrational quantum number is equal to the dissociation energy of the molecule. The assumption that the differences approach zero linearly is the basis of the Birge–Sponer extrapolation.

Although the Morse oscillator is quite useful theoretically, in practice the more general expression

$$G(v) = (v + \frac{1}{2})\tilde{\nu} - (v + \frac{1}{2})^2 x_e \tilde{\nu} + (v + \frac{1}{2})^3 y_e \tilde{\nu} + \dots \quad (13.56)$$

where $x_e, y_e, \dots$ are empirical dimensionless constants characteristic of the molecule, is used to fit the experimental data and to find the dissociation energy of the molecule. When anharmonicities are present, the wavenumbers of transitions with $\Delta v = +1$ are

$$\Delta G_{v+\frac{1}{2}} = \tilde{\nu} - 2(v+1)x_e \tilde{\nu} + \dots \quad (13.57)$$

Equation 13.57 shows that, when $x_e > 0$, the transitions move to lower wavenumbers as v increases.

Anharmonicity also accounts for the appearance of additional weak absorption lines corresponding to the transitions $2 \leftarrow 0, 3 \leftarrow 0, \dots$, even though these first, second, $\dots$ **overtones** are forbidden by the selection rule $\Delta v = \pm 1$. The first overtone, for example, gives rise to an absorption at

$$G(v+2) - G(v) = 2\tilde{\nu} - 2(2v+3)x_e \tilde{\nu} + \dots \quad (13.58)$$

The reason for the appearance of overtones is that the selection rule is derived from the properties of harmonic oscillator wavefunctions, which are only approximately valid when anharmonicity is present. Therefore, the selection rule is also only an approximation. For an anharmonic oscillator, all values of Δv are allowed, but transitions with $\Delta v > 1$ are allowed only weakly if the anharmonicity is slight.

(b) The Birge–Sponer plot

When several vibrational transitions are detectable, a graphical technique called a **Birge–Sponer plot** may be used to determine the dissociation energy, D_0 , of the bond. The basis of the Birge–Sponer plot is that the sum of successive intervals $\Delta G_{v+\frac{1}{2}}$ from the zero-point level to the dissociation limit is the dissociation energy:

$$D_0 = \Delta G_{1/2} + \Delta G_{3/2} + \dots = \sum_v \Delta G_{v+\frac{1}{2}} \quad (13.59)$$

just as the height of the ladder is the sum of the separations of its rungs (Fig. 13.31). The construction in Fig. 13.32 shows that the area under the plot of $\Delta G_{v+\frac{1}{2}}$ against $v + \frac{1}{2}$ is equal to the sum, and therefore to D_0 . The successive terms decrease linearly when only the x_e anharmonicity constant is taken into account and the inaccessible part of the spectrum can be estimated by linear extrapolation. Most actual plots differ from the linear plot as shown in Fig. 13.32, so the value of D_0 obtained in this way is usually an overestimate of the true value.

Example 13.5 Using a Birge–Sponer plot

The observed vibrational intervals of H_2^+ lie at the following values for $1 \leftarrow 0, 2 \leftarrow 1, \dots$ respectively (in cm^{-1}): 2191, 2064, 1941, 1821, 1705, 1591, 1479, 1368, 1257, 1145, 1033, 918, 800, 677, 548, 411. Determine the dissociation energy of the molecule.

Method Plot the separations against $v + \frac{1}{2}$, extrapolate linearly to the point cutting the horizontal axis, and then measure the area under the curve.

Answer The points are plotted in Fig. 13.33, and a linear extrapolation is shown as a dotted line. The area under the curve (use the formula for the area of a triangle or count the squares) is 214. Each square corresponds to 100 cm^{-1} (refer to the scale of the vertical axis); hence the dissociation energy is $21\,400 \text{ cm}^{-1}$ (corresponding to 256 kJ mol^{-1}).

Fig. 13.33 The Birge-Sponer plot used in Example 13.5. The area is obtained simply by counting the squares beneath the line or using the formula for the area of a right triangle.

Fig. 13.34 A high-resolution vibration-rotation spectrum of HCl. The lines appear in pairs because H^{35}Cl and H^{37}Cl both contribute (their abundance ratio is 3:1). There is no Q branch, because $\Delta J = 0$ is forbidden for this molecule.

Self-test 13.7 The vibrational levels of HgH converge rapidly, and successive intervals are 1203.7 (which corresponds to the $1 \leftarrow 0$ transition), 965.6, 632.4, and 172 cm^{-1} . Estimate the dissociation energy. [35.6 kJ mol^{-1}]

13.12 Vibration-rotation spectra

Each line of the high resolution vibrational spectrum of a gas-phase heteronuclear diatomic molecule is found to consist of a large number of closely spaced components (Fig. 13.34). Hence, molecular spectra are often called **band spectra**. The separation between the components is less than 10 cm^{-1} , which suggests that the structure is due to rotational transitions accompanying the vibrational transition. A rotational change should be expected because classically we can think of the transition as leading to a sudden increase or decrease in the instantaneous bond length. Just as ice-skaters rotate more rapidly when they bring their arms in, and more slowly when they throw them out, so the molecular rotation is either accelerated or retarded by a vibrational transition.

(a) Spectral branches

A detailed analysis of the quantum mechanics of simultaneous vibrational and rotational changes shows that the rotational quantum number J changes by ± 1 during the vibrational transition of a diatomic molecule. If the molecule also possesses angular momentum about its axis, as in the case of the electronic orbital angular momentum of the paramagnetic molecule NO, then the selection rules also allow $\Delta J = 0$.

The appearance of the vibration-rotation spectrum of a diatomic molecule can be discussed in terms of the combined vibration-rotation terms, S :

$$S(v, J) = G(v) + F(J) \quad (13.60)$$

If we ignore anharmonicity and centrifugal distortion,

$$S(v, J) = (v + \frac{1}{2})\tilde{\nu} + BJ(J+1) \quad (13.61)$$

Fig. 13.35 The formation of P, Q, and R branches in a vibration-rotation spectrum. The intensities reflect the populations of the initial rotational levels.

Fig. 13.36 The method of combination differences makes use of the fact that some transitions share a common level.

In a more detailed treatment, B is allowed to depend on the vibrational state because, as v increases, the molecule swells slightly and the moment of inertia changes. We shall continue with the simple expression initially.

When the vibrational transition $v+1 \leftarrow v$ occurs, J changes by ± 1 and in some cases by 0 (when $\Delta J = 0$ is allowed). The absorptions then fall into three groups called **branches** of the spectrum. The **P branch** consists of all transitions with $\Delta J = -1$:

$$\tilde{\nu}_P(J) = S(v+1, J-1) - S(v, J) = \tilde{\nu} - 2BJ \quad (13.62a)$$

This branch consists of lines at $\tilde{\nu} - 2B, \tilde{\nu} - 4B, \dots$ with an intensity distribution reflecting both the populations of the rotational levels and the magnitude of the $J-1 \leftarrow J$ transition moment (Fig. 13.35). The **Q branch** consists of all lines with $\Delta J = 0$, and its wavenumbers are all

$$\tilde{\nu}_Q(J) = S(v+1, J) - S(v, J) = \tilde{\nu} \quad (13.62b)$$

for all values of J . This branch, when it is allowed (as in NO), appears at the vibrational transition wavenumber. In Fig. 13.35 there is a gap at the expected location of the Q branch because it is forbidden in HCl. The **R branch** consists of lines with $\Delta J = +1$:

$$\tilde{\nu}_R(J) = S(v+1, J+1) - S(v, J) = \tilde{\nu} + 2B(J+1) \quad (13.62c)$$

This branch consists of lines displaced from $\tilde{\nu}$ to high wavenumber by $2B, 4B, \dots$

The separation between the lines in the P and R branches of a vibrational transition gives the value of B . Therefore, the bond length can be deduced without needing to take a pure rotational microwave spectrum. However, the latter is more precise.

(b) Combination differences

The rotational constant of the vibrationally excited state, B_1 (in general, B_v), is in fact slightly smaller than that of the ground vibrational state, B_0 , because the anharmonicity of the vibration results in a slightly extended bond in the upper state. As a result, the Q branch (if it exists) consists of a series of closely spaced lines. The lines of the R branch converge slightly as J increases; and those of the P branch diverge:

$$\begin{aligned} \tilde{\nu}_P(J) &= \tilde{\nu} - (B_1 + B_0)J + (B_1 - B_0)J^2 \\ \tilde{\nu}_Q(J) &= \tilde{\nu} + (B_1 - B_0)J(J+1) \\ \tilde{\nu}_R(J) &= \tilde{\nu} + (B_1 + B_0)(J+1) + (B_1 - B_0)(J+1)^2 \end{aligned} \quad (13.63)$$

To determine the two rotational constants individually, we use the method of **combination differences**. This procedure is used widely in spectroscopy to extract information about a particular state. It involves setting up expressions for the difference in the wavenumbers of transitions to a common state; the resulting expression then depends solely on properties of the other state.

As can be seen from Fig. 13.36, the transitions $\tilde{\nu}_R(J-1)$ and $\tilde{\nu}_P(J+1)$ have a common upper state, and hence can be anticipated to depend on B_0 . Indeed, it is easy to show from eqn 13.63 that

$$\tilde{\nu}_R(J-1) - \tilde{\nu}_P(J+1) = 4B_0(J + \frac{1}{2}) \quad (13.64a)$$

Therefore, a plot of the combination difference against $J + \frac{1}{2}$ should be a straight line of slope $4B_0$, so the rotational constant of the molecule in the state $v=0$ can be determined. (Any deviation from a straight line is a consequence of centrifugal distortion, so that effect can be investigated too.) Similarly, $\tilde{\nu}_R(J)$ and $\tilde{\nu}_P(J)$ have a common

lower state, and hence their combination difference gives information about the upper state:

$$\tilde{\nu}_R(J) - \tilde{\nu}_P(J) = 4B_1(J + \frac{1}{2}) \quad (13.64b)$$

The two rotational constants of $^1\text{H}^{35}\text{Cl}$ found in this way are $B_0 = 10.440 \text{ cm}^{-1}$ and $B_1 = 10.136 \text{ cm}^{-1}$.

13.13 Vibrational Raman spectra of diatomic molecules

The gross selection rule for vibrational Raman transitions is that *the polarizability should change as the molecule vibrates*. As homonuclear and heteronuclear diatomic molecules swell and contract during a vibration, the control of the nuclei over the electrons varies, and hence the molecular polarizability changes. Both types of diatomic molecule are therefore vibrationally Raman active. The specific selection rule for vibrational Raman transitions in the harmonic approximation is $\Delta v = \pm 1$. The formal basis for the gross and specific selection rules is given in *Further information 13.2*.

The lines to high frequency of the incident radiation, the anti-Stokes lines, are those for which $\Delta v = -1$. The lines to low frequency, the Stokes lines, correspond to $\Delta v = +1$. The intensities of the anti-Stokes and Stokes lines are governed largely by the Boltzmann populations of the vibrational states involved in the transition. It follows that anti-Stokes lines are usually weak because very few molecules are in an excited vibrational state initially.

In gas-phase spectra, the Stokes and anti-Stokes lines have a branch structure arising from the simultaneous rotational transitions that accompany the vibrational excitation (Fig. 13.37). The selection rules are $\Delta J = 0, \pm 2$ (as in pure rotational Raman spectroscopy), and give rise to the **O branch** ($\Delta J = -2$), the **Q branch** ($\Delta J = 0$), and the **S branch** ($\Delta J = +2$):

$$\begin{aligned} \tilde{\nu}_O(J) &= \tilde{\nu}_i - \tilde{\nu} - 2B + 4BJ \\ \tilde{\nu}_Q(J) &= \tilde{\nu}_i - \tilde{\nu} \\ \tilde{\nu}_S(J) &= \tilde{\nu}_i - \tilde{\nu} - 6B + 4BJ \end{aligned} \quad (13.65)$$

Note that, unlike in infrared spectroscopy, a Q branch is obtained for all linear molecules. The spectrum of CO, for instance, is shown in Fig. 13.38: the structure of the Q branch arises from the differences in rotational constants of the upper and lower vibrational states.

The information available from vibrational Raman spectra adds to that from infrared spectroscopy because homonuclear diatomics can also be studied. The spectra can be interpreted in terms of the force constants, dissociation energies, and bond lengths, and some of the information obtained is included in Table 13.2.

Fig. 13.37 The formation of O, Q, and S branches in a vibration–rotation Raman spectrum of a linear rotor. Note that the frequency scale runs in the opposite direction to that in Fig. 13.35, because the higher energy transitions (on the right) extract more energy from the incident beam and leave it at lower frequency.

Synoptic table 13.2* Properties of diatomic molecules

	$\tilde{\nu}/\text{cm}^{-1}$	R_e/pm	B/cm^{-1}	$k/(\text{N m}^{-1})$	$D_e/(\text{kJ mol}^{-1})$

Fig. 13.39 (a) The orientation of a linear molecule requires the specification of two angles. (b) The orientation of a nonlinear molecule requires the specification of three angles.

The vibrations of polyatomic molecules

There is only one mode of vibration for a diatomic molecule, the bond stretch. In polyatomic molecules there are several modes of vibration because all the bond lengths and angles may change and the vibrational spectra are very complex. Nonetheless, we shall see that infrared and Raman spectroscopy can be used to obtain information about the structure of systems as large as animal and plant tissues (see *Impact I13.3*).

13.14 Normal modes

We begin by calculating the total number of vibrational modes of a polyatomic molecule. We then see that we can choose combinations of these atomic displacements that give the simplest description of the vibrations.

As shown in the *Justification* below, for a nonlinear molecule that consists of N atoms, there are $3N - 6$ independent modes of vibration. If the molecule is linear, there are $3N - 5$ independent vibrational modes.

Justification 13.5 The number of vibrational modes

The total number of coordinates needed to specify the locations of N atoms is $3N$. Each atom may change its location by varying one of its three coordinates (x , y , and z), so the total number of displacements available is $3N$. These displacements can be grouped together in a physically sensible way. For example, three coordinates are needed to specify the location of the centre of mass of the molecule, so three of the $3N$ displacements correspond to the translational motion of the molecule as a whole. The remaining $3N - 3$ are non-translational ‘internal’ modes of the molecule.

Two angles are needed to specify the orientation of a linear molecule in space: in effect, we need to give only the latitude and longitude of the direction in which the molecular axis is pointing (Fig. 13.39a). However, three angles are needed for a nonlinear molecule because we also need to specify the orientation of the molecule around the direction defined by the latitude and longitude (Fig. 13.39b). Therefore, two (linear) or three (nonlinear) of the $3N - 3$ internal displacements are rotational. This leaves $3N - 5$ (linear) or $3N - 6$ (nonlinear) displacements of the atoms relative to one another: these are the vibrational modes. It follows that the number of modes of vibration N_{vib} is $3N - 5$ for linear molecules and $3N - 6$ for nonlinear molecules.

Illustration 13.5 Determining the number of vibrational modes

Water, H_2O , is a nonlinear triatomic molecule, and has three modes of vibration (and three modes of rotation); CO_2 is a linear triatomic molecule, and has four modes of vibration (and only two modes of rotation). Even a middle-sized molecule such as naphthalene (C_{10}H_8) has 48 distinct modes of vibration.

The next step is to find the best description of the modes. One choice for the four modes of CO_2 , for example, might be the ones in Fig. 13.40a. This illustration shows the stretching of one bond (the mode ν_L), the stretching of the other (ν_R), and the two perpendicular bending modes (ν_2). The description, while permissible, has a

disadvantage: when one CO bond vibration is excited, the motion of the C atom sets the other CO bond in motion, so energy flows backwards and forwards between ν_L and ν_R . Moreover, the position of the centre of mass of the molecule varies in the course of either vibration.

The description of the vibrational motion is much simpler if linear combinations of ν_L and ν_R are taken. For example, one combination is ν_1 in Fig. 13.40b: this mode is the **symmetric stretch**. In this mode, the C atom is buffeted simultaneously from each side and the motion continues indefinitely. Another mode is ν_3 , the **antisymmetric stretch**, in which the two O atoms always move in the same direction and opposite to that of the C atom. Both modes are independent in the sense that, if one is excited, then it does not excite the other. They are two of the ‘normal modes’ of the molecule, its independent, collective vibrational displacements. The two other normal modes are the bending modes ν_2 . In general, a **normal mode** is an independent, synchronous motion of atoms or groups of atoms that may be excited without leading to the excitation of any other normal mode and without involving translation or rotation of the molecule as a whole.

The four normal modes of CO₂, and the N_{vib} normal modes of polyatomics in general, are the key to the description of molecular vibrations. Each normal mode, q , behaves like an independent harmonic oscillator (if anharmonicities are neglected), so each has a series of terms

$$G_q(v) = (v + \tfrac{1}{2})\tilde{\nu}_q \quad \tilde{\nu}_q = \frac{1}{2\pi c} \left(\frac{k_q}{m_q} \right)^{1/2} \quad (13.66)$$

where $\tilde{\nu}_q$ is the wavenumber of mode q and depends on the force constant k_q for the mode and on the effective mass m_q of the mode. The effective mass of the mode is a measure of the mass that is swung about by the vibration and in general is a complicated function of the masses of the atoms. For example, in the symmetric stretch of CO₂, the C atom is stationary, and the effective mass depends on the masses of only the O atoms. In the antisymmetric stretch and in the bends, all three atoms move, so all contribute to the effective mass. The three normal modes of H₂O are shown in Fig. 13.41: note that the predominantly bending mode (ν_2) has a lower frequency than the others, which are predominantly stretching modes. It is generally the case that the frequencies of bending motions are lower than those of stretching modes. One point that must be appreciated is that only in special cases (such as the CO₂ molecule) are the normal modes purely stretches or purely bends. In general, a normal mode is a composite motion of simultaneous stretching and bending of bonds. Another point in this connection is that heavy atoms generally move less than light atoms in normal modes.

13.15 Infrared absorption spectra of polyatomic molecules

The gross selection rule for infrared activity is that *the motion corresponding to a normal mode should be accompanied by a change of dipole moment*. Deciding whether this is so can sometimes be done by inspection. For example, the symmetric stretch of CO₂ leaves the dipole moment unchanged (at zero, see Fig. 13.40), so this mode is infrared inactive. The antisymmetric stretch, however, changes the dipole moment because the molecule becomes unsymmetrical as it vibrates, so this mode is infrared active. Because the dipole moment change is parallel to the principal axis, the transitions arising from this mode are classified as **parallel bands** in the spectrum. Both bending modes are infrared active: they are accompanied by a changing dipole perpendicular to the principal axis, so transitions involving them lead to a **perpendicular band** in the spectrum. The latter bands eliminate the linearity of the molecule, and as a result a Q branch is observed; a parallel band does not have a Q branch.

Fig. 13.40 Alternative descriptions of the vibrations of CO₂. (a) The stretching modes are not independent, and if one C—O group is excited the other begins to vibrate. They are not normal modes of vibration of the molecule. (b) The symmetric and antisymmetric stretches are independent, and one can be excited without affecting the other: they are normal modes. (c) The two perpendicular bending motions are also normal modes.

Fig. 13.41 The three normal modes of H₂O. The mode ν_2 is predominantly bending, and occurs at lower wavenumber than the other two.

Comment 13.6

The web site for this text contains links to sites where you can perform quantum mechanical calculations of frequencies and atomic displacements of normal modes of simple molecules.

Comment 13.7

The web site for this text contains links to databases of infrared spectra.

Synoptic table 13.3* Typical vibrational wavenumbers

Vibration type	$\tilde{\nu}/\text{cm}^{-1}$
C—H stretch	2850–2960
C—H bend	1340–1465
C—C stretch, bend	700–1250
C=C stretch	1620–1680

* More values are given in the Data section.

The active modes are subject to the specific selection rule $\Delta v_q = \pm 1$ in the harmonic approximation, so the wavenumber of the fundamental transition (the ‘first harmonic’) of each active mode is $\tilde{\nu}_q$. From the analysis of the spectrum, a picture may be constructed of the stiffness of various parts of the molecule, that is, we can establish its **force field**, the set of force constants corresponding to all the displacements of the atoms. The force field may also be estimated by using the semi-empirical, *ab initio*, and DFT computational techniques described in Section 11.7. Superimposed on the simple force field scheme are the complications arising from anharmonicities and the effects of molecular rotation. Very often the sample is a liquid or a solid, and the molecules are unable to rotate freely. In a liquid, for example, a molecule may be able to rotate through only a few degrees before it is struck by another, so it changes its rotational state frequently. This random changing of orientation is called **tumbling**.

The lifetimes of rotational states in liquids are very short, so in most cases the rotational energies are ill-defined. Collisions occur at a rate of about 10^{13} s^{-1} and, even allowing for only a 10 per cent success rate in knocking the molecule into another rotational state, a lifetime broadening (eqn 13.19) of more than 1 cm^{-1} can easily result. The rotational structure of the vibrational spectrum is blurred by this effect, so the infrared spectra of molecules in condensed phases usually consist of broad lines spanning the entire range of the resolved gas-phase spectrum, and showing no branch structure.

One very important application of infrared spectroscopy to condensed phase samples, and for which the blurring of the rotational structure by random collisions is a welcome simplification, is to chemical analysis. The vibrational spectra of different groups in a molecule give rise to absorptions at characteristic frequencies because a normal mode of even a very large molecule is often dominated by the motion of a small group of atoms. The intensities of the vibrational bands that can be identified with the motions of small groups are also transferable between molecules. Consequently, the molecules in a sample can often be identified by examining its infrared spectrum and referring to a table of characteristic frequencies and intensities (Table 13.3).

IMPACT ON ENVIRONMENTAL SCIENCE

113.2 Global warming¹

Solar energy strikes the top of the Earth’s atmosphere at a rate of 343 W m^{-2} . About 30 per cent of this energy is reflected back into space by the Earth or the atmosphere. The Earth–atmosphere system absorbs the remaining energy and re-emits it into space as black-body radiation, with most of the intensity being carried by infrared radiation in the range $200\text{--}2500 \text{ cm}^{-1}$ ($4\text{--}50 \mu\text{m}$). The Earth’s average temperature is maintained by an energy balance between solar radiation absorbed by the Earth and black-body radiation emitted by the Earth.

The trapping of infrared radiation by certain gases in the atmosphere is known as the *greenhouse effect*, so called because it warms the Earth as if the planet were enclosed in a huge greenhouse. The result is that the natural greenhouse effect raises the average surface temperature well above the freezing point of water and creates an environment in which life is possible. The major constituents to the Earth’s atmosphere, O_2 and N_2 , do not contribute to the greenhouse effect because homonuclear diatomic molecules cannot absorb infrared radiation. However, the minor atmospheric gases, water vapour and CO_2 , do absorb infrared radiation and hence are responsible for the

¹ This section is based on a similar contribution initially prepared by Loretta Jones and appearing in *Chemical principles*, Peter Atkins and Loretta Jones, W.H. Freeman and Co., New York (2005).

greenhouse effect (Fig. 13.42). Water vapour absorbs strongly in the ranges $1300\text{--}1900\text{ cm}^{-1}$ ($5.3\text{--}7.7\text{ }\mu\text{m}$) and $3550\text{--}3900\text{ cm}^{-1}$ ($2.6\text{--}2.8\text{ }\mu\text{m}$), whereas CO_2 shows strong absorption in the ranges $500\text{--}725\text{ cm}^{-1}$ ($14\text{--}20\text{ }\mu\text{m}$) and $2250\text{--}2400\text{ cm}^{-1}$ ($4.2\text{--}4.4\text{ }\mu\text{m}$).

Increases in the levels of greenhouse gases, which also include methane, dinitrogen oxide, ozone, and certain chlorofluorocarbons, as a result of human activity have the potential to enhance the natural greenhouse effect, leading to significant warming of the planet. This problem is referred to as *global warming*, which we now explore in some detail.

The concentration of water vapour in the atmosphere has remained steady over time, but concentrations of some other greenhouse gases are rising. From about the year 1000 until about 1750, the CO_2 concentration remained fairly stable, but, since then, it has increased by 28 per cent. The concentration of methane, CH_4 , has more than doubled during this time and is now at its highest level for 160 000 years (160 ka; a is the SI unit denoting 1 year). Studies of air pockets in ice cores taken from Antarctica show that increases in the concentration of both atmospheric CO_2 and CH_4 over the past 160 ka correlate well with increases in the global surface temperature.

Human activities are primarily responsible for the rising concentrations of atmospheric CO_2 and CH_4 . Most of the atmospheric CO_2 comes from the burning of hydrocarbon fuels, which began on a large scale with the Industrial Revolution in the middle of the nineteenth century. The additional methane comes mainly from the petroleum industry and from agriculture.

The temperature of the surface of the Earth has increased by about 0.5 K since the late nineteenth century (Fig. 13.43). If we continue to rely on hydrocarbon fuels and current trends in population growth and energy are not reversed, then by the middle of the twenty-first century, the concentration of CO_2 in the atmosphere will be about twice its value prior to the Industrial Revolution. The Intergovernmental Panel on Climate Change (IPCC) estimated in 1995 that, by the year 2100, the Earth will undergo an increase in temperature of 3 K. Furthermore, the rate of temperature change is likely to be greater than at any time in the last 10 ka. To place a temperature rise of 3 K in perspective, it is useful to consider that the average temperature of the Earth during the last ice age was only 6 K colder than at present. Just as cooling the planet (for example, during an ice age) can lead to detrimental effects on ecosystems, so too can a dramatic warming of the globe. One example of a significant change in the

Fig. 13.42 The intensity of infrared radiation that would be lost from Earth in the absence of greenhouse gases is shown by the blue line. The purple line is the intensity of the radiation actually emitted. The maximum wavelength of radiation absorbed by each greenhouse gas is indicated.

Fig. 13.43 The average change in surface temperature of the Earth from 1855 to 2002.

environment caused by a temperature increase of 3 K is a rise in sea level by about 0.5 m, which is sufficient to alter weather patterns and submerge currently coastal ecosystems.

Computer projections for the next 200 years predict further increases in atmospheric CO_2 levels and suggest that, to maintain CO_2 at its current concentration, we would have to reduce hydrocarbon fuel consumption immediately by about 50 per cent. Clearly, in order to reverse global warming trends, we need to develop alternatives to fossil fuels, such as hydrogen (which can be used in fuel cells, *Impact I25.3*) and solar energy technologies.

13.16 Vibrational Raman spectra of polyatomic molecules

The normal modes of vibration of molecules are Raman active if they are accompanied by a changing polarizability. It is sometimes quite difficult to judge by inspection when this is so. The symmetric stretch of CO_2 , for example, alternately swells and contracts the molecule: this motion changes the polarizability of the molecule, so the mode is Raman active. The other modes of CO_2 leave the polarizability unchanged, so they are Raman inactive.

A more exact treatment of infrared and Raman activity of normal modes leads to the **exclusion rule**:

If the molecule has a centre of symmetry, then no modes can be both infrared and Raman active.

(A mode may be inactive in both.) Because it is often possible to judge intuitively if a mode changes the molecular dipole moment, we can use this rule to identify modes that are not Raman active. The rule applies to CO_2 but to neither H_2O nor CH_4 because they have no centre of symmetry. In general, it is necessary to use group theory to predict whether a mode is infrared or Raman active (Section 13.17).

(a) Depolarization

The assignment of Raman lines to particular vibrational modes is aided by noting the state of polarization of the scattered light. The **depolarization ratio**, ρ , of a line is the ratio of the intensities, I , of the scattered light with polarizations perpendicular and parallel to the plane of polarization of the incident radiation:

$$\rho = \frac{I_{\perp}}{I_{\parallel}} \quad [13.67]$$

To measure ρ , the intensity of a Raman line is measured with a polarizing filter (a ‘half-wave plate’) first parallel and then perpendicular to the polarization of the incident beam. If the emergent light is not polarized, then both intensities are the same and ρ is close to 1; if the light retains its initial polarization, then $I_{\perp} = 0$, so $\rho = 0$ (Fig. 13.44). A line is classified as **depolarized** if it has ρ close to or greater than 0.75 and as **polarized** if $\rho < 0.75$. Only totally symmetrical vibrations give rise to polarized lines in which the incident polarization is largely preserved. Vibrations that are not totally symmetrical give rise to depolarized lines because the incident radiation can give rise to radiation in the perpendicular direction too.

(b) Resonance Raman spectra

A modification of the basic Raman effect involves using incident radiation that nearly coincides with the frequency of an electronic transition of the sample (Fig. 13.45). The

Fig. 13.44 The definition of the planes used for the specification of the depolarization ratio, ρ , in Raman scattering.

Fig. 13.45 In the *resonance Raman effect*, the incident radiation has a frequency corresponding to an actual electronic excitation of the molecule. A photon is emitted when the excited state returns to a state close to the ground state.

technique is then called **resonance Raman spectroscopy**. It is characterized by a much greater intensity in the scattered radiation. Furthermore, because it is often the case that only a few vibrational modes contribute to the more intense scattering, the spectrum is greatly simplified.

Resonance Raman spectroscopy is used to study biological molecules that absorb strongly in the ultraviolet and visible regions of the spectrum. Examples include the pigments β -carotene and chlorophyll, which capture solar energy during plant photosynthesis (see *Impact I23.2*). The resonance Raman spectra of Fig. 13.46 show vibrational transitions from only the few pigment molecules that are bound to very large proteins dissolved in an aqueous buffer solution. This selectivity arises from the fact that water (the solvent), amino acid residues, and the peptide group do not have electronic transitions at the laser wavelengths used in the experiment, so their *conventional* Raman spectra are weak compared to the enhanced spectra of the pigments. Comparison of the spectra in Figs. 13.46a and 13.46b also shows that, with proper choice of excitation wavelength, it is possible to examine individual classes of pigments bound to the same protein: excitation at 488 nm, where β -carotene absorbs strongly, shows vibrational bands from β -carotene only, whereas excitation at 442 nm, where chlorophyll *a* and β -carotene absorb, reveals features from both types of pigments.

(c) Coherent anti-Stokes Raman spectroscopy

The intensity of Raman transitions may be enhanced by **coherent anti-Stokes Raman spectroscopy** (CARS, Fig. 13.47). The technique relies on the fact that, if two laser beams of frequencies ν_1 and ν_2 pass through a sample, then they may mix together and give rise to coherent radiation of several different frequencies, one of which is

$$\nu' = 2\nu_1 - \nu_2 \quad (13.68)$$

Suppose that ν_2 is varied until it matches any Stokes line from the sample, such as the one with frequency $\nu_1 - \Delta\nu$; then the coherent emission will have frequency

$$\nu' = 2\nu_1 - (\nu_1 - \Delta\nu) = \nu_1 + \Delta\nu \quad (13.69)$$

which is the frequency of the corresponding anti-Stokes line. This coherent radiation forms a narrow beam of high intensity.

An advantage of CARS is that it can be used to study Raman transitions in the presence of competing incoherent background radiation, and so can be used to observe the Raman spectra of species in flames. One example is the vibration–rotation CARS spectrum of N_2 gas in a methane–air flame shown in Fig 13.48.

Fig. 13.47 The experimental arrangement for the CARS experiment.

Fig. 13.46 The resonance Raman spectra of a protein complex that is responsible for some of the initial electron transfer events in plant photosynthesis. (a) Laser excitation of the sample at 407 nm shows Raman bands due to both chlorophyll *a* and β -carotene bound to the protein because both pigments absorb light at this wavelength. (b) Laser excitation at 488 nm shows Raman bands from β -carotene only because chlorophyll *a* does not absorb light very strongly at this wavelength. (Adapted from D.F. Ghanotakis *et al.*, *Biochim. Biophys. Acta* **974**, 44 (1989).)

IMPACT ON BIOCHEMISTRY

113.3 Vibrational microscopy

Optical microscopes can now be combined with infrared and Raman spectrometers and the vibrational spectra of specimens as small as single biological cells obtained. The techniques of *vibrational microscopy* provide details of cellular events that cannot be observed with traditional light or electron microscopy.

The principles behind the operation of infrared and Raman microscopes are simple: radiation illuminates a small area of the sample, and the transmitted, reflected, or scattered light is first collected by a microscope and then analysed by a spectrometer. The sample is then moved by very small increments along a plane perpendicular to the direction of illumination and the process is repeated until vibrational spectra for all sections the sample are obtained. The size of a sample that can be studied by vibrational microscopy depends on a number of factors, such as the area of illumination and the excitation and wavelength of the incident radiation. Up to a point, the smaller the area that is illuminated, the smaller the area from which a spectrum can be obtained. High excitation is required to increase the rate of arrival of photons at the detector from small illuminated areas. For this reason, lasers and synchrotron radiation (see *Further information 13.1*) are the preferred radiation sources.

In a conventional light microscope, an image is constructed from a pattern of diffracted light waves that emanate from the illuminated object. As a result, some information about the specimen is lost by destructive interference of scattered light waves. Ultimately, this *diffraction limit* prevents the study of samples that are much smaller than the wavelength of light used as a probe. In practice, two objects will appear as distinct images under a microscope if the distance between their centres is greater than the *Airy radius*, $r_{\text{Airy}} = 0.61\lambda/a$, where λ is the wavelength of the incident beam of radiation and a is the numerical aperture of the *objective lens*, the lens that collects light scattered by the object. The numerical aperture of the objective lens is defined as $a = n_r \sin \alpha$, where n_r is the refractive index of the lens material (the greater the refractive index, the greater the bending of a ray of light by the lens) and the angle α is the half-angle of the widest cone of scattered light that can be collected by the lens (so the lens collects light beams sweeping a cone with angle 2α). Use of the best equipment makes it possible to probe areas as small as $9 \mu\text{m}^2$ by vibrational microscopy.

Figure 13.49 shows the infrared spectra of a single mouse cell, living and dying. Both spectra have features at 1545 cm^{-1} and 1650 cm^{-1} that are due to the peptide carbonyl groups of proteins and a feature at 1240 cm^{-1} that is due to the phosphodiester (PO_2^-) groups of lipids. The dying cell shows an additional absorption at 1730 cm^{-1} , which is due to the ester carbonyl group from an unidentified compound. From a plot of the intensities of individual absorption features as a function of position in the cell, it has been possible to map the distribution of proteins and lipids during cell division and cell death.

Vibrational microscopy has also been used in biomedical and pharmaceutical laboratories. Examples include the determination of the size and distribution of a drug in a tablet, the observation of conformational changes in proteins of cancerous cells upon administration of anti-tumour drugs, and the measurement of differences between diseased and normal tissue, such as diseased arteries and the white matter from brains of multiple sclerosis patients.

Fig. 13.49 Infrared absorption spectra of a single mouse cell: (purple) living cell, (blue) dying cell. Adapted from N. Jamin *et al.*, *Proc. Natl. Acad. Sci. USA* **95**, 4837 (1998).

13.17 Symmetry aspects of molecular vibrations

One of the most powerful ways of dealing with normal modes, especially of complex molecules, is to classify them according to their symmetries. Each normal mode must

belong to one of the symmetry species of the molecular point group, as discussed in Chapter 12.

Example 13.6 Identifying the symmetry species of a normal mode

Establish the symmetry species of the normal mode vibrations of CH_4 , which belongs to the group T_d .

Method The first step in the procedure is to identify the symmetry species of the irreducible representations spanned by all the $3N$ displacements of the atoms, using the characters of the molecular point group. Find these characters by counting 1 if the displacement is unchanged under a symmetry operation, -1 if it changes sign, and 0 if it is changed into some other displacement. Next, subtract the symmetry species of the translations. Translational displacements span the same symmetry species as x , y , and z , so they can be obtained from the right-most column of the character table. Finally, subtract the symmetry species of the rotations, which are also given in the character table (and denoted there by R_x , R_y , or R_z).

Answer There are $3 \times 5 = 15$ degrees of freedom, of which $(3 \times 5) - 6 = 9$ are vibrations. Refer to Fig. 13.50. Under E , no displacement coordinates are changed, so the character is 15. Under C_3 , no displacements are left unchanged, so the character is 0. Under the C_2 indicated, the z -displacement of the central atom is left unchanged, whereas its x - and y -components both change sign. Therefore $\chi(C_2) = 1 - 1 - 1 + 0 + 0 + \dots = -1$. Under the S_4 indicated, the z -displacement of the central atom is reversed, so $\chi(S_4) = -1$. Under σ_d , the x - and z -displacements of C, H₃, and H₄ are left unchanged and the y -displacements are reversed; hence $\chi(\sigma_d) = 3 + 3 - 3 = 3$. The characters are therefore 15, 0, -1 , -1 , 3. By decomposing the direct product (Section 12.5a), we find that this representation spans $A_1 + E + T_1 + 3T_2$. The translations span T_2 ; the rotations span T_1 . Hence, the nine vibrations span $A_1 + E + 2T_2$.

The modes themselves are shown in Fig. 13.51. We shall see that symmetry analysis gives a quick way of deciding which modes are active.

Self-test 13.8 Establish the symmetry species of the normal modes of H_2O .

$$[2A_1 + B_2]$$

(a) Infrared activity of normal modes

It is best to use group theory to judge the activities of more complex modes of vibration. This is easily done by checking the character table of the molecular point group for the symmetry species of the irreducible representations spanned by x , y , and z , for their species are also the symmetry species of the components of the electric dipole moment. Then apply the following rule:

If the symmetry species of a normal mode is the same as any of the symmetry species of x , y , or z , then the mode is infrared active.

Justification 13.6 Using group theory to identify infrared active normal modes

The rule hinges on the form of the transition dipole moment between the ground-state vibrational wavefunction, ψ_0 , and that of the first excited state, ψ_1 . The x -component is

Fig. 13.50 The atomic displacements of CH_4 and the symmetry elements used to calculate the characters.

Fig. 13.51 Typical normal modes of vibration of a tetrahedral molecule. There are in fact two modes of symmetry species E and three modes of each T_2 symmetry species.

$$\mu_{x,10} = -e \int \psi_1^* x \psi_0 d\tau \quad (13.70)$$

with similar expressions for the two other components of the transition moment. The ground-state vibrational wavefunction is a Gaussian function of the form e^{-x^2} , so it is symmetrical in x . The wavefunction for the first excited state gives a non-vanishing integral only if it is proportional to x , for then the integrand is proportional to x^2 rather than to xy or xz . Consequently, the excited state wavefunction must have the same symmetry as the displacement x .

Example 13.7 Identifying infrared active modes

Which modes of CH_4 are infrared active?

Method Refer to the T_d character table to establish the symmetry species of x , y , and z for this molecule, and then use the rule given above.

Answer The functions x , y , and z span T_2 . We found in Example 13.6 that the symmetry species of the normal modes are $A_1 + E + 2T_2$. Therefore, only the T_2 modes are infrared active. The distortions accompanying these modes lead to a changing dipole moment. The A_1 mode, which is inactive, is the symmetrical ‘breathing’ mode of the molecule.

Self-test 13.9 Which of the normal modes of H_2O are infrared active? [All three]

(b) Raman activity of normal modes

Group theory provides an explicit recipe for judging the Raman activity of a normal mode. In this case, the symmetry species of the quadratic forms (x^2 , xy , etc.) listed in the character table are noted (they transform in the same way as the polarizability), and then we use the following rule:

If the symmetry species of a normal mode is the same as the symmetry species of a quadratic form, then the mode is Raman active.

Illustration 13.6 Identifying Raman active modes

To decide which of the vibrations of CH_4 are Raman active, refer to the T_d character table. It was established in Example 13.6 that the symmetry species of the normal modes are $A_1 + E + 2T_2$. Because the quadratic forms span $A_1 + E + T_2$, all the normal modes are Raman active. By combining this information with that in Example 13.6, we see how the infrared and Raman spectra of CH_4 are assigned. The assignment of spectral features to the T_2 modes is straightforward because these are the only modes that are both infrared and Raman active. This leaves the A_1 and E modes to be assigned in the Raman spectrum. Measurement of the depolarization ratio distinguishes between these modes because the A_1 mode, being totally symmetric, is polarized and the E mode is depolarized.

Self-test 13.10 Which of the vibrational modes of H_2O are Raman active?

[All three]

Checklist of key ideas

- ☐ 1. Emission spectroscopy is based on the detection of a transition from a state of high energy to a state of lower energy; absorption spectroscopy is based on the detection of the net absorption of nearly monochromatic incident radiation as the radiation is swept over a range of frequencies.
- ☐ 2. In Raman spectroscopy molecular energy levels are explored by examining the frequencies present in scattered radiation. Stokes and anti-Stokes radiation are scattered radiation at a lower and higher frequency, respectively, than the incident radiation. Rayleigh radiation is the component of radiation scattered into the forward direction without change of frequency.
- ☐ 3. The Beer–Lambert law is $I(\tilde{\nu}) = I_0(\tilde{\nu})10^{-\epsilon(\tilde{\nu})[l]I}$, where $I(\tilde{\nu})$ is the transmitted intensity, $I_0(\tilde{\nu})$ is the incident intensity, and $\epsilon(\tilde{\nu})$ is the molar absorption coefficient.
- ☐ 4. The transmittance, $T = I/I_0$, and the absorbance, A , of a sample at a given wavenumber are related by $A = -\log T$.
- ☐ 5. The integrated absorption coefficient, $\mathcal{A}$, is the sum of the absorption coefficients over the entire band, $\mathcal{A} = \int_{\text{band}} \epsilon(\tilde{\nu}) d\tilde{\nu}$.
- ☐ 6. Stimulated absorption is the radiation-driven transition from a low energy state to one of higher energy. Stimulated emission is the radiation-driven transition from a high energy state to one of lower energy. Spontaneous emission is radiative emission independent of the intensity of the radiation (of any frequency) that is already present.
- ☐ 7. The natural linewidth of a spectral line is due to spontaneous emission. Spectral lines are affected by Doppler broadening, lifetime broadening, and collisional deactivation of excited states.
- ☐ 8. A rigid rotor is a body that does not distort under the stress of rotation. A spherical rotor is a rigid rotor with three equal moments of inertia. A symmetric rotor is a rigid rotor with two equal moments of inertia. A linear rotor is a rigid rotor with one moment of inertia equal to zero. An asymmetric rotor is a rigid rotor with three different moments of inertia.
- ☐ 9. The rotational terms of a spherical rotor are $F(J) = BJ(J+1)$ with $B = \hbar^2/4\pi cI$, $J = 0, 1, 2, \dots$, and are $(2J+1)^2$ -fold degenerate.
- ☐ 10. The principal axis (figure axis) is the unique axis of a symmetric top. In an oblate top, $I_{\parallel} > I_{\perp}$. In a prolate top, $I_{\parallel} < I_{\perp}$.
- ☐ 11. The rotational terms of a symmetric rotor are $F(J, K) = BJ(J+1) + (A-B)K^2$, $J = 0, 1, 2, \dots$, $K = 0, \pm 1, \dots, \pm J$.
- ☐ 12. The rotational terms of a linear rotor are $F(J) = BJ(J+1)$, $J = 0, 1, 2, \dots$ and are $(2J+1)$ -fold degenerate.
- ☐ 13. The centrifugal distortion constant, D_J , is the empirical constant in the expression $F(J) = BJ(J+1) - D_J J^2(J+1)^2$ that takes into account centrifugal distortion, $D_J \approx 4B^3/\tilde{\nu}^2$.
- ☐ 14. The gross rotational selection rule for microwave spectra is: for a molecule to give a pure rotational spectrum, it must be polar. The specific rotational selection rule is: $\Delta J = \pm 1$, $\Delta M_J = 0, \pm 1$, $\Delta K = 0$. The rotational wavenumbers in the absence and presence of centrifugal distortion are given by eqns 13.37 and 13.38, respectively.
- ☐ 15. The gross selection rule for rotational Raman spectra is: the molecule must be anisotropically polarizable. The specific selection rules are: (i) linear rotors, $\Delta J = 0, \pm 2$; (ii) symmetric rotors, $\Delta J = 0, \pm 1, \pm 2$; $\Delta K = 0$.
- ☐ 16. The appearance of rotational spectra is affected by nuclear statistics, the selective occupation of rotational states that stems from the Pauli principle.
- ☐ 17. The vibrational energy levels of a diatomic molecule modelled as a harmonic oscillator are $E_v = (v + \frac{1}{2})\hbar\omega$, $\omega = (k/m_{\text{eff}})^{1/2}$; the vibrational terms are $G(v) = (v + \frac{1}{2})\tilde{\nu}$, $\tilde{\nu} = (1/2\pi c)(k/m_{\text{eff}})^{1/2}$.
- ☐ 18. The gross selection rule for infrared spectra is: the electric dipole moment of the molecule must change when the atoms are displaced relative to one another. The specific selection rule is: $\Delta v = \pm 1$.
- ☐ 19. Morse potential energy, eqn 13.54, describes anharmonic motion, oscillatory motion in which the restoring force is not proportional to the displacement; the vibrational terms of a Morse oscillator are given by eqn 13.55.
- ☐ 20. A Birge–Sponer plot is a graphical procedure for determining the dissociation energy of a bond.
- ☐ 21. The P branch consists of vibration–rotation infrared transitions with $\Delta J = -1$; the Q branch has transitions with $\Delta J = 0$; the R branch has transitions with $\Delta J = +1$.
- ☐ 22. The gross selection rule for vibrational Raman spectra is: the polarizability must change as the molecule vibrates. The specific selection rule is: $\Delta v = \pm 1$.
- ☐ 23. A normal mode is an independent, synchronous motion of atoms or groups of atoms that may be excited without leading to the excitation of any other normal mode. The number of normal modes is $3N - 6$ (for nonlinear molecules) or $3N - 5$ (linear molecules).
- ☐ 24. A symmetric stretch is a symmetrically stretching vibrational mode. An antisymmetric stretch is a stretching mode, one half of which is the mirror image of the other half.
- ☐ 25. The exclusion rule states that, if the molecule has a centre of symmetry, then no modes can be both infrared and Raman active.
- ☐ 26. The depolarization ratio, ρ , the ratio of the intensities, I , of the scattered light with polarizations perpendicular and parallel to the plane of polarization of the incident radiation, $\rho = I_{\perp}/I_{\parallel}$. A depolarized line is a line with ρ close to or greater than 0.75. A polarized line is a line with $\rho < 0.75$.
- ☐ 27. Resonance Raman spectroscopy is a Raman technique in which the frequency of the incident radiation nearly coincides with the frequency of an electronic transition of the sample. Coherent anti-Stokes Raman spectroscopy (CARS) is a

Raman technique that relies on the use of two incident beams of radiation.

- 28. A normal mode is infrared active if its symmetry species is the same as any of the symmetry species of x , y , or z , then the

mode is infrared active. A normal mode is Raman active if its symmetry species is the same as the symmetry species of a quadratic form.

Further information

Further information 13.1 Spectrometers

Here we provide additional detail on the principles of operation of spectrometers, describing radiation sources, dispersing elements, detectors, and Fourier transform techniques.

Sources of radiation

Sources of radiation are either *monochromatic*, those spanning a very narrow range of frequencies around a central value, or *polychromatic*, those spanning a wide range of frequencies. Monochromatic sources that can be tuned over a range of frequencies include the *klystron* and the *Gunn diode*, which operate in the microwave range, and lasers, which are discussed in Chapter 14.

Polychromatic sources that take advantage of black-body radiation from hot materials. For far infrared radiation with $35\text{ cm}^{-1} < \tilde{\nu} < 200\text{ cm}^{-1}$, a typical source is a mercury arc inside a quartz envelope, most of the radiation being generated by the hot quartz. Either a *Nernst filament* or a *globar* is used as a source of mid-infrared radiation with $200\text{ cm}^{-1} < \tilde{\nu} < 4000\text{ cm}^{-1}$. The Nernst filament consists of a ceramic filament of lanthanoid oxides that is heated to temperatures ranging from 1200 to 2000 K. The globar consists of a rod of silicon carbide, which is heated electrically to about 1500 K.

A *quartz-tungsten-halogen lamp* consists of a tungsten filament that, when heated to about 3000 K, emits light in the range $320\text{ nm} < \lambda < 2500\text{ nm}$. Near the surface of the lamp's quartz envelope, iodine atoms and tungsten atoms ejected from the filament combine to make a variety of tungsten-iodine compounds that decompose at the hot filament, replenishing it with tungsten atoms.

A *gas discharge lamp* is a common source of ultraviolet and visible radiation. In a *xenon discharge lamp*, an electrical discharge excites xenon atoms to excited states, which then emit ultraviolet radiation. At pressures exceeding 1 kPa, the output consists of sharp lines on a broad, intense background due to emission from a mixture of ions formed by the electrical discharge. These high-pressure xenon lamps have emission profiles similar to that of a black body heated to 6000 K. In a *deuterium lamp*, excited D_2 molecules dissociate into electronically excited D atoms, which emit intense radiation between 200–400 nm.

For certain applications, synchrotron radiation is generated in a *synchrotron storage ring*, which consists of an electron beam travelling in a circular path with circumferences of up to several hundred metres. As electrons travelling in a circle are constantly accelerated by the forces that constrain them to their path, they generate radiation (Fig. 13.52). Synchrotron radiation spans a wide range of frequencies,

Fig. 13.52 A synchrotron storage ring. The electrons injected into the ring from the linear accelerator and booster synchrotron are accelerated to high speed in the main ring. An electron in a curved path is subject to constant acceleration, and an accelerated charge radiates electromagnetic energy.

including the infrared and X-rays. Except in the microwave region, synchrotron radiation is much more intense than can be obtained by most conventional sources.

The dispersing element

The dispersing element in most absorption spectrometers operating in the ultraviolet to near-infrared region of the spectrum is a **diffraction grating**, which consists of a glass or ceramic plate into which fine grooves have been cut and covered with a reflective aluminium coating. The grating causes interference between waves reflected from its surface, and constructive interference occurs when

$$n\lambda = d(\sin \theta - \sin \phi) \quad (13.71)$$

where $n = 1, 2, \dots$ is the *diffraction order*, λ is the wavelength of the diffracted radiation, d is the distance between grooves, θ is the angle of incidence of the beam, and ϕ is the angle of emergence of the beam (Fig. 13.53). For given values of n and θ , larger differences in ϕ are

Fig. 13.53 One common dispersing element is a diffraction grating, which separates wavelengths spatially as a result of the scattering of light by fine grooves cut into a coated piece of glass. When a polychromatic light beam strikes the surface at an angle θ , several light beams of different wavelengths emerge at different angles ϕ (eqn 13.71).

Fig. 13.54 A polychromatic beam is dispersed by a diffraction grating into three component wavelengths λ_1 , λ_2 , and λ_3 . In the configuration shown, only radiation with λ_2 passes through a narrow slit and reaches the detector. Rotating the diffraction grating as shown by the double arrows allows λ_1 or λ_3 to reach the detector.

observed for different wavelengths when d is similar to the wavelength of radiation being analysed. Wide angular separation results in wide spatial separation between wavelengths some distance away from the grating, where a detector is placed.

In a **monochromator**, a narrow exit slit allows only a narrow range of wavelengths to reach the detector (Fig. 13.54). Turning the grating around an axis perpendicular to the incident and diffracted beams allows different wavelengths to be analysed; in this way, the absorption spectrum is built up one narrow wavelength range at a time. Typically, the grating is swept through an angle that investigates only the first order of diffraction ($n = 1$). In a **polychromator**, there is no slit and a broad range of wavelengths can be analysed simultaneously by *array detectors*, such as those discussed below.

Fourier transform techniques

In a Fourier transform instrument, the diffraction grating is replaced by a Michelson interferometer, which works by splitting the beam from the sample into two and introducing a varying path difference, p , into one of them (Fig. 13.55). When the two components

Fig. 13.55 A Michelson interferometer. The beam-splitting element divides the incident beam into two beams with a path difference that depends on the location of the mirror M_1 . The compensator ensures that both beams pass through the same thickness of material.

Fig. 13.56 An interferogram produced as the path length p is changed in the interferometer shown in Fig. 13.55. Only a single frequency component is present in the signal, so the graph is a plot of the function $I(p) = I_0(1 + \cos 2\pi\tilde{\nu}p)$, where I_0 is the intensity of the radiation.

Exploration Referring to Fig. 13.55, the mirror M_1 moves in finite distance increments, so the path difference p is also incremented in finite steps. Explore the effect of increasing the step size on the shape of the interferogram for a monochromatic beam of wavenumber $\tilde{\nu}$ and intensity I_0 . That is, draw plots of $I(p)/I_0$ against $\tilde{\nu}p$, each with a different number of data points spanning the same total distance path taken by the movable mirror M_1 .

recombine, there is a phase difference between them, and they interfere either constructively or destructively depending on the difference in path lengths. The detected signal oscillates as the two components alternately come into and out of phase as the path difference is changed (Fig. 13.56). If the radiation has wavenumber $\tilde{\nu}$, the intensity of the detected signal due to radiation in the range of wavenumbers $\tilde{\nu}$ to $\tilde{\nu} + d\tilde{\nu}$, which we denote $I(p, \tilde{\nu})d\tilde{\nu}$, varies with p as

$$I(p, \tilde{\nu})d\tilde{\nu} = I(\tilde{\nu})(1 + \cos 2\pi\tilde{\nu}p)d\tilde{\nu} \quad (13.72)$$

Hence, the interferometer converts the presence of a particular wavenumber component in the signal into a variation in intensity of the radiation reaching the detector. An actual signal consists of radiation spanning a large number of wavenumbers, and the total intensity at the detector, which we write $I(p)$, is the sum of contributions from all the wavenumbers present in the signal (Fig. 13.57):

$$I(p) = \int_0^\infty I(p, \tilde{\nu})d\tilde{\nu} = \int_0^\infty I(\tilde{\nu})(1 + \cos 2\pi\tilde{\nu}p)d\tilde{\nu} \quad (13.73)$$

The problem is to find $I(\tilde{\nu})$, the variation of intensity with wavenumber, which is the spectrum we require, from the record of values of $I(p)$. This step is a standard technique of mathematics, and is the ‘Fourier transformation’ step from which this form of spectroscopy takes its name. Specifically:

Fig. 13.57 An interferogram obtained when several (in this case, three) frequencies are present in the radiation.

Exploration For a signal consisting of only a few monochromatic beams, the integral in eqn 13.73 can be replaced by a sum over the finite number of wavenumbers. Use this information to draw your own version of Fig. 13.57. Then, go on to explore the effect of varying the wavenumbers and intensities of the three components of the radiation on the shape of the interferogram.

$$I(\tilde{\nu}) = 4 \int_0^\infty \{I(p) - \frac{1}{2}I(0)\} \cos 2\pi\tilde{\nu}p dp \quad (13.74)$$

where $I(0)$ is given by eqn 13.73 with $p = 0$. This integration is carried out numerically in a computer connected to the spectrometer, and the output, $I(\tilde{\nu})$, is the transmission spectrum of the sample (Fig. 13.58).

Fig. 13.58 The three frequency components and their intensities that account for the appearance of the interferogram in Fig. 13.57. This spectrum is the Fourier transform of the interferogram, and is a depiction of the contributing frequencies.

Exploration Calculate the Fourier transforms of the functions you generated in the previous *Exploration*.

A major advantage of the Fourier transform procedure is that all the radiation emitted by the source is monitored continuously. This is in contrast to a spectrometer in which a monochromator discards most of the generated radiation. As a result, Fourier transform spectrometers have a higher sensitivity than conventional spectrometers.

Detectors

A **detector** is a device that converts radiation into an electric current or voltage for appropriate signal processing and display. Detectors may consist of a single radiation sensing element or of several small elements arranged in one or two-dimensional arrays.

A microwave detector is typically a *crystal diode* consisting of a tungsten tip in contact with a semiconductor. The most common detectors found in commercial infrared spectrometers are sensitive in the mid-infrared region. In a *photovoltaic device* the potential difference changes upon exposure to infrared radiation. In a *pyroelectric device* the capacitance is sensitive to temperature and hence the presence of infrared radiation.

A common detector for work in the ultraviolet and visible ranges is the *photomultiplier tube* (PMT), in which the photoelectric effect (Section 8.2a) is used to generate an electrical signal proportional to the intensity of light that strikes the detector. In a PMT, photons first strike the *photocathode*, usually a metallic surface to which a large negative potential is applied. Each electron ejected from the photocathode is accelerated by a potential difference to another metallic surface, called the *dynode*, from which more electrons are ejected. After travelling through a chain of dynodes, with each dynode at a more positive potential than the preceding dynode in the chain, all the ejected electrons are collected at a final metallic surface called the *anode*. Depending on how the detector is constructed, a PMT can produce up to 10^8 electrons per photon that strikes the photocathode. This sensitivity is important for the detection of light from weak sources, but can pose problems as well. At room temperature, a small number of electrons on the surfaces of the photocathode and dynodes have sufficient energy to be ejected even in the dark. When amplified through the dynode chain, these electrons give rise to a *dark current*, which interferes with measurements on the sample of interest. To minimize the dark current, it is common to lower the temperature of the PMT detector.

A common, but less sensitive, alternative to the PMT is the *photodiode*, a solid-state device that conducts electricity when struck by photons because light-induced electron transfer reactions in the detector material create mobile charge carriers (negatively charged electrons and positively charged ‘holes’). In an *avalanche photodiode*, the photo-generated electrons are accelerated through a very large electrical potential difference. The high-energy electrons then collide with other atoms in the solid and ionize them, thus creating an avalanche of secondary charge carriers and increasing the sensitivity of the device toward photons.

The *charge-coupled device* (CCD) is a two-dimensional array of several million small photodiode detectors. With a CCD, a wide range of wavelengths that emerge from a polychromator are detected simultaneously, thus eliminating the need to measure light intensity one narrow wavelength range at a time. CCD detectors are the imaging devices in digital cameras, but are also used widely in

spectroscopy to measure absorption, emission, and Raman scattering. In Raman microscopy, a CCD detector can be used in a variation of the technique known as *Raman imaging*: a special optical filter allows only one Stokes line to reach the two-dimensional detector, which then contains a map of the distribution of the intensity of that line in the illuminated area.

Resolution

A number of factors determine a spectrometer’s resolution, the smallest observable separation between two closely spaced spectral bands. We have already seen that the ability of a diffraction grating to disperse light depends on the distance between the grating’s grooves and on the wavelength of the incident radiation. Furthermore, the distance between the grating and the slit placed in front of a detector must be long enough and the slit’s width must be narrow enough so full advantage can be taken of the grating’s dispersing ability (Fig. 13.54). It follows that a bad choice of grating, slit width, and detector placement may result in the failure to distinguish between closely spaced lines or to measure the actual linewidth of any one band in the spectrum.

The resolution of Fourier transform spectrometers is determined by the maximum path length difference, $p_{\max}$, of the interferometer:

$$\Delta\tilde{\nu} = \frac{1}{2p_{\max}} \quad (13.75)$$

To achieve a resolution of 0.1 cm^{-1} requires a maximum path length difference of 5 cm.

Assuming that all instrumental factors have been optimized, the highest resolution is obtained when the sample is gaseous and at such low pressure that collisions between the molecules are infrequent (see Section 13.3b). In liquids and solids, the actual linewidths can be so broad that the sample itself can limit the resolution.

Further information 13.2 Selection rules for rotational and vibrational spectroscopy

Here we derive the gross and specific selection rules for microwave, infrared, and rotational and vibrational Raman spectroscopy. The starting point for our discussion is the total wavefunction for a molecule, which can be written as

$$\Psi_{\text{total}} = \psi_{\text{c.m.}} \psi$$

where $\psi_{\text{c.m.}}$ describes the motion of the centre of mass and ψ describes the internal motion of the molecule. If we neglect the effect of electron spin, the Born–Oppenheimer approximation allows us to write ψ as the product of an electronic part, $|\epsilon\rangle$, a vibrational part, $|v\rangle$, and a rotational part, which for a diatomic molecule can be represented by the spherical harmonics $Y_{J,M_J}(\theta,\phi)$ (Section 9.7). To simplify the form of the integrals that will soon follow, we are using the Dirac bracket notation introduced in *Further information 9.1*. The transition dipole moment for a spectroscopic transition can now be written as:

$$\mu_{fi} = \langle \epsilon_f v_f Y_{J_f, M_{J_f}} | \hat{\mu} | \epsilon_i v_i Y_{J_i, M_{J_i}} \rangle \quad (13.76)$$

and our task is to explore conditions for which this integral vanishes or has a non-zero value.

Microwave spectra

During a pure rotational transition the molecule does not change electronic or vibrational states, so that $\langle \varepsilon_f v_f | = \langle \varepsilon_i v_i | = \langle \varepsilon v |$ and we identify $\boldsymbol{\mu}_{\varepsilon v} = \langle \varepsilon v | \hat{\boldsymbol{\mu}} | \varepsilon v \rangle$ with the *permanent* electric dipole moment of the molecule in the state εv . Equation 13.76 becomes

$$\boldsymbol{\mu}_{fi} = \langle Y_{J_f, M_{J_f}} | \hat{\boldsymbol{\mu}}_{\varepsilon v} | Y_{J_i, M_{J_i}} \rangle$$

The electric dipole moment has components $\mu_{\varepsilon v, x}$, $\mu_{\varepsilon v, y}$, and $\mu_{\varepsilon v, z}$, which, in spherical polar coordinates, are written in terms of μ_0 , the magnitude of the vector, and the angles θ and ϕ as

$$\mu_{\varepsilon v, x} = \mu_0 \sin \theta \cos \phi \quad \mu_{\varepsilon v, y} = \mu_0 \sin \theta \sin \phi \quad \mu_{\varepsilon v, z} = \mu_0 \cos \theta$$

Here, we have taken the z -axis to be coincident with the figure axis. The transition dipole moment has three components, given by:

$$\mu_{fi, x} = \mu_0 \langle Y_{J_f, M_{J_f}} | \sin \theta \cos \phi | Y_{J_i, M_{J_i}} \rangle$$

$$\mu_{fi, y} = \mu_0 \langle Y_{J_f, M_{J_f}} | \sin \theta \sin \phi | Y_{J_i, M_{J_i}} \rangle$$

$$\mu_{fi, z} = \mu_0 \langle Y_{J_f, M_{J_f}} | \cos \theta | Y_{J_i, M_{J_i}} \rangle$$

We see immediately that the molecule must have a permanent dipole moment in order to have a microwave spectrum. This is the gross selection rule for microwave spectroscopy.

For the specific selection rules we need to examine the conditions for which the integrals do not vanish, and we must consider each component. For the z -component, we simplify the integral by using $\cos \theta \propto Y_{1,0}$ (Table 9.3). It follows that

$$\mu_{fi, z} \propto \langle Y_{J_f, M_{J_f}} | Y_{1,0} | Y_{J_i, M_{J_i}} \rangle$$

According to the properties of the spherical harmonics (Comment 13.8), this integral vanishes unless $J_f - J_i = \pm 1$ and $M_{J_f} - M_{J_i} = 0$. These are two of the selection rules stated in eqn 13.35.

Comment 13.8

An important ‘triple integral’ involving the spherical harmonics is

$$\int_0^\pi \int_0^{2\pi} Y_{l'', m''}(\theta, \phi) Y_{l', m'}(\theta, \phi) Y_{l, m}(\theta, \phi) \sin \theta d\theta d\phi = 0$$

unless $m'' = m'_i + m_i$ and lines of length l'' , l' , and l can form a triangle.

For the x - and y -components, we use $\cos \phi = \frac{1}{2}(e^{i\phi} + e^{-i\phi})$ and $\sin \phi = \frac{1}{2i}(e^{i\phi} - e^{-i\phi})$ to write $\sin \theta \cos \phi \propto Y_{1,1} + Y_{1,-1}$ and $\sin \theta \sin \phi \propto Y_{1,1} - Y_{1,-1}$. It follows that

$$\mu_{fi, x} \propto \langle Y_{J_f, M_{J_f}} | (Y_{1,1} + Y_{1,-1}) | Y_{J_i, M_{J_i}} \rangle$$

$$\mu_{fi, y} \propto \langle Y_{J_f, M_{J_f}} | (Y_{1,1} - Y_{1,-1}) | Y_{J_i, M_{J_i}} \rangle$$

According to the properties of the spherical harmonics, these integrals vanish unless $J_f - J_i = \pm 1$ and $M_{J_f} - M_{J_i} = \pm 1$. This completes the selection rules of eqn 13.35.

Rotational Raman spectra

We understand the origin of the gross and specific selection rules for rotational Raman spectroscopy by using a diatomic molecule as an example. The incident electric field of a wave of electromagnetic radiation of frequency ω_i induces a molecular dipole moment that is given by

$$\mu_{\text{ind}} = \alpha \mathcal{E}(t) = \alpha \mathcal{E} \cos \omega_i t$$

If the molecule is rotating at a circular frequency ω_R , to an external observer its polarizability is also time dependent (if it is anisotropic), and we can write

$$\alpha = \alpha_0 + \Delta\alpha \cos 2\omega_R t$$

where $\Delta\alpha = \alpha_{\parallel} - \alpha_{\perp}$ and α ranges from $\alpha_0 + \Delta\alpha$ to $\alpha_0 - \Delta\alpha$ as the molecule rotates. The 2 appears because the polarizability returns to its initial value twice each revolution (Fig. 13.59). Substituting this expression into the expression for the induced dipole moment gives

$$\begin{aligned} \mu_{\text{ind}} &= (\alpha_0 + \Delta\alpha \cos 2\omega_R t) \times (\mathcal{E} \cos \omega_i t) \\ &= \alpha_0 \mathcal{E} \cos \omega_i t + \mathcal{E} \Delta\alpha \cos 2\omega_R t \cos \omega_i t \\ &= \alpha_0 \mathcal{E} \cos \omega_i t + \frac{1}{2} \mathcal{E} \Delta\alpha \{ \cos(\omega_i + 2\omega_R)t + \cos(\omega_i - 2\omega_R)t \} \end{aligned}$$

This calculation shows that the induced dipole has a component oscillating at the incident frequency (which generates Rayleigh radiation), and that it also has two components at $\omega_i \pm 2\omega_R$, which give rise to the shifted Raman lines. These lines appear only if $\Delta\alpha \neq 0$; hence the polarizability must be anisotropic for there to be Raman lines. This is the gross selection rule for rotational Raman spectroscopy. We also see that the distortion induced in the molecule by the incident electric field returns to its initial value after a rotation of 180° (that is, twice a revolution). This is the origin of the specific selection rule $\Delta J = \pm 2$.

We now use a quantum mechanical formalism to understand the selection rules. First, we write the x -, y -, and z -components of the induced dipole moment as

$$\mu_{\text{ind}, x} = \mu_x \sin \theta \cos \phi \quad \mu_{\text{ind}, y} = \mu_y \sin \theta \sin \phi \quad \mu_{\text{ind}, z} = \mu_z \cos \theta$$

where μ_x , μ_y , and μ_z are the components of the electric dipole moment of the molecule and the z -axis is coincident with the molecular figure axis. The incident electric field also has components along the x -, y -, and z -axes:

$$\mathcal{E}_x = \mathcal{E} \sin \theta \cos \phi \quad \mathcal{E}_y = \mathcal{E} \sin \theta \sin \phi \quad \mathcal{E}_z = \mathcal{E} \cos \theta$$

Using eqn 13.40 and the preceding equations, it follows that

$$\begin{aligned} \mu_{\text{ind}} &= \alpha_{\perp} \mathcal{E}_x \sin \theta \cos \phi + \alpha_{\perp} \mathcal{E}_y \sin \theta \sin \phi + \alpha_{\parallel} \mathcal{E} \cos \theta \\ &= \alpha_{\perp} \mathcal{E} \sin^2 \theta + \alpha_{\parallel} \mathcal{E} \cos^2 \theta \end{aligned}$$

By using the spherical harmonic $Y_{2,0}(\theta, \phi) = (5/16\pi)^{1/2}(3 \cos^2 \theta - 1)$ and the relation $\sin^2 \theta = 1 - \cos^2 \theta$, it follows that:

$$\mu_{\text{ind}} = \left\{ \frac{1}{3} \alpha_{\parallel} + \frac{2}{3} \alpha_{\perp} + \frac{4}{3} \left(\frac{\pi}{5} \right)^{1/2} \Delta\alpha Y_{2,0}(\theta, \phi) \right\} \mathcal{E}$$

For a transition between two rotational states, we calculate the integral $\langle Y_{J_f, M_{J_f}} | \mu_{\text{ind}} | Y_{J_i, M_{J_i}} \rangle$, which has two components:

$$\left(\frac{1}{3} \alpha_{\parallel} + \frac{2}{3} \alpha_{\perp} \right) \langle Y_{J_f, M_{J_f}} | Y_{J_i, M_{J_i}} \rangle \quad \text{and} \quad \mathcal{E} \Delta\alpha \langle Y_{J_f, M_{J_f}} | Y_{2,0} Y_{J_i, M_{J_i}} \rangle$$

According to the properties of the spherical harmonics (Table 9.3), the first integral vanishes unless $J_f - J_i = 0$ and the second integral vanishes unless $J_f - J_i = \pm 2$ and $\Delta\alpha \neq 0$. These are the gross and specific selection rules for linear rotors.

Infrared spectra

The gross selection rule for infrared spectroscopy is based on an analysis of the transition dipole moment $\langle v_f | \hat{\boldsymbol{\mu}} | v_i \rangle$, which arises from eqn 13.76 when the molecule does not change electronic or rotational

Fig. 13.59 The distortion induced in a molecule by an applied electric field returns to its initial value after a rotation of only 180° (that is, twice a revolution). This is the origin of the $\Delta J = \pm 2$ selection rule in rotational Raman spectroscopy.

states. For simplicity, we shall consider a one-dimensional oscillator (like a diatomic molecule). The electric dipole moment operator depends on the location of all the electrons and all the nuclei in the molecule, so it varies as the internuclear separation changes

Fig. 13.60 The electric dipole moment of a heteronuclear diatomic molecule varies as shown by the purple curve. For small displacements the change in dipole moment is proportional to the displacement.

(Fig. 13.60). If we think of the dipole moment as arising from two partial charges $\pm\delta q$ separated by a distance $R = R_e + x$, we can write its variation with displacement from the equilibrium separation, x , as

$$\mu = R\delta q = R_e\delta q + x\delta q = \mu_0 + x\delta q$$

where μ_0 is the electric dipole moment operator when the nuclei have their equilibrium separation. It then follows that, with $f \neq i$,

$$\langle v_f | \hat{\mu} | v_i \rangle = \mu_0 \langle v_f | v_i \rangle + \delta q \langle v_f | x | v_i \rangle$$

The term proportional to μ_0 is zero because the states with different values of v are orthogonal. It follows that the transition dipole moment is

$$\langle v_f | \hat{\mu} | v_i \rangle = \langle v_f | x | v_i \rangle \delta q$$

Because

$$\delta q = \frac{d\mu}{dx}$$

we can write the transition dipole moment more generally as

$$\langle v_f | \hat{\mu} | v_i \rangle = \langle v_f | x | v_i \rangle \left(\frac{d\mu}{dx} \right)$$

and we see that the right-hand side is zero unless the dipole moment varies with displacement. This is the gross selection rule for infrared spectroscopy.

The specific selection rule is determined by considering the value of $\langle v_f | x | v_i \rangle$. We need to write out the wavefunctions in terms of the Hermite polynomials given in Section 9.5 and then to use their properties (Example 9.4 should be reviewed, for it gives further details of the calculation). We note that $x = \alpha y$ with $\alpha = (\hbar^2/m_{\text{eff}}k)^{1/4}$ (eqn 9.28; note that in this context α is not the polarizability). Then we write

$$\langle v_f | x | v_i \rangle = N_{v_f} N_{v_i} \int_{-\infty}^{\infty} H_{v_f} x H_{v_i} e^{-y^2} dx = \alpha^2 N_{v_f} N_{v_i} \int_{-\infty}^{\infty} H_{v_f} y H_{v_i} e^{-y^2} dy$$

To evaluate the integral we use the recursion relation

$$yH_v = vH_{v-1} + \frac{1}{2}H_{v+1}$$

which turns the matrix element into

$$\langle v_f | x | v_i \rangle = \alpha^2 N_{v_f} N_{v_i} \left\{ v_i \int_{-\infty}^{\infty} H_{v_f} H_{v_i-1} e^{-y^2} dy + \frac{1}{2} \int_{-\infty}^{\infty} H_{v_f} H_{v_i+1} e^{-y^2} dy \right\}$$

The first integral is zero unless $v_f = v_i - 1$ and that the second is zero unless $v_f = v_i + 1$. It follows that the transition dipole moment is zero unless $\Delta v = \pm 1$.

Comment 13.9

An important integral involving Hermite polynomials is

$$\int_{-\infty}^{\infty} H_v H_{v'} e^{-y^2} dy = \begin{cases} 0 & \text{if } v' \neq v \\ \pi^{1/2} 2^v v! & \text{if } v' = v \end{cases}$$

Vibrational Raman spectra

The gross selection rule for vibrational Raman spectroscopy is based on an analysis of the transition dipole moment $\langle \epsilon v_f | \hat{\mu} | \epsilon v_i \rangle$, which is written from eqn 13.76 by using the Born–Oppenheimer

approximation and neglecting the effect of rotation and electron spin. For simplicity, we consider a one-dimensional harmonic oscillator (like a diatomic molecule).

First, we use eqn 13.40 to write the transition dipole moment as

$$\mu_{fi} = \langle \epsilon v_f | \hat{\mu} | \epsilon v_i \rangle = \langle \epsilon v_f | \alpha | \epsilon v_i \rangle \mathcal{E} = \langle v_f | \alpha(x) | v_i \rangle \mathcal{E}$$

where $\alpha(x) = \langle \epsilon | \alpha | \epsilon \rangle$ is the polarizability of the molecule, which we expect to be a function of small displacements x from the equilibrium bond length of the molecule (Section 13.13). Next, we expand $\alpha(x)$ as a Taylor series, so the transition dipole moment becomes

$$\begin{aligned} \mu_{fi} &= \left\langle v_f \left| \alpha(0) + \left(\frac{d\alpha}{dx} \right)_0 x + \cdots \right| v_i \right\rangle \mathcal{E} \\ &= \langle v_f | v_i \rangle \alpha(0) \mathcal{E} + \left(\frac{d\alpha}{dx} \right)_0 \langle v_f | x | v_i \rangle \mathcal{E} + \cdots \end{aligned}$$

The term containing $\langle v_f | v_i \rangle$ vanishes for $f \neq i$ because the harmonic oscillator wavefunctions are orthogonal. Therefore, the vibration is Raman active if $(d\alpha/dx)_0 \neq 0$ and $\langle v_f | x | v_i \rangle \neq 0$. Therefore, the polarizability of the molecule must change during the vibration; this is the gross selection rule of Raman spectroscopy. Also, we already know that $\langle v_f | x | v_i \rangle \neq 0$ if $v_f - v_i = \pm 1$; this is the specific selection rule of Raman spectroscopy.

Discussion questions

13.1 Describe the physical origins of linewidths in the absorption and emission spectra of gases, liquids, and solids.

13.2 Discuss the physical origins of the gross selection rules for microwave and infrared spectroscopy.

13.3 Discuss the physical origins of the gross selection rules for rotational and vibrational Raman spectroscopy.

13.4 Consider a diatomic molecule that is highly susceptible to centrifugal distortion in its ground vibrational state. Do you expect excitation to high rotational energy levels to change the equilibrium bond length of this molecule? Justify your answer.

13.5 Suppose that you wish to characterize the normal modes of benzene in the gas phase. Why is it important to obtain both infrared absorption and Raman spectra of your sample?

Exercises

13.1a Calculate the ratio of the Einstein coefficients of spontaneous and stimulated emission, A and B , for transitions with the following characteristics: (a) 70.8 pm X-rays, (b) 500 nm visible light, (c) 3000 cm^{-1} infrared radiation.

13.1b Calculate the ratio of the Einstein coefficients of spontaneous and stimulated emission, A and B , for transitions with the following characteristics: (a) 500 MHz radiofrequency radiation, (e) 3.0 cm microwave radiation.

13.2a What is the Doppler-shifted wavelength of a red (660 nm) traffic light approached at 80 km h^{-1} ?

13.2b At what speed of approach would a red (660 nm) traffic light appear green (520 nm)?

13.3a Estimate the lifetime of a state that gives rise to a line of width (a) 0.10 cm^{-1} , (b) 1.0 cm^{-1} .

13.3b Estimate the lifetime of a state that gives rise to a line of width (a) 100 MHz, (b) 2.14 cm^{-1} .

13.4a A molecule in a liquid undergoes about 1.0×10^{13} collisions in each second. Suppose that (a) every collision is effective in deactivating the

molecule vibrationally and (b) that one collision in 100 is effective. Calculate the width (in cm^{-1}) of vibrational transitions in the molecule.

13.4b A molecule in a gas undergoes about 1.0×10^9 collisions in each second. Suppose that (a) every collision is effective in deactivating the molecule rotationally and (b) that one collision in 10 is effective. Calculate the width (in hertz) of rotational transitions in the molecule.

13.5a Calculate the frequency of the $J = 4 \leftarrow 3$ transition in the pure rotational spectrum of $^{14}\text{N}^{16}\text{O}$. The equilibrium bond length is 115 pm.

13.5b Calculate the frequency of the $J = 3 \leftarrow 2$ transition in the pure rotational spectrum of $^{12}\text{C}^{16}\text{O}$. The equilibrium bond length is 112.81 pm.

13.6a If the wavenumber of the $J = 3 \leftarrow 2$ rotational transition of $^1\text{H}^{35}\text{Cl}$ considered as a rigid rotator is 63.56 cm^{-1} , what is (a) the moment of inertia of the molecule, (b) the bond length?

13.6b If the wavenumber of the $J = 1 \leftarrow 0$ rotational transition of $^1\text{H}^{81}\text{Br}$ considered as a rigid rotator is 16.93 cm^{-1} , what is (a) the moment of inertia of the molecule, (b) the bond length?

13.7a Given that the spacing of lines in the microwave spectrum of $^{27}\text{Al}^1\text{H}$ is constant at 12.604 cm^{-1} , calculate the moment of inertia and bond length of the molecule ($m(^{27}\text{Al}) = 26.9815\text{ u}$).

13.7b Given that the spacing of lines in the microwave spectrum of $^{35}\text{Cl}^{19}\text{F}$ is constant at 1.033 cm^{-1} , calculate the moment of inertia and bond length of the molecule ($m(^{35}\text{Cl}) = 34.9688\text{ u}$, $m(^{19}\text{F}) = 18.9984\text{ u}$).

13.8a The rotational constant of $^{127}\text{I}^{35}\text{Cl}$ is 0.1142 cm^{-1} . Calculate the ICl bond length ($m(^{35}\text{Cl}) = 34.9688\text{ u}$, $m(^{127}\text{I}) = 126.9045\text{ u}$).

13.8b The rotational constant of $^{12}\text{C}^{16}\text{O}_2$ is 0.39021 cm^{-1} . Calculate the bond length of the molecule ($m(^{12}\text{C}) = 12\text{ u}$ exactly, $m(^{16}\text{O}) = 15.9949\text{ u}$).

13.9a Determine the HC and CN bond lengths in HCN from the rotational constants $B(^1\text{H}^{12}\text{C}^{14}\text{N}) = 44.316\text{ GHz}$ and $B(^2\text{H}^{12}\text{C}^{14}\text{N}) = 36.208\text{ GHz}$.

13.9b Determine the CO and CS bond lengths in OCS from the rotational constants $B(^{16}\text{O}^{12}\text{C}^{32}\text{S}) = 6081.5\text{ MHz}$, $B(^{16}\text{O}^{12}\text{C}^{34}\text{S}) = 5932.8\text{ MHz}$.

13.10a The wavenumber of the incident radiation in a Raman spectrometer is $20\,487\text{ cm}^{-1}$. What is the wavenumber of the scattered Stokes radiation for the $J = 2 \leftarrow 0$ transition of $^{14}\text{N}_2$?

13.10b The wavenumber of the incident radiation in a Raman spectrometer is $20\,623\text{ cm}^{-1}$. What is the wavenumber of the scattered Stokes radiation for the $J = 4 \leftarrow 2$ transition of $^{16}\text{O}_2$?

13.11a The rotational Raman spectrum of $^{35}\text{Cl}_2$ ($m(^{35}\text{Cl}) = 34.9688\text{ u}$) shows a series of Stokes lines separated by 0.9752 cm^{-1} and a similar series of anti-Stokes lines. Calculate the bond length of the molecule.

13.11b The rotational Raman spectrum of $^{19}\text{F}_2$ ($m(^{19}\text{F}) = 18.9984\text{ u}$) shows a series of Stokes lines separated by 3.5312 cm^{-1} and a similar series of anti-Stokes lines. Calculate the bond length of the molecule.

13.12a Which of the following molecules may show a pure rotational microwave absorption spectrum: (a) H_2 , (b) HCl , (c) CH_4 , (d) CH_3Cl , (e) CH_2Cl_2 ?

13.12b Which of the following molecules may show a pure rotational microwave absorption spectrum: (a) H_2O , (b) H_2O_2 , (c) NH_3 , (d) N_2O ?

13.13a Which of the following molecules may show a pure rotational Raman spectrum: (a) H_2 , (b) HCl , (c) CH_4 , (d) CH_3Cl ?

13.13b Which of the following molecules may show a pure rotational Raman spectrum: (a) CH_2Cl_2 , (b) CH_3CH_3 , (c) SF_6 , (d) N_2O ?

13.14a An object of mass 1.0 kg suspended from the end of a rubber band has a vibrational frequency of 2.0 Hz . Calculate the force constant of the rubber band.

13.14b An object of mass 2.0 g suspended from the end of a spring has a vibrational frequency of 3.0 Hz . Calculate the force constant of the spring.

13.15a Calculate the percentage difference in the fundamental vibration wavenumber of $^{23}\text{Na}^{35}\text{Cl}$ and $^{23}\text{Na}^{37}\text{Cl}$ on the assumption that their force constants are the same.

13.15b Calculate the percentage difference in the fundamental vibration wavenumber of $^1\text{H}^{35}\text{Cl}$ and $^2\text{H}^{37}\text{Cl}$ on the assumption that their force constants are the same.

13.16a The wavenumber of the fundamental vibrational transition of $^{35}\text{Cl}_2$ is 564.9 cm^{-1} . Calculate the force constant of the bond ($m(^{35}\text{Cl}) = 34.9688\text{ u}$).

13.16b The wavenumber of the fundamental vibrational transition of $^{79}\text{Br}^{81}\text{Br}$ is 323.2 cm^{-1} . Calculate the force constant of the bond ($m(^{79}\text{Br}) = 78.9183\text{ u}$, $m(^{81}\text{Br}) = 80.9163\text{ u}$).

13.17a Calculate the relative numbers of Cl_2 molecules ($\bar{\nu} = 559.7\text{ cm}^{-1}$) in the ground and first excited vibrational states at (a) 298 K , (b) 500 K .

13.17b Calculate the relative numbers of Br_2 molecules ($\bar{\nu} = 321\text{ cm}^{-1}$) in the second and first excited vibrational states at (a) 298 K , (b) 800 K .

13.18a The hydrogen halides have the following fundamental vibrational wavenumbers: 4141.3 cm^{-1} (HF); 2988.9 cm^{-1} (H^{35}Cl); 2649.7 cm^{-1} (H^{81}Br); 2309.5 cm^{-1} (H^{127}I). Calculate the force constants of the hydrogen-halogen bonds.

13.18b From the data in Exercise 13.18a, predict the fundamental vibrational wavenumbers of the deuterium halides.

13.19a For $^{16}\text{O}_2$, ΔG values for the transitions $\nu = 1 \leftarrow 0$, $2 \leftarrow 0$, and $3 \leftarrow 0$ are, respectively, 1556.22 , 3088.28 , and 4596.21 cm^{-1} . Calculate $\bar{\nu}$ and x_e . Assume y_e to be zero.

13.19b For $^{14}\text{N}_2$, ΔG values for the transitions $\nu = 1 \leftarrow 0$, $2 \leftarrow 0$, and $3 \leftarrow 0$ are, respectively, 2345.15 , 4661.40 , and 6983.73 cm^{-1} . Calculate $\bar{\nu}$ and x_e . Assume y_e to be zero.

13.20a The first five vibrational energy levels of HCl are at 1481.86 , 4367.50 , 7149.04 , 9826.48 , and $12\,399.8\text{ cm}^{-1}$. Calculate the dissociation energy of the molecule in reciprocal centimetres and electronvolts.

13.20b The first five vibrational energy levels of HI are at 1144.83 , 3374.90 , 5525.51 , 7596.66 , and 9588.35 cm^{-1} . Calculate the dissociation energy of the molecule in reciprocal centimetres and electronvolts.

13.21a Infrared absorption by $^1\text{H}^{81}\text{Br}$ gives rise to an R branch from $\nu = 0$. What is the wavenumber of the line originating from the rotational state with $J = 2$? Use the information in Table 13.2.

13.21b Infrared absorption by $^1\text{H}^{127}\text{I}$ gives rise to an R branch from $\nu = 0$. What is the wavenumber of the line originating from the rotational state with $J = 2$? Use the information in Table 13.2.

13.22a Which of the following molecules may show infrared absorption spectra: (a) H_2 , (b) HCl , (c) CO_2 , (d) H_2O ?

13.22b Which of the following molecules may show infrared absorption spectra: (a) CH_3CH_3 , (b) CH_4 , (c) CH_3Cl , (d) N_2 ?

13.23a How many normal modes of vibration are there for the following molecules: (a) H_2O , (b) H_2O_2 , (c) C_2H_4 ?

13.23b How many normal modes of vibration are there for the following molecules: (a) C_6H_6 , (b) $\text{C}_6\text{H}_5\text{CH}_3$, (c) $\text{HC}\equiv\text{C}-\text{C}\equiv\text{CH}$.

13.24a Which of the three vibrations of an AB_2 molecule are infrared or Raman active when it is (a) angular, (b) linear?

13.24b Which of the vibrations of an AB_3 molecule are infrared or Raman active when it is (a) trigonal planar, (b) trigonal pyramidal?

13.25a Consider the vibrational mode that corresponds to the uniform expansion of the benzene ring. Is it (a) Raman, (b) infrared active?

13.25b Consider the vibrational mode that corresponds to the boat-like bending of a benzene ring. Is it (a) Raman, (b) infrared active?

13.26a The molecule CH_2Cl_2 belongs to the point group C_{2v} . The displacements of the atoms span $5\text{A}_1 + 2\text{A}_2 + 4\text{B}_1 + 4\text{B}_2$. What are the symmetries of the normal modes of vibration?

13.26b A carbon disulfide molecule belongs to the point group $D_{\infty h}$. The nine displacements of the three atoms span $\text{A}_{1g} + \text{A}_{1u} + \text{A}_{2g} + 2\text{E}_{1u} + \text{E}_{1g}$. What are the symmetries of the normal modes of vibration?

Problems*

Numerical problems

13.1 Use mathematical software to evaluate the Planck distribution at any temperature and wavelength or frequency, and evaluate integrals for the energy density of the radiation between any two wavelengths. Calculate the total energy density in the visible region (700 nm to 400 nm) for a black body at (a) 1500 K, a typical operating temperature for globars, (b) 2500 K, a typical operating temperature for tungsten filament lamps, (c) 5800 K, the surface temperature of the Sun. What are the classical values at these temperatures?

13.2 Calculate the Doppler width (as a fraction of the transition wavelength) for any kind of transition in (a) HCl, (b) ICl at 25°C. What would be the widths of the rotational and vibrational transitions in these molecules (in MHz and cm^{-1} , respectively), given $B(\text{ICl}) = 0.1142 \text{ cm}^{-1}$ and $\tilde{\nu}(\text{ICl}) = 384 \text{ cm}^{-1}$ and additional information in Table 13.2.

13.3 The collision frequency z of a molecule of mass m in a gas at a pressure p is $z = 4\sigma(kT/\pi m)^{1/2}p/kT$, where σ is the collision cross-section. Find an expression for the collision-limited lifetime of an excited state assuming that every collision is effective. Estimate the width of rotational transition in HCl ($\sigma = 0.30 \text{ nm}^2$) at 25°C and 1.0 atm. To what value must the pressure of the gas be reduced in order to ensure that collision broadening is less important than Doppler broadening?

13.4 The rotational constant of NH_3 is equivalent to 298 GHz. Compute the separation of the pure rotational spectrum lines in GHz, cm^{-1} , and mm, and show that the value of B is consistent with an N—H bond length of 101.4 pm and a bond angle of 106.78° .

13.5 The rotational constant for CO is 1.9314 cm^{-1} and 1.6116 cm^{-1} in the ground and first excited vibrational states, respectively. By how much does the internuclear distance change as a result of this transition?

13.6 Pure rotational Raman spectra of gaseous C_6H_6 and C_6D_6 yield the following rotational constants: $B(\text{C}_6\text{H}_6) = 0.18960 \text{ cm}^{-1}$, $B(\text{C}_6\text{D}_6) = 0.15681 \text{ cm}^{-1}$. The moments of inertia of the molecules about any axis perpendicular to the C_6 axis were calculated from these data as $I(\text{C}_6\text{H}_6) = 1.4759 \times 10^{-45} \text{ kg m}^2$, $I(\text{C}_6\text{D}_6) = 1.7845 \times 10^{-45} \text{ kg m}^2$. Calculate the CC, CH, and CD bond lengths.

13.7 Rotational absorption lines from $^1\text{H}^{35}\text{Cl}$ gas were found at the following wavenumbers (R.L. Hausler and R.A. Oetjen, *J. Chem. Phys.* **21**, 1340 (1953)): 83.32, 104.13, 124.73, 145.37, 165.89, 186.23, 206.60, 226.86 cm^{-1} . Calculate the moment of inertia and the bond length of the molecule. Predict the positions of the corresponding lines in $^2\text{H}^{35}\text{Cl}$.

13.8 Is the bond length in HCl the same as that in DCl? The wavenumbers of the $J = 1 \leftarrow 0$ rotational transitions for H^{35}Cl and $^2\text{H}^{35}\text{Cl}$ are 20.8784 and 10.7840 cm^{-1} , respectively. Accurate atomic masses are 1.007825 u and 2.0140 u for ^1H and ^2H , respectively. The mass of ^{35}Cl is 34.96885 u . Based on this information alone, can you conclude that the bond lengths are the same or different in the two molecules?

13.9 Thermodynamic considerations suggest that the copper monohalides CuX should exist mainly as polymers in the gas phase, and indeed it proved difficult to obtain the monomers in sufficient abundance to detect spectroscopically. This problem was overcome by flowing the halogen gas over copper heated to 1100 K (E.L. Manson, F.C. de Lucia, and W. Gordy, *J. Chem. Phys.* **63**, 2724 (1975)). For CuBr the $J = 13\text{--}14$, $14\text{--}15$, and $15\text{--}16$ transitions

occurred at 84 421.34, 90 449.25, and 96 476.72 MHz, respectively. Calculate the rotational constant and bond length of CuBr .

13.10 The microwave spectrum of $^{16}\text{O}^{12}\text{CS}$ (C.H. Townes, A.N. Holden, and F.R. Merritt, *Phys. Rev.* **74**, 1113 (1948)) gave absorption lines (in GHz) as follows:

J	1	2	3	4
^{32}S	24.325 92	36.488 82	48.651 64	60.814 08
^{34}S	23.732 33		47.462 40	

Use the expressions for moments of inertia in Table 13.1 and assume that the bond lengths are unchanged by substitution; calculate the CO and CS bond lengths in OCS.

13.11† In a study of the rotational spectrum of the linear FeCO radical, K. Tanaka, M. Shirasaka, and T. Tanaka (*J. Chem. Phys.* **106**, 6820 (1997)) report the following $J + 1 \leftarrow J$ transitions:

J	24	25	26	27	28	29
$\tilde{\nu}/\text{m}^{-1}$	214 777.7	223 379.0	231 981.2	240 584.4	249 188.5	257 793.5

Evaluate the rotational constant of the molecule. Also, estimate the value of J for the most highly populated rotational energy level at 298 K and at 100 K.

13.12 The vibrational energy levels of NaI lie at the wavenumbers 142.81, 427.31, 710.31, and 991.81 cm^{-1} . Show that they fit the expression $(v + \frac{1}{2})\tilde{\nu} - (v + \frac{1}{2})^2 x\tilde{\nu}$, and deduce the force constant, zero-point energy, and dissociation energy of the molecule.

13.13 Predict the shape of the nitronium ion, NO_2^+ , from its Lewis structure and the VSEPR model. It has one Raman active vibrational mode at 1400 cm^{-1} , two strong IR active modes at 2360 and 540 cm^{-1} , and one weak IR mode at 3735 cm^{-1} . Are these data consistent with the predicted shape of the molecule? Assign the vibrational wavenumbers to the modes from which they arise.

13.14 At low resolution, the strongest absorption band in the infrared absorption spectrum of $^{12}\text{C}^{16}\text{O}$ is centred at 2150 cm^{-1} . Upon closer examination at higher resolution, this band is observed to be split into two sets of closely spaced peaks, one on each side of the centre of the spectrum at 2143.26 cm^{-1} . The separation between the peaks immediately to the right and left of the centre is 7.655 cm^{-1} . Make the harmonic oscillator and rigid rotor approximations and calculate from these data: (a) the vibrational wavenumber of a CO molecule, (b) its molar zero-point vibrational energy, (c) the force constant of the CO bond, (d) the rotational constant B , and (e) the bond length of CO.

13.15 The HCl molecule is quite well described by the Morse potential with $D_e = 5.33 \text{ eV}$, $\tilde{\nu} = 2989.7 \text{ cm}^{-1}$, and $x\tilde{\nu} = 52.05 \text{ cm}^{-1}$. Assuming that the potential is unchanged on deuteration, predict the dissociation energies (D_0) of (a) HCl, (b) DCl.

13.16 The Morse potential (eqn 13.54) is very useful as a simple representation of the actual molecular potential energy. When RbH was studied, it was found that $\tilde{\nu} = 936.8 \text{ cm}^{-1}$ and $x\tilde{\nu} = 14.15 \text{ cm}^{-1}$. Plot the potential energy curve from 50 pm to 800 pm around $R_e = 236.7 \text{ pm}$. Then go on to explore how the rotation of a molecule may weaken its bond by allowing for the kinetic energy of rotation of a molecule and plotting $V^* = V + hcBJ(J+1)$ with $B = \hbar/4\pi c\mu R^2$. Plot these curves on the same diagram for $J = 40, 80$, and 100, and observe how the dissociation energy is affected by the

* Problems denoted with the symbol † were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

rotation. (Taking $B = 3.020 \text{ cm}^{-1}$ at the equilibrium bond length will greatly simplify the calculation.)

13.17‡ F. Luo, G.C. McBane, G. Kim, C.F. Giese, and W.R. Gentry (*J. Chem. Phys.* **98**, 3564 (1993)) reported experimental observation of the He_2 complex, a species that had escaped detection for a long time. The fact that the observation required temperatures in the neighbourhood of 1 mK is consistent with computational studies that suggest that hcD_e for He_2 is about $1.51 \times 10^{-23} \text{ J}$, hcD_0 about $2 \times 10^{-26} \text{ J}$, and R_e about 297 pm. (a) Estimate the fundamental vibrational wavenumber, force constant, moment of inertia, and rotational constant based on the harmonic oscillator and rigid-rotor approximations. (b) Such a weakly bound complex is hardly likely to be rigid. Estimate the vibrational wavenumber and anharmonicity constant based on the Morse potential.

13.18 As mentioned in Section 13.15, the semi-empirical, *ab initio*, and DFT methods discussed in Chapter 11 can be used to estimate the force field of a molecule. The molecule's vibrational spectrum can be simulated, and it is then possible to determine the correspondence between a vibrational frequency and the atomic displacements that give rise to a normal mode. (a) Using molecular modelling software³ and the computational method of your choice (semi-empirical, *ab initio*, or DFT methods), calculate the fundamental vibrational wavenumbers and visualize the vibrational normal modes of SO_2 in the gas phase. (b) The experimental values of the fundamental vibrational wavenumbers of SO_2 in the gas phase are 525 cm^{-1} , 1151 cm^{-1} , and 1336 cm^{-1} . Compare the calculated and experimental values. Even if agreement is poor, is it possible to establish a correlation between an experimental value of the vibrational wavenumber with a specific vibrational normal mode?

13.19 Consider the molecule CH_3Cl . (a) To what point group does the molecule belong? (b) How many normal modes of vibration does the molecule have? (c) What are the symmetries of the normal modes of vibration for this molecule? (d) Which of the vibrational modes of this molecule are infrared active? (e) Which of the vibrational modes of this molecule are Raman active?

13.20 Suppose that three conformations are proposed for the nonlinear molecule H_2O_2 (2, 3, and 4). The infrared absorption spectrum of gaseous H_2O_2 has bands at 870 , 1370 , 2869 , and 3417 cm^{-1} . The Raman spectrum of the same sample has bands at 877 , 1408 , 1435 , and 3407 cm^{-1} . All bands correspond to fundamental vibrational wavenumbers and you may assume that: (i) the 870 and 877 cm^{-1} bands arise from the same normal mode, and (ii) the 3417 and 3407 cm^{-1} bands arise from the same normal mode. (a) If H_2O_2 were linear, how many normal modes of vibration would it have? (b) Give the symmetry point group of each of the three proposed conformations of nonlinear H_2O_2 . (c) Determine which of the proposed conformations is inconsistent with the spectroscopic data. Explain your reasoning.

Theoretical problems

13.21 Show that the moment of inertia of a diatomic molecule composed of atoms of masses m_A and m_B and bond length R is equal to $m_{\text{eff}}R^2$, where $m_{\text{eff}} = m_A m_B / (m_A + m_B)$.

13.22 Derive eqn 13.34 for the centrifugal distortion constant D_J of a diatomic molecule of effective mass m_{eff} . Treat the bond as an elastic spring

with force constant k and equilibrium length r_e that is subjected to a centrifugal distortion to a new length r_c . Begin the derivation by letting the particles experience a restoring force of magnitude $k(r_c - r_e)$ that is countered perfectly by a centrifugal force $m_{\text{eff}}\omega^2 r_c$, where ω is the angular velocity of the rotating molecule. Then introduce quantum mechanical effects by writing the angular momentum as $\{J(J+1)\}^{1/2}\hbar$. Finally, write an expression for the energy of the rotating molecule, compare it with eqn 13.33, and write an expression for D_J . For help with the classical aspects of this derivation, see Appendix 3.

13.23 In the group theoretical language developed in Chapter 12, a spherical rotor is a molecule that belongs to a cubic or icosahedral point group, a symmetric rotor is a molecule with at least a threefold axis of symmetry, and an asymmetric rotor is a molecule without a threefold (or higher) axis. Linear molecules are linear rotors. Classify each of the following molecules as a spherical, symmetric, linear, or asymmetric rotor and justify your answers with group theoretical arguments: (a) CH_4 , (b) CH_3CN , (c) CO_2 , (d) CH_3OH , (e) benzene, (f) pyridine.

13.24 Derive an expression for the value of J corresponding to the most highly populated rotational energy level of a diatomic rotor at a temperature T remembering that the degeneracy of each level is $2J+1$. Evaluate the expression for ICl (for which $B = 0.1142 \text{ cm}^{-1}$) at 25°C . Repeat the problem for the most highly populated level of a spherical rotor, taking note of the fact that each level is $(2J+1)^2$ -fold degenerate. Evaluate the expression for CH_4 (for which $B = 5.24 \text{ cm}^{-1}$) at 25°C .

13.25 The moments of inertia of the linear mercury(II) halides are very large, so the O and S branches of their vibrational Raman spectra show little rotational structure. Nevertheless, the peaks of both branches can be identified and have been used to measure the rotational constants of the molecules (R.J.H. Clark and D.M. Rippon, *J. Chem. Soc. Faraday Soc. II*, **69**, 1496 (1973)). Show, from a knowledge of the value of J corresponding to the intensity maximum, that the separation of the peaks of the O and S branches is given by the Placzek–Teller relation $\delta\tilde{\nu} = (32BkT/hc)^{1/2}$. The following widths were obtained at the temperatures stated:

	HgCl_2	HgBr_2	HgI_2
$\theta/^\circ\text{C}$	282	292	292
$\delta\tilde{\nu}/\text{cm}^{-1}$	23.8	15.2	11.4

Calculate the bond lengths in the three molecules.

13.26 Confirm that a Morse oscillator has a finite number of bound states, the states with $V < hcD_e$. Determine the value of v_{max} for the highest bound state.

Applications: to biology, environmental science, and astrophysics

13.27 The protein haemerythrin is responsible for binding and carrying O_2 in some invertebrates. Each protein molecule has two Fe^{2+} ions that are in very close proximity and work together to bind one molecule of O_2 . The Fe_2O_2 group of oxygenated haemerythrin is coloured and has an electronic absorption band at 500 nm . The resonance Raman spectrum of oxygenated haemerythrin obtained with laser excitation at 500 nm has a band at 844 cm^{-1} that has been attributed to the O–O stretching mode of bound $^{16}\text{O}_2$. (a) Why is resonance Raman spectroscopy and not infrared spectroscopy the method of choice for the study of the binding of O_2 to haemerythrin? (b) Proof that the 844 cm^{-1} band arises from a bound O_2 species may be obtained by conducting experiments on samples of haemerythrin that have been mixed with $^{18}\text{O}_2$, instead of $^{16}\text{O}_2$. Predict the fundamental vibrational wavenumber of the ^{18}O – ^{18}O stretching mode in a sample of haemerythrin that has been treated with $^{18}\text{O}_2$. (c) The fundamental vibrational wavenumbers for the

³ The web site contains links to molecular modelling freeware and to other sites where you may perform molecular orbital calculations directly from your web browser.

O—O stretching modes of O_2 , O_2^- (superoxide anion), and O_2^{2-} (peroxide anion) are 1555, 1107, and 878 cm^{-1} , respectively. Explain this trend in terms of the electronic structures of O_2 , O_2^- , and O_2^{2-} . *Hint:* Review Section 11.4. What are the bond orders of O_2 , O_2^- , and O_2^{2-} ? (d) Based on the data given above, which of the following species best describes the Fe_2O_2 group of haemerythrin: $\text{Fe}_2^{3+}\text{O}_2$, $\text{Fe}^{2+}\text{Fe}^{3+}\text{O}_2^-$, or $\text{Fe}_2^{3+}\text{O}_2^{2-}$? Explain your reasoning. (e) The resonance Raman spectrum of haemerythrin mixed with $^{16}\text{O}^{18}\text{O}$ has two bands that can be attributed to the O—O stretching mode of bound oxygen. Discuss how this observation may be used to exclude one or more of the four proposed schemes (5–8) for binding of O_2 to the Fe_2 site of haemerythrin.

13.28‡ A mixture of carbon dioxide (2.1 per cent) and helium, at 1.00 bar and 298 K in a gas cell of length 10 cm has an infrared absorption band centred at 2349 cm^{-1} with absorbances, $A(\tilde{\nu})$, described by:

$$A(\tilde{\nu}) = \frac{a_1}{1 + a_2(\tilde{\nu} - a_3)^2} + \frac{a_4}{1 + a_5(\tilde{\nu} - a_6)^2}$$

where the coefficients are $a_1 = 0.932$, $a_2 = 0.005050\text{ cm}^2$, $a_3 = 2333\text{ cm}^{-1}$, $a_4 = 1.504$, $a_5 = 0.01521\text{ cm}^2$, $a_6 = 2362\text{ cm}^{-1}$. (a) Draw graphs of $A(\tilde{\nu})$ and $\epsilon(\tilde{\nu})$. What is the origin of both the band and the band width? What are the allowed and forbidden transitions of this band? (b) Calculate the transition wavenumbers and absorbances of the band with a simple harmonic oscillator-rigid rotor model and compare the result with the experimental spectra. The CO bond length is 116.2 pm. (c) Within what height, h , is basically all the infrared emission from the Earth in this band absorbed by atmospheric carbon dioxide? The mole fraction of CO_2 in the atmosphere is 3.3×10^{-4} and $T/\text{K} = 288 - 0.0065(h/\text{m})$ below 10 km. Draw a surface plot of the atmospheric transmittance of the band as a function of both height and wavenumber.

13.29 In Problem 10.27, we saw that Doppler shifts of atomic spectral lines are used to estimate the speed of recession or approach of a star. From the discussion in Section 13.3a, it is easy to see that Doppler broadening of an atomic spectral line depends on the temperature of the star that emits the

radiation. A spectral line of $^{48}\text{Ti}^{8+}$ (of mass 47.95 u) in a distant star was found to be shifted from 654.2 nm to 706.5 nm and to be broadened to 61.8 pm. What is the speed of recession and the surface temperature of the star?

13.30 A. Dalgarno, in *Chemistry in the interstellar medium*, *Frontiers of Astrophysics*, E.H. Avrett (ed.), Harvard University Press, Cambridge (1976), notes that although both CH and CN spectra show up strongly in the interstellar medium in the constellation Ophiuchus, the CN spectrum has become the standard for the determination of the temperature of the cosmic microwave background radiation. Demonstrate through a calculation why CH would not be as useful for this purpose as CN. The rotational constant B_0 for CH is 14.190 cm^{-1} .

13.31‡ There is a gaseous interstellar cloud in the constellation Ophiuchus that is illuminated from behind by the star ζ -Ophiuci. Analysis of the electronic–vibrational–rotational absorption lines obtained by H.S. Uhler and R.A. Patterson (*Astrophys. J.* **42**, 434 (1915)) shows the presence of CN molecules in the interstellar medium. A strong absorption line in the ultraviolet region at $\lambda = 387.5\text{ nm}$ was observed corresponding to the transition $J = 0 \rightarrow 1$. Unexpectedly, a second strong absorption line with 25 per cent of the intensity of the first was found at a slightly longer wavelength ($\Delta\lambda = 0.061\text{ nm}$) corresponding to the transition $J = 1 \rightarrow 1$ (here allowed). Calculate the temperature of the CN molecules. Gerhard Herzberg, who was later to receive the Nobel Prize for his contributions to spectroscopy, calculated the temperature as 2.3 K. Although puzzled by this result, he did not realize its full significance. If he had, his prize might have been for the discovery of the cosmic microwave background radiation.

13.32‡ The H_3^+ ion has recently been found in the interstellar medium and in the atmospheres of Jupiter, Saturn, and Uranus. The rotational energy levels of H_3^+ , an oblate symmetric rotor, are given by eqn 13.29, with C replacing A , when centrifugal distortion and other complications are ignored. Experimental values for vibrational–rotational constants are $\tilde{\nu}(E') = 2521.6\text{ cm}^{-1}$, $B = 43.55\text{ cm}^{-1}$, and $C = 20.71\text{ cm}^{-1}$. (a) Show that, for a nonlinear planar molecule (such as H_3^+), $I_C = 2I_B$. The rather large discrepancy with the experimental values is due to factors ignored in eqn 13.29. (b) Calculate an approximate value of the H—H bond length in H_3^+ . (c) The value of R_e obtained from the best quantum mechanical calculations by J.B. Anderson (*J. Chem. Phys.* **96**, 3702 (1991)) is 87.32 pm. Use this result to calculate the values of the rotational constants B and C . (d) Assuming that the geometry and force constants are the same in D_3^+ and H_3^+ , calculate the spectroscopic constants of D_3^+ . The molecular ion D_3^+ was first produced by J.T. Shy, J.W. Farley, W.E. Lamb Jr, and W.H. Wing (*Phys. Rev. Lett* **45**, 535 (1980)) who observed the $\nu_2(E')$ band in the infrared.

13.33 The space immediately surrounding stars, also called the *circumstellar space*, is significantly warmer because stars are very intense black-body emitters with temperatures of several thousand kelvin. Discuss how such factors as cloud temperature, particle density, and particle velocity may affect the rotational spectrum of CO in an interstellar cloud. What new features in the spectrum of CO can be observed in gas ejected from and still near a star with temperatures of about 1000 K, relative to gas in a cloud with temperature of about 10 K? Explain how these features may be used to distinguish between circumstellar and interstellar material on the basis of the rotational spectrum of CO.

Molecular spectroscopy 2: electronic transitions

14

Simple analytical expressions for the electronic energy levels of molecules cannot be given, so this chapter concentrates on the qualitative features of electronic transitions. A common theme throughout the chapter is that electronic transitions occur within a stationary nuclear framework. We pay particular attention to spontaneous radiative decay processes, which include fluorescence and phosphorescence. A specially important example of stimulated radiative decay is that responsible for the action of lasers, and we see how this stimulated emission may be achieved and employed.

The energies needed to change the electron distributions of molecules are of the order of several electronvolts (1 eV is equivalent to about 8000 cm^{-1} or 100 kJ mol^{-1}). Consequently, the photons emitted or absorbed when such changes occur lie in the visible and ultraviolet regions of the spectrum (Table 14.1).

One of the revolutions that has occurred in physical chemistry in recent years is the application of lasers to spectroscopy and kinetics. Lasers have brought unprecedented precision to spectroscopy, made Raman spectroscopy a widely useful technique, and have made it possible to study chemical reactions on a femtosecond time scale. We shall see the principles of their action in this chapter and their applications throughout the rest of the book.

The characteristics of electronic transitions

In the ground state of a molecule the nuclei are at equilibrium in the sense that they experience no net force from the electrons and other nuclei in the molecule. Immediately after an electronic transition they are subjected to different forces and

Comment 14.1

It is important to distinguish between the (upright) term symbol Σ and the (sloping) quantum number Σ .

the molecule may respond by starting to vibrate. The resulting vibrational structure of electronic transitions can be resolved for gaseous samples, but in a liquid or solid the lines usually merge together and result in a broad, almost featureless band (Fig. 14.1). Superimposed on the vibrational transitions that accompany the electronic transition of a molecule in the gas phase is an additional branch structure that arises from rotational transitions. The electronic spectra of gaseous samples are therefore very complicated but rich in information.

14.1 The electronic spectra of diatomic molecules

We examine some general features of electronic transitions by using diatomic molecules as examples. We begin by assigning term symbols to ground and excited electronic states. Then we use the symmetry designations to formulate selection rules. Finally, we examine the origin of vibrational structure in electronic spectra.

(a) Term symbols

The term symbols of linear molecules (the analogues of the symbols ^2P , etc. for atoms) are constructed in a similar way to those for atoms, but now we must pay attention to the component of total orbital angular momentum about the internuclear axis, $\Lambda\hbar$. The value of $|\Lambda|$ is denoted by the symbols $\Sigma, \Pi, \Delta, \dots$ for $|\Lambda| = 0, 1, 2, \dots$, respectively. These labels are the analogues of S, P, D, $\dots$ for atoms. The value of Λ is the sum of the values of λ , the quantum number for the component $\lambda\hbar$ of orbital angular momentum of an individual electron around the internuclear axis. A single electron in a σ orbital has $\lambda = 0$: the orbital is cylindrically symmetrical and has no angular nodes when viewed along the internuclear axis. Therefore, if that is the only electron present, $\Lambda = 0$. The term symbol for H_2^+ is therefore Σ .

As in atoms, we use a superscript with the value of $2S + 1$ to denote the multiplicity of the term. The component of total spin angular momentum about the internuclear axis is denoted Σ , where $\Sigma = S, S - 1, S - 2, \dots, -S$. For H_2^+ , because there is only one electron, $S = s = \frac{1}{2}$ ($\Sigma = \pm\frac{1}{2}$) and the term symbol is $^2\Sigma$, a doublet term. The overall parity of the term is added as a right subscript. For H_2^+ , the parity of the only occupied orbital is g (Section 11.3c), so the term itself is also g, and in full dress is $^2\Sigma_g$. If there are several electrons, the overall parity is calculated by using

$$g \times g = g \quad u \times u = g \quad u \times g = u \quad (14.1)$$

These rules are generated by interpreting g as +1 and u as -1. The term symbol for the ground state of any closed-shell homonuclear diatomic molecule is $^1\Sigma_g$ because the spin is zero (a singlet term in which all electrons paired), there is no orbital angular momentum from a closed shell, and the overall parity is g.

A π electron in a diatomic molecule has one unit of orbital angular momentum about the internuclear axis ($\lambda = \pm 1$), and if it is the only electron outside a closed shell, gives rise to a Π term. If there are two π electrons (as in the ground state of O_2 , with configuration $1\pi_u^4 1\pi_g^2$) then the term symbol may be either Σ (if the electrons are travelling in opposite directions, which is the case if they occupy different π orbitals, one with $\lambda = +1$ and the other with $\lambda = -1$) or Δ (if they are travelling in the same direction, which is the case if they occupy the same π orbital, both $\lambda = +1$, for instance). For O_2 , the two π electrons occupy different orbitals with parallel spins (a triplet term), so the ground term is $^3\Sigma$. The overall parity of the molecule is

$$(\text{closed shell}) \times g \times g = g$$

The term symbol is therefore $^3\Sigma_g$.

Table 14.2 Properties of O₂ in its lower electronic states*

Configuration [†]	Term	Relative energy/cm ⁻¹	$\tilde{\nu}$ /cm ⁻¹	R_e /pm
$\pi_u^2 \pi_g^2 \pi_g^1 \pi_g^1$	$^3\Sigma_g^-$	0	1580	120.74
$\pi_u^2 \pi_u^2 \pi_g^2 \pi_g^0$	$^1\Delta_g$	7 882.39	1509	121.55
$\pi_u^2 \pi_u^2 \pi_g^1 \pi_g^1$	$^1\Sigma_g^+$	13 120.9	1433	122.68
$\pi_u^2 \pi_u^1 \pi_g^2 \pi_g^1$	$^3\Sigma_u^+$	35 713	819	142
$\pi_u^2 \pi_u^1 \pi_g^2 \pi_g^1$	$^3\Sigma_u^-$	49 363	700	160

* Adapted from G. Herzberg, *Spectra of diatomic molecules*, Van Nostrand, New York (1950) and D.C. Harris and M.D. Bertolucci, *Symmetry and spectroscopy: an introduction to vibrational and electronic spectroscopy*, Dover, New York (1989).

[†] The configuration $\pi_u^2 \pi_u^1 \pi_g^2 \pi_g^1$ should also give rise to a $^3\Delta_u$ term, but electronic transitions to or from this state have not been observed.

For Σ terms, a $\pm$ superscript denotes the behaviour of the molecular wavefunction under reflection in a plane containing the nuclei (Fig. 14.2). If, for convenience, we think of O₂ as having one electron in $1\pi_{g,x}$, which changes sign under reflection in the yz -plane, and the other electron in $1\pi_{g,y}$, which does not change sign under reflection in the same plane, then the overall reflection symmetry is

$$(\text{closed shell}) \times (+) \times (-) = (-)$$

and the full term symbol of the ground electronic state of O₂ is $^3\Sigma_g^-$.

The term symbols of excited electronic states are constructed in a similar way. For example, the term symbol for the excited state of O₂ formed by placing two electrons in a $1\pi_{g,x}$ (or in a $1\pi_{g,y}$) orbital is $^1\Delta_g$ because $|\Lambda| = 2$ (two electrons in the same π orbital), the spin is zero (all electrons are paired), and the overall parity is (closed shell) $\times g \times g = g$. Table 14.2 and Fig. 14.3 summarize the configurations, term symbols, and energies of the ground and some excited states of O₂.

(b) Selection rules

A number of selection rules govern which transitions will be observed in the electronic spectrum of a molecule. The selection rules concerned with changes in angular momentum are

$$\Delta\Lambda = 0, \pm 1 \quad \Delta S = 0 \quad \Delta\Sigma = 0 \quad \Delta\Omega = 0, \pm 1$$

where $\Omega = \Lambda + \Sigma$ is the quantum number for the component of total angular momentum (orbital and spin) around the internuclear axis (Fig. 14.4). As in atoms (Section 10.9), the origins of these rules are conservation of angular momentum during a transition and the fact that a photon has a spin of 1.

There are two selection rules concerned with changes in symmetry. First, for Σ terms, only $\Sigma^+ \leftrightarrow \Sigma^+$ and $\Sigma^- \leftrightarrow \Sigma^-$ transitions are allowed. Second, the **Laporte selection rule** for centrosymmetric molecules (those with a centre of inversion) and atoms states that:

The only allowed transitions are transitions that are accompanied by a change of parity.

That is, $u \rightarrow g$ and $g \rightarrow u$ transitions are allowed, but $g \rightarrow g$ and $u \rightarrow u$ transitions are forbidden.

Fig. 14.2 The + or – on a term symbol refers to the overall symmetry of a configuration under reflection in a plane containing the two nuclei.

Fig. 14.3 The electronic states of dioxygen.

Fig. 14.4 The coupling of spin and orbital angular momenta in a linear molecule: only the components along the internuclear axis are conserved.

Fig. 14.5 A $d-d$ transition is parity-forbidden because it corresponds to a $g \rightarrow g$ transition. However, a vibration of the molecule can destroy the inversion symmetry of the molecule and the g, u classification no longer applies. The removal of the centre of symmetry gives rise to a vibronically allowed transition.

Fig. 14.6 The electronic spectra of some molecules show significant vibrational structure. Shown here is the ultraviolet spectrum of gaseous SO_2 at 298 K. As explained in the text, the sharp lines in this spectrum are due to transitions from a lower electronic state to different vibrational levels of a higher electronic state.

Justification 14.1 The Laporte selection rule

The last two selection rules result from the fact that the electric-dipole transition moment

$$\mu_{fi} = \int \psi_f^* \hat{\mu} \psi_i d\tau$$

vanishes unless the integrand is invariant under all symmetry operations of the molecule. The three components of the dipole moment operator transform like x , y , and z , and are all u . Therefore, for a $g \rightarrow g$ transition, the overall parity of the transition dipole moment is $g \times u \times g = u$, so it must be zero. Likewise, for a $u \rightarrow u$ transition, the overall parity is $u \times u \times u = u$, so the transition dipole moment must also vanish. Hence, transitions without a change of parity are forbidden. The z -component of the dipole moment operator, the only component of $\hat{\mu}$ responsible for $\Sigma \leftrightarrow \Sigma$ transitions, has $(+)$ symmetry. Therefore, for a $(+) \leftrightarrow (-)$ transition, the overall symmetry of the transition dipole moment is $(+) \times (+) \times (-) = (-)$, so it must be zero. Therefore, for Σ terms, $\Sigma^+ \leftrightarrow \Sigma^-$ transitions are not allowed.

A forbidden $g \rightarrow g$ transition can become allowed if the centre of symmetry is eliminated by an asymmetrical vibration, such as the one shown in Fig. 14.5. When the centre of symmetry is lost, $g \rightarrow g$ and $u \rightarrow u$ transitions are no longer parity-forbidden and become weakly allowed. A transition that derives its intensity from an asymmetrical vibration of a molecule is called a **vibronic transition**.

Self-test 14.1 Which of the following electronic transitions are allowed in O_2 : ${}^3\Sigma_g^- \leftrightarrow {}^1\Delta_g$, ${}^3\Sigma_g^- \leftrightarrow {}^1\Sigma_g^+$, ${}^3\Sigma_g^- \leftrightarrow {}^3\Delta_u$, ${}^3\Sigma_g^- \leftrightarrow {}^3\Sigma_u^+$, ${}^3\Sigma_g^- \leftrightarrow {}^3\Sigma_u^-$? [${}^3\Sigma_g^- \leftrightarrow {}^3\Sigma_u^-$]

(c) Vibrational structure

To account for the vibrational structure in electronic spectra of molecules (Fig. 14.6), we apply the **Franck–Condon principle**:

Because the nuclei are so much more massive than the electrons, an electronic transition takes place very much faster than the nuclei can respond.

As a result of the transition, electron density is rapidly built up in new regions of the molecule and removed from others. The initially stationary nuclei suddenly experience a new force field, to which they respond by beginning to vibrate and (in classical terms) swing backwards and forwards from their original separation (which was maintained during the rapid electronic excitation). The stationary equilibrium separation of the nuclei in the initial electronic state therefore becomes a stationary turning point in the final electronic state (Fig. 14.7).

The quantum mechanical version of the Franck–Condon principle refines this picture. Before the absorption, the molecule is in the lowest vibrational state of its lowest electronic state (Fig. 14.8); the most probable location of the nuclei is at their equilibrium separation, R_e . The electronic transition is most likely to take place when the nuclei have this separation. When the transition occurs, the molecule is excited to the state represented by the upper curve. According to the Franck–Condon principle, the nuclear framework remains constant during this excitation, so we may imagine the transition as being up the vertical line in Fig. 14.7. The vertical line is the origin of the expression **vertical transition**, which is used to denote an electronic transition that occurs without change of nuclear geometry.

The vertical transition cuts through several vibrational levels of the upper electronic state. The level marked * is the one in which the nuclei are most probably at

the same initial separation R_e (because the vibrational wavefunction has maximum amplitude there), so this vibrational state is the most probable state for the termination of the transition. However, it is not the only accessible vibrational state because several nearby states have an appreciable probability of the nuclei being at the separation R_e . Therefore, transitions occur to all the vibrational states in this region, but most intensely to the state with a vibrational wavefunction that peaks most strongly near R_e .

The vibrational structure of the spectrum depends on the relative horizontal position of the two potential energy curves, and a long **vibrational progression**, a lot of vibrational structure, is stimulated if the upper potential energy curve is appreciably displaced horizontally from the lower. The upper curve is usually displaced to greater equilibrium bond lengths because electronically excited states usually have more antibonding character than electronic ground states.

The separation of the vibrational lines of an electronic absorption spectrum depends on the vibrational energies of the *upper* electronic state. Hence, electronic absorption spectra may be used to assess the force fields and dissociation energies of electronically excited molecules (for example, by using a Birge–Sponer plot, as in Problem 14.2).

(d) Franck–Condon factors

The quantitative form of the Franck–Condon principle is derived from the expression for the transition dipole moment, $\mu_{fi} = \langle f | \mu | i \rangle$. The dipole moment operator is a sum over all nuclei and electrons in the molecule:

$$\hat{\mu} = -e \sum_i \mathbf{r}_i + e \sum_I Z_I \mathbf{R}_I \quad (14.2)$$

where the vectors are the distances from the centre of charge of the molecule. The intensity of the transition is proportional to the square modulus, $|\mu_{fi}|^2$, of the magnitude of the transition dipole moment (eqn 9.70), and we show in the *Justification* below that this intensity is proportional to the square modulus of the overlap integral, $S(v_f, v_i)$, between the vibrational states of the initial and final electronic states. This overlap integral is a measure of the match between the vibrational wavefunctions in the upper and lower electronic states: $S = 1$ for a perfect match and $S = 0$ when there is no similarity.

Justification 14.2 The Franck–Condon approximation

The overall state of the molecule consists of an electronic part, $|\epsilon\rangle$, and a vibrational part, $|v\rangle$. Therefore, within the Born–Oppenheimer approximation, the transition dipole moment factorizes as follows:

$$\begin{aligned} \mu_{fi} &= \langle \epsilon_f v_f | \{-e \sum_i \mathbf{r}_i + e \sum_I Z_I \mathbf{R}_I\} | \epsilon_i v_i \rangle \\ &= -e \sum_i \langle \epsilon_f | \mathbf{r}_i | \epsilon_i \rangle \langle v_f | v_i \rangle + e \sum_I Z_I \langle \epsilon_f | \epsilon_i \rangle \langle v_f | \mathbf{R}_I | v_i \rangle \end{aligned}$$

The second term on the right of the second row is zero, because $\langle \epsilon_f | \epsilon_i \rangle = 0$ for two different electronic states (they are orthogonal). Therefore,

$$\mu_{fi} = -e \sum_i \langle \epsilon_f | \mathbf{r}_i | \epsilon_i \rangle \langle v_f | v_i \rangle = \mu_{\epsilon_f, \epsilon_i} S(v_f, v_i) \quad (14.3)$$

where

$$\mu_{\epsilon_f, \epsilon_i} = -e \sum_i \langle \epsilon_f | \mathbf{r}_i | \epsilon_i \rangle \quad S(v_f, v_i) = \langle v_f | v_i \rangle \quad (14.4)$$

The matrix element $\mu_{\epsilon_f, \epsilon_i}$ is the electric-dipole transition moment arising from the redistribution of electrons (and a measure of the ‘kick’ this redistribution gives to the electromagnetic field, and vice versa for absorption). The factor $S(v_f, v_i)$, is the overlap integral between the vibrational state $|v_i\rangle$ in the initial electronic state of the molecule, and the vibrational state $|v_f\rangle$ in the final electronic state of the molecule.

Fig. 14.7 According to the Franck–Condon principle, the most intense vibronic transition is from the ground vibrational state to the vibrational state lying vertically above it. Transitions to other vibrational levels also occur, but with lower intensity.

Fig. 14.8 In the quantum mechanical version of the Franck–Condon principle, the molecule undergoes a transition to the upper vibrational state that most closely resembles the vibrational wavefunction of the vibrational ground state of the lower electronic state. The two wavefunctions shown here have the greatest overlap integral of all the vibrational states of the upper electronic state and hence are most closely similar.

Fig. 14.9 The Franck–Condon factor for the arrangement discussed in Example 14.1.

Fig. 14.10 The model wavefunctions used in Self-test 14.2.

Because the transition intensity is proportional to the square of the magnitude of the transition dipole moment, the intensity of an absorption is proportional to $|S(v_f, v_i)|^2$, which is known as the **Franck–Condon factor** for the transition. It follows that, the greater the overlap of the vibrational state wavefunction in the upper electronic state with the vibrational wavefunction in the lower electronic state, the greater the absorption intensity of that particular simultaneous electronic and vibrational transition. This conclusion is the basis of the illustration in Fig. 14.8, where we see that the vibrational wavefunction of the ground state has the greatest overlap with the vibrational states that have peaks at similar bond lengths in the upper electronic state.

Example 14.1 Calculating a Franck–Condon factor

Consider the transition from one electronic state to another, their bond lengths being R_e and R'_e and their force constants equal. Calculate the Franck–Condon factor for the 0–0 transition and show that the transition is most intense when the bond lengths are equal.

Method We need to calculate $S(0,0)$, the overlap integral of the two ground-state vibrational wavefunctions, and then take its square. The difference between harmonic and anharmonic vibrational wavefunctions is negligible for $v = 0$, so harmonic oscillator wavefunctions can be used (Table 9.1).

Answer We use the (real) wavefunctions

$$\psi_0 = \left(\frac{1}{\alpha\pi^{1/2}} \right)^{1/2} e^{-x^2/2\alpha^2} \quad \psi'_0 = \left(\frac{1}{\alpha\pi^{1/2}} \right)^{1/2} e^{-x'^2/2\alpha^2}$$

where $x = R - R_e$ and $x' = R - R'_e$, with $\alpha = (\hbar^2/mk)^{1/4}$ (Section 9.5a). The overlap integral is

$$S(0,0) = \langle 0|0 \rangle = \int_{-\infty}^{\infty} \psi'_0 \psi_0 dR = \frac{1}{\alpha\pi^{1/2}} \int_{-\infty}^{\infty} e^{-(x^2+x'^2)/2\alpha^2} dx$$

We now write $\alpha z = R - \frac{1}{2}(R_e + R'_e)$, and manipulate this expression into

$$S(0,0) = \frac{1}{\pi^{1/2}} e^{-(R_e - R'_e)^2/4\alpha^2} \int_{-\infty}^{\infty} e^{-z^2} dz$$

The value of the integral is $\pi^{1/2}$. Therefore, the overlap integral is

$$S(0,0) = e^{-(R_e - R'_e)^2/4\alpha^2}$$

and the Franck–Condon factor is

$$S(0,0)^2 = e^{-(R_e - R'_e)^2/2\alpha^2}$$

This factor is equal to 1 when $R'_e = R_e$ and decreases as the equilibrium bond lengths diverge from each other (Fig. 14.9).

For Br_2 , $R_e = 228$ pm and there is an upper state with $R'_e = 266$ pm. Taking the vibrational wavenumber as 250 cm^{-1} gives $S(0,0)^2 = 5.1 \times 10^{-10}$, so the intensity of the 0–0 transition is only 5.1×10^{-10} what it would have been if the potential curves had been directly above each other.

Self-test 14.2 Suppose the vibrational wavefunctions can be approximated by rectangular functions of width W and W' , centred on the equilibrium bond lengths (Fig. 14.10). Find the corresponding Franck–Condon factors when the centres are coincident and $W' < W$. $[S^2 = W'/W]$

(e) Rotational structure

Just as in vibrational spectroscopy, where a vibrational transition is accompanied by rotational excitation, so rotational transitions accompany the excitation of the vibrational excitation that accompanies electronic excitation. We therefore see P, Q, and R branches for each vibrational transition, and the electronic transition has a very rich structure. However, the principal difference is that electronic excitation can result in much larger changes in bond length than vibrational excitation causes alone, and the rotational branches have a more complex structure than in vibration–rotation spectra.

We suppose that the rotational constants of the electronic ground and excited states are B and B' , respectively. The rotational energy levels of the initial and final states are

$$E(J) = hcBJ(J+1) \quad E(J') = hcB'J'(J'+1)$$

and the rotational transitions occur at the following positions relative to the vibrational transition of wavenumber $\tilde{\nu}$ that they accompany:

$$\text{P branch } (\Delta J = -1): \quad \tilde{\nu}_P(J) = \tilde{\nu} - (B' + B)J + (B' - B)J^2 \quad (14.5a)$$

$$\text{Q branch } (\Delta J = 0): \quad \tilde{\nu}_Q(J) = \tilde{\nu} + (B' - B)J(J+1) \quad (14.5b)$$

$$\text{R branch } (\Delta J = +1): \quad \tilde{\nu}_R(J) = \tilde{\nu} + (B' + B)(J+1) + (B' - B)(J+1)^2 \quad (14.5c)$$

(These are the analogues of eqn 13.63.) First, suppose that the bond length in the electronically excited state is greater than that in the ground state; then $B' < B$ and $B' - B$ is negative. In this case the lines of the R branch converge with increasing J and when J is such that $|B' - B|(J+1) > B' + B$ the lines start to appear at successively decreasing wavenumbers. That is, the R branch has a **band head** (Fig. 14.11a). When the bond is shorter in the excited state than in the ground state, $B' > B$ and $B' - B$ is positive. In this case, the lines of the P branch begin to converge and go through a head when J is such that $(B' - B)J > B' + B$ (Fig. 14.11b).

Fig. 14.11 When the rotational constants of a diatomic molecule differ significantly in the initial and final states of an electronic transition, the P and R branches show a head. (a) The formation of a head in the R branch when $B' < B$; (b) the formation of a head in the P branch when $B' > B$.

14.2 The electronic spectra of polyatomic molecules

The absorption of a photon can often be traced to the excitation of specific types of electrons or to electrons that belong to a small group of atoms in a polyatomic molecule. For example, when a carbonyl group ($>C=O$) is present, an absorption at about 290 nm is normally observed, although its precise location depends on the nature of the rest of the molecule. Groups with characteristic optical absorptions are called **chromophores** (from the Greek for ‘colour bringer’), and their presence often accounts for the colours of substances (Table 14.3).

(a) d–d transitions

In a free atom, all five d orbitals of a given shell are degenerate. In a d -metal complex, where the immediate environment of the atom is no longer spherical, the d orbitals

Fig. 14.12 The classification of d -orbitals in an octahedral environment.

are not all degenerate, and electrons can absorb energy by making transitions between them. We show in the following *Justification* that in an octahedral complex, such as $[\text{Ti}(\text{OH}_2)_6]^{3+}$ (1), the five d orbitals of the central atom are split into two sets (2), a triply degenerate set labelled t_{2g} and a doubly degenerate set labelled e_g . The three t_{2g} orbitals lie below the two e_g orbitals; the difference in energy is denoted Δ_O and called the **ligand-field splitting parameter** (the O denoting octahedral symmetry).

Justification 14.3 *The splitting of d -orbitals in an octahedral d -metal complex*

In an octahedral d -metal complex, six identical ions or molecules, the *ligands*, are at the vertices of a regular octahedron, with the metal ion at its centre. The ligands can be regarded as point negative charges that are repelled by the d -electrons of the central ion. Figure 14.12 shows the consequence of this arrangement: the five d -orbitals fall into two groups, with $d_{x^2-y^2}$ and d_{z^2} pointing directly towards the ligand positions, and d_{xy} , d_{yz} , and d_{zx} pointing between them. An electron occupying an orbital of the former group has a less favourable potential energy than when it occupies any of the three orbitals of the other group, and so the d -orbitals split into the two sets shown in (2) with an energy difference Δ_O : a triply degenerate set comprising the d_{xy} , d_{yz} , and d_{zx} orbitals and labelled t_{2g} , and a doubly degenerate set comprising the $d_{x^2-y^2}$ and d_{z^2} orbitals and labelled e_g .

The d -orbitals also divide into two sets in a tetrahedral complex, but in this case the e orbitals lie below the t_2 orbitals and their separation is written Δ_T . Neither Δ_O nor Δ_T is large, so transitions between the two sets of orbitals typically occur in the visible region of the spectrum. The transitions are responsible for many of the colours that are so characteristic of d -metal complexes. As an example, the spectrum of $[\text{Ti}(\text{OH}_2)_6]^{3+}$ near $20\,000\text{ cm}^{-1}$ (500 nm) is shown in Fig. 14.13, and can be ascribed to the promotion of its single d electron from a t_{2g} orbital to an e_g orbital. The wavenumber of the absorption maximum suggests that $\Delta_O \approx 20\,000\text{ cm}^{-1}$ for this complex, which corresponds to about 2.5 eV.

According to the Laporte rule (Section 14.1b), $d-d$ transitions are parity-forbidden in octahedral complexes because they are $g \rightarrow g$ transitions (more specifically $e_g \leftarrow t_{2g}$ transitions). However, $d-d$ transitions become weakly allowed as vibronic transitions as a result of coupling to asymmetrical vibrations such as that shown in Fig. 14.5.

(b) Charge-transfer transitions

A complex may absorb radiation as a result of the transfer of an electron from the ligands into the d -orbitals of the central atom, or vice versa. In such **charge-transfer transitions** the electron moves through a considerable distance, which means that the transition dipole moment may be large and the absorption is correspondingly intense. This mode of chromophore activity is shown by the permanganate ion, MnO_4^- , and accounts for its intense violet colour (which arises from strong absorption within the range 420–700 nm). In this oxoanion, the electron migrates from an orbital that is largely confined to the O atom ligands to an orbital that is largely confined to the Mn atom. It is therefore an example of a **ligand-to-metal charge-transfer transition** (LMCT). The reverse migration, a **metal-to-ligand charge-transfer transition** (MLCT), can also occur. An example is the transfer of a d electron into the antibonding π orbitals of an aromatic ligand. The resulting excited state may have a very long lifetime if the electron is extensively delocalized over several aromatic rings, and such species can participate in photochemically induced redox reactions (see Section 23.7).

The intensities of charge-transfer transitions are proportional to the square of the transition dipole moment, in the usual way. We can think of the transition moment as a measure of the distance moved by the electron as it migrates from metal to ligand or vice versa, with a large distance of migration corresponding to a large transition dipole moment and therefore a high intensity of absorption. However, because the integrand in the transition dipole is proportional to the product of the initial and final wavefunctions, it is zero unless the two wavefunctions have nonzero values in the same region of space. Therefore, although large distances of migration favour high intensities, the diminished overlap of the initial and final wavefunctions for large separations of metal and ligands favours low intensities (see Problem 14.17). We encounter similar considerations when we examine electron transfer reactions (Chapter 24), which can be regarded as a special type of charge-transfer transition.

(c) $\pi^* \leftarrow \pi$ and $\pi^* \leftarrow n$ transitions

Absorption by a $\text{C}=\text{C}$ double bond results in the excitation of a π electron into an antibonding π^* orbital (Fig. 14.14). The chromophore activity is therefore due to a $\pi^* \leftarrow \pi$ transition (which is normally read ‘ π to π -star transition’). Its energy is about 7 eV for an unconjugated double bond, which corresponds to an absorption at 180 nm (in the ultraviolet). When the double bond is part of a conjugated chain, the energies of the molecular orbitals lie closer together and the $\pi^* \leftarrow \pi$ transition moves to longer wavelength; it may even lie in the visible region if the conjugated system is long enough. An important example of an $\pi^* \leftarrow \pi$ transition is provided by the photochemical mechanism of vision (*Impact I14.1*).

The transition responsible for absorption in carbonyl compounds can be traced to the lone pairs of electrons on the O atom. The Lewis concept of a ‘lone pair’ of electrons is represented in molecular orbital theory by a pair of electrons in an orbital confined largely to one atom and not appreciably involved in bond formation. One of these electrons may be excited into an empty π^* orbital of the carbonyl group (Fig. 14.15), which gives rise to a $\pi^* \leftarrow n$ transition (an ‘ n to π -star transition’). Typical absorption energies are about 4 eV (290 nm). Because $\pi^* \leftarrow n$ transitions in carbonyls are symmetry forbidden, the absorptions are weak.

Fig. 14.14 A $\text{C}=\text{C}$ double bond acts as a chromophore. One of its important transitions is the $\pi^* \leftarrow \pi$ transition illustrated here, in which an electron is promoted from a π orbital to the corresponding antibonding orbital.

Fig. 14.15 A carbonyl group ($\text{C}=\text{O}$) acts as a chromophore primarily on account of the excitation of a nonbonding O lone-pair electron to an antibonding CO π orbital.

Fig. 14.16 Electromagnetic radiation consists of a wave of electric and magnetic fields perpendicular to the direction of propagation (in this case the x -direction), and mutually perpendicular to each other. This illustration shows a plane-polarized wave, with the electric and magnetic fields oscillating in the xy and xz planes, respectively.

(d) Circular dichroism spectroscopy

Electronic spectra can reveal additional details of molecular structure when experiments are conducted with **polarized light**, electromagnetic radiation with electric and magnetic fields that oscillate only in certain directions. Light is **plane polarized** when the electric and magnetic fields each oscillate in a single plane (Fig. 14.16). The plane of polarization may be oriented in any direction around the direction of propagation (the x -direction in Fig. 14.16), with the electric and magnetic fields perpendicular to that direction (and perpendicular to each other). An alternative mode of polarization is **circular polarization**, in which the electric and magnetic fields rotate around the direction of propagation in either a clockwise or a counter-clockwise sense but remain perpendicular to it and each other.

When plane-polarized radiation passes through samples of certain kinds of matter, the plane of polarization is rotated around the direction of propagation. This rotation is the familiar phenomenon of optical activity, observed when the molecules in the sample are chiral (Section 12.3b). Chiral molecules have a second characteristic: they absorb left and right circularly polarized light to different extents. In a circularly polarized ray of light, the electric field describes a helical path as the wave travels through space (Fig. 14.17), and the rotation may be either clockwise or counterclockwise. The differential absorption of left- and right-circularly polarized light is called **circular dichroism**. In terms of the absorbances for the two components, A_L and A_R , the circular dichroism of a sample of molar concentration $[J]$ is reported as

$$\Delta\varepsilon = \varepsilon_L - \varepsilon_R = \frac{A_L - A_R}{[J]l} \quad (14.6)$$

where l is the path length of the sample.

Circular dichroism is a useful adjunct to visible and UV spectroscopy. For example, the CD spectra of the enantiomeric pairs of chiral d -metal complexes are distinctly different, whereas there is little difference between their absorption spectra (Fig. 14.18). Moreover, CD spectra can be used to assign the absolute configuration of complexes by comparing the observed spectrum with the CD spectrum of a similar complex of known handedness. We shall see in Chapter 19 that the CD spectra of biological polymers, such as proteins and nucleic acids, give similar structural information. In these cases the spectrum of the polymer chain arises from the chirality of individual monomer units and, in addition, a contribution from the three-dimensional structure of the polymer itself.

Fig. 14.17 In circularly polarized light, the electric field at different points along the direction of propagation rotates. The arrays of arrows in these illustrations show the view of the electric field when looking toward the oncoming ray: (a) right-circularly polarized, (b) left-circularly polarized light.

IMPACT ON BIOCHEMISTRY I14.1 Vision

The eye is an exquisite photochemical organ that acts as a transducer, converting radiant energy into electrical signals that travel along neurons. Here we concentrate on the events taking place in the human eye, but similar processes occur in all animals. Indeed, a single type of protein, rhodopsin, is the primary receptor for light throughout the animal kingdom, which indicates that vision emerged very early in evolutionary history, no doubt because of its enormous value for survival.

Photons enter the eye through the cornea, pass through the ocular fluid that fills the eye, and fall on the retina. The ocular fluid is principally water, and passage of light through this medium is largely responsible for the *chromatic aberration* of the eye, the blurring of the image as a result of different frequencies being brought to slightly different focuses. The chromatic aberration is reduced to some extent by the tinted region called the *macular pigment* that covers part of the retina. The pigments in this region are the carotene-like xanthophylls (3), which absorb some of the blue light and

Fig. 14.18 (a) The absorption spectra of two isomers, denoted mer and fac, of $[\text{Co}(\text{ala})_3]$, where ala is the conjugate base of alanine, and (b) the corresponding CD spectra. The left- and right-handed forms of these isomers give identical absorption spectra. However, the CD spectra are distinctly different, and the absolute configurations (denoted Λ and Δ) have been assigned by comparison with the CD spectra of a complex of known absolute configuration.

3 A xanthophyll

hence help to sharpen the image. They also protect the photoreceptor molecules from too great a flux of potentially dangerous high energy photons. The xanthophylls have delocalized electrons that spread along the chain of conjugated double bonds, and the $\pi^* \leftarrow \pi$ transition lies in the visible.

About 57 per cent of the photons that enter the eye reach the retina; the rest are scattered or absorbed by the ocular fluid. Here the primary act of vision takes place, in which the chromophore of a rhodopsin molecule absorbs a photon in another $\pi^* \leftarrow \pi$ transition. A rhodopsin molecule consists of an opsin protein molecule to which is attached a 11-*cis*-retinal molecule (4). The latter resembles half a carotene molecule, showing Nature's economy in its use of available materials. The attachment is by the formation of a protonated Schiff's base, utilizing the $-\text{CHO}$ group of the chromophore and the terminal NH_2 group of the sidechain, a lysine residue from opsin. The free 11-*cis*-retinal molecule absorbs in the ultraviolet, but attachment to the opsin protein molecule shifts the absorption into the visible region. The rhodopsin molecules are situated in the membranes of special cells (the 'rods' and the 'cones') that cover the retina. The opsin molecule is anchored into the cell membrane by two hydrophobic groups and largely surrounds the chromophore (Fig. 14.19).

Immediately after the absorption of a photon, the 11-*cis*-retinal molecule undergoes photoisomerization into all-*trans*-retinal (5). Photoisomerization takes about

4 11-*cis*-retinal

Fig. 14.19 The structure of the rhodopsin molecule, consisting of an opsin protein to which is attached an 11-*cis*-retinal molecule embedded in the space surrounded by the helical regions.

5 All-*trans*-retinal

Fig. 14.20 The empirical (observation-based) distinction between fluorescence and phosphorescence is that the former is extinguished very quickly after the exciting source is removed, whereas the latter continues with relatively slowly diminishing intensity.

200 fs and about 67 pigment molecules isomerize for every 100 photons that are absorbed. The process occurs because the $\pi^* \leftarrow \pi$ excitation of an electron loosens one of the π -bonds (the one indicated by the arrow in 5), its torsional rigidity is lost, and one part of the molecule swings round into its new position. At that point, the molecule returns to its ground state, but is now trapped in its new conformation. The straightened tail of all-*trans*-retinal results in the molecule taking up more space than 11-*cis*-retinal did, so the molecule presses against the coils of the opsin molecule that surrounds it. In about 0.25–0.50 ms from the initial absorption event, the rhodopsin molecule is activated both by the isomerization of retinal and deprotonation of its Schiff's base tether to opsin, forming an intermediate known as *metarhodopsin II*.

In a sequence of biochemical events known as the *biochemical cascade*, metarhodopsin II activates the protein transducin, which in turn activates a phosphodiesterase enzyme that hydrolyses cyclic guanine monophosphate (cGMP) to GMP. The reduction in the concentration of cGMP causes ion channels, proteins that mediate the movement of ions across biological membranes, to close and the result is a sizable change in the transmembrane potential (see *Impact 17.2* for a discussion of transmembrane potentials). The pulse of electric potential travels through the optical nerve and into the optical cortex, where it is interpreted as a signal and incorporated into the web of events we call 'vision'.

The resting state of the rhodopsin molecule is restored by a series of nonradiative chemical events powered by ATP. The process involves the escape of all-*trans*-retinal as all-*trans*-retinol (in which $-\text{CHO}$ has been reduced to $-\text{CH}_2\text{OH}$) from the opsin molecule by a process catalysed by the enzyme rhodopsin kinase and the attachment of another protein molecule, arrestin. The free all-*trans*-retinol molecule now undergoes enzyme-catalysed isomerization into 11-*cis*-retinol followed by dehydrogenation to form 11-*cis*-retinal, which is then delivered back into an opsin molecule. At this point, the cycle of excitation, photoisomerization, and regeneration is ready to begin again.

The fates of electronically excited states

A **radiative decay process** is a process in which a molecule discards its excitation energy as a photon. A more common fate is **nonradiative decay**, in which the excess energy is transferred into the vibration, rotation, and translation of the surrounding molecules. This thermal degradation converts the excitation energy completely into thermal motion of the environment (that is, to 'heat'). An excited molecule may also take part in a chemical reaction, as we discuss in Chapter 23.

14.3 Fluorescence and phosphorescence

In **fluorescence**, spontaneous emission of radiation occurs within a few nanoseconds after the exciting radiation is extinguished (Fig. 14.20). In **phosphorescence**, the spontaneous emission may persist for long periods (even hours, but characteristically seconds or fractions of seconds). The difference suggests that fluorescence is a fast conversion of absorbed radiation into re-emitted energy, and that phosphorescence involves the storage of energy in a reservoir from which it slowly leaks.

(a) Fluorescence

Figure 14.21 shows the sequence of steps involved in fluorescence. The initial absorption takes the molecule to an excited electronic state, and if the absorption spectrum were monitored it would look like the one shown in Fig. 14.22a. The excited molecule

Fig. 14.21 The sequence of steps leading to fluorescence. After the initial absorption, the upper vibrational states undergo radiationless decay by giving up energy to the surroundings. A radiative transition then occurs from the vibrational ground state of the upper electronic state.

Fig. 14.22 An absorption spectrum (a) shows a vibrational structure characteristic of the upper state. A fluorescence spectrum (b) shows a structure characteristic of the lower state; it is also displaced to lower frequencies (but the 0–0 transitions are coincident) and resembles a mirror image of the absorption.

is subjected to collisions with the surrounding molecules, and as it gives up energy nonradiatively it steps down the ladder of vibrational levels to the lowest vibrational level of the electronically excited molecular state. The surrounding molecules, however, might now be unable to accept the larger energy difference needed to lower the molecule to the ground electronic state. It might therefore survive long enough to undergo spontaneous emission, and emit the remaining excess energy as radiation. The downward electronic transition is vertical (in accord with the Franck–Condon principle) and the fluorescence spectrum has a vibrational structure characteristic of the *lower* electronic state (Fig. 14.22b).

Provided they can be seen, the 0–0 absorption and fluorescence transitions can be expected to be coincident. The absorption spectrum arises from 1–0, 2–0, . . . transitions that occur at progressively higher wavenumber and with intensities governed by the Franck–Condon principle. The fluorescence spectrum arises from 0–0, 0–1, . . . *downward* transitions that hence occur with decreasing wavenumbers. The 0–0 absorption and fluorescence peaks are not always exactly coincident, however, because the solvent may interact differently with the solute in the ground and excited states (for instance, the hydrogen bonding pattern might differ). Because the solvent molecules do not have time to rearrange during the transition, the absorption occurs in an environment characteristic of the solvated ground state; however, the fluorescence occurs in an environment characteristic of the solvated excited state (Fig. 14.23).

Fluorescence occurs at lower frequencies (longer wavelengths) than the incident radiation because the emissive transition occurs after some vibrational energy has been discarded into the surroundings. The vivid oranges and greens of fluorescent dyes are an everyday manifestation of this effect: they absorb in the ultraviolet and blue, and fluoresce in the visible. The mechanism also suggests that the intensity of the fluorescence ought to depend on the ability of the solvent molecules to accept the

Fig. 14.23 The solvent can shift the fluorescence spectrum relative to the absorption spectrum. On the left we see that the absorption occurs with the solvent (the ellipses) in the arrangement characteristic of the ground electronic state of the molecule (the sphere). However, before fluorescence occurs, the solvent molecules relax into a new arrangement, and that arrangement is preserved during the subsequent radiative transition.

Fig. 14.24 The sequence of steps leading to phosphorescence. The important step is the intersystem crossing, the switch from a singlet state to a triplet state brought about by spin–orbit coupling. The triplet state acts as a slowly radiating reservoir because the return to the ground state is spin-forbidden.

Fig. 14.25 A Jablonski diagram (here, for naphthalene) is a simplified portrayal of the relative positions of the electronic energy levels of a molecule. Vibrational levels of states of a given electronic state lie above each other, but the relative horizontal locations of the columns bear no relation to the nuclear separations in the states. The ground vibrational states of each electronic state are correctly located vertically but the other vibrational states are shown only schematically. (IC: internal conversion; ISC: intersystem crossing.)

electronic and vibrational quanta. It is indeed found that a solvent composed of molecules with widely spaced vibrational levels (such as water) can in some cases accept the large quantum of electronic energy and so extinguish, or ‘quench’, the fluorescence. We examine the mechanisms of fluorescence quenching in Chapter 23.

(b) Phosphorescence

Figure 14.24 shows the sequence of events leading to phosphorescence for a molecule with a singlet ground state. The first steps are the same as in fluorescence, but the presence of a triplet excited state plays a decisive role. The singlet and triplet excited states share a common geometry at the point where their potential energy curves intersect. Hence, if there is a mechanism for unpairing two electron spins (and achieving the conversion of $\uparrow\downarrow$ to $\uparrow\uparrow$), the molecule may undergo **intersystem crossing**, a nonradiative transition between states of different multiplicity, and become a triplet state. We saw in the discussion of atomic spectra (Section 10.9d) that singlet–triplet transitions may occur in the presence of spin–orbit coupling, and the same is true in molecules. We can expect intersystem crossing to be important when a molecule contains a moderately heavy atom (such as S), because then the spin–orbit coupling is large.

If an excited molecule crosses into a triplet state, it continues to deposit energy into the surroundings. However, it is now stepping down the triplet’s vibrational ladder, and at the lowest energy level it is trapped because the triplet state is at a lower energy than the corresponding singlet (recall Hund’s rule, Section 13.7). The solvent cannot absorb the final, large quantum of electronic excitation energy, and the molecule cannot radiate its energy because return to the ground state is spin-forbidden (Section 14.1). The radiative transition, however, is not totally forbidden because the spin–orbit coupling that was responsible for the intersystem crossing also breaks the selection rule. The molecules are therefore able to emit weakly, and the emission may continue long after the original excited state was formed.

The mechanism accounts for the observation that the excitation energy seems to get trapped in a slowly leaking reservoir. It also suggests (as is confirmed experimentally) that phosphorescence should be most intense from solid samples: energy transfer is then less efficient and intersystem crossing has time to occur as the singlet excited state steps slowly past the intersection point. The mechanism also suggests that the phosphorescence efficiency should depend on the presence of a moderately heavy atom (with strong spin–orbit coupling), which is in fact the case. The confirmation of the mechanism is the experimental observation (using the sensitive magnetic resonance techniques described in Chapter 15) that the sample is paramagnetic while the reservoir state, with its unpaired electron spins, is populated.

The various types of nonradiative and radiative transitions that can occur in molecules are often represented on a schematic **Jablonski diagram** of the type shown in Fig. 14.25.

IMPACT ON BIOCHEMISTRY 14.2 Fluorescence microscopy

Apart from a small number of co-factors, such as the chlorophylls and flavins, the majority of the building blocks of proteins and nucleic acids do not fluoresce strongly. Four notable exceptions are the amino acids tryptophan ($\lambda_{\text{abs}} \approx 280$ nm and $\lambda_{\text{fluor}} \approx 348$ nm in water), tyrosine ($\lambda_{\text{abs}} \approx 274$ nm and $\lambda_{\text{fluor}} \approx 303$ nm in water), and phenylalanine ($\lambda_{\text{abs}} \approx 257$ nm and $\lambda_{\text{fluor}} \approx 282$ nm in water), and the oxidized form of the sequence serine–tyrosine–glycine (6) found in the green fluorescent protein (GFP) of certain jellyfish. The wild type of GFP from *Aequora victoria* absorbs strongly at 395 nm and emits maximally at 509 nm.

In **fluorescence microscopy**, images of biological cells at work are obtained by attaching a large number of fluorescent molecules to proteins, nucleic acids, and membranes and then measuring the distribution of fluorescence intensity within the illuminated area. A common fluorescent label is GFP. With proper filtering to remove light due to Rayleigh scattering of the incident beam, it is possible to collect light from the sample that contains only fluorescence from the label. However, great care is required to eliminate fluorescent impurities from the sample.

14.4 Dissociation and predissociation

Another fate for an electronically excited molecule is **dissociation**, the breaking of bonds (Fig. 14.26). The onset of dissociation can be detected in an absorption spectrum by seeing that the vibrational structure of a band terminates at a certain energy. Absorption occurs in a continuous band above this **dissociation limit** because the final state is an unquantized translational motion of the fragments. Locating the dissociation limit is a valuable way of determining the bond dissociation energy.

In some cases, the vibrational structure disappears but resumes at higher photon energies. This **predissociation** can be interpreted in terms of the molecular potential energy curves shown in Fig. 14.27. When a molecule is excited to a vibrational level, its electrons may undergo a redistribution that results in it undergoing an **internal conversion**, a radiationless conversion to another state of the same multiplicity. An internal conversion occurs most readily at the point of intersection of the two molecular potential energy curves, because there the nuclear geometries of the two states are the same. The state into which the molecule converts may be dissociative, so the states near the intersection have a finite lifetime, and hence their energies are imprecisely defined. As a result, the absorption spectrum is blurred in the vicinity of the intersection. When the incoming photon brings enough energy to excite the molecule

6 The chromophore of GFP

Fig. 14.26 When absorption occurs to unbound states of the upper electronic state, the molecule dissociates and the absorption is a continuum. Below the dissociation limit the electronic spectrum shows a normal vibrational structure.

Fig. 14.27 When a dissociative state crosses a bound state, as in the upper part of the illustration, molecules excited to levels near the crossing may dissociate. This process is called predissociation, and is detected in the spectrum as a loss of vibrational structure that resumes at higher frequencies.

to a vibrational level high above the intersection, the internal conversion does not occur (the nuclei are unlikely to have the same geometry). Consequently, the levels resume their well-defined, vibrational character with correspondingly well-defined energies, and the line structure resumes on the high-frequency side of the blurred region.

Lasers

Lasers have transformed chemistry as much as they have transformed the everyday world. They lie very much on the frontier of physics and chemistry, for their operation depends on details of optics and, in some cases, of solid-state processes. In this section, we discuss the mechanisms of laser action, and then explore their applications in chemistry. In *Further information 14.1*, we discuss the modes of operation of a number of commonly available laser systems.

14.5 General principles of laser action

The word laser is an acronym formed from light **amplification** by **stimulated emission** of **radiation**. In stimulated emission, an excited state is stimulated to emit a photon by radiation of the same frequency; the more photons that are present, the greater the probability of the emission. The essential feature of laser action is positive-feedback: the more photons present of the appropriate frequency, the more photons of that frequency that will be stimulated to form.

(a) Population inversion

One requirement of laser action is the existence of a **metastable excited state**, an excited state with a long enough lifetime for it to participate in stimulated emission. Another requirement is the existence of a greater population in the metastable state than in the lower state where the transition terminates, for then there will be a net emission of radiation. Because at thermal equilibrium the opposite is true, it is necessary to achieve a **population inversion** in which there are more molecules in the upper state than in the lower.

One way of achieving population inversion is illustrated in Fig. 14.28. The molecule is excited to an intermediate state I , which then gives up some of its energy nonradiatively and changes into a lower state A ; the laser transition is the return of A to the ground state X . Because three energy levels are involved overall, this arrangement leads to a **three-level laser**. In practice, I consists of many states, all of which can convert to the upper of the two laser states A . The $I \leftarrow X$ transition is stimulated with an intense flash of light in the process called **pumping**. The pumping is often achieved with an electric discharge through xenon or with the light of another laser. The conversion of I to A should be rapid, and the laser transitions from A to X should be relatively slow.

The disadvantage of this three-level arrangement is that it is difficult to achieve population inversion, because so many ground-state molecules must be converted to the excited state by the pumping action. The arrangement adopted in a **four-level laser** simplifies this task by having the laser transition terminate in a state A' other than the ground state (Fig. 14.29). Because A' is unpopulated initially, any population in A corresponds to a population inversion, and we can expect laser action if A is sufficiently metastable. Moreover, this population inversion can be maintained if the $A' \leftarrow X$ transitions are rapid, for these transitions will deplete any population in A' that stems from the laser transition, and keep the state A' relatively empty.

Fig. 14.28 The transitions involved in one kind of three-level laser. The pumping pulse populates the intermediate state I , which in turn populates the laser state A . The laser transition is the stimulated emission $A \rightarrow X$.

Fig. 14.29 The transitions involved in a four-level laser. Because the laser transition terminates in an excited state (A'), the population inversion between A and A' is much easier to achieve.

(b) Cavity and mode characteristics

The laser medium is confined to a cavity that ensures that only certain photons of a particular frequency, direction of travel, and state of polarization are generated abundantly. The cavity is essentially a region between two mirrors, which reflect the light back and forth. This arrangement can be regarded as a version of the particle in a box, with the particle now being a photon. As in the treatment of a particle in a box (Section 9.1), the only wavelengths that can be sustained satisfy

$$n \times \frac{1}{2}\lambda = L \quad (14.7)$$

where n is an integer and L is the length of the cavity. That is, only an integral number of half-wavelengths fit into the cavity; all other waves undergo destructive interference with themselves. In addition, not all wavelengths that can be sustained by the cavity are amplified by the laser medium (many fall outside the range of frequencies of the laser transitions), so only a few contribute to the laser radiation. These wavelengths are the **resonant modes** of the laser.

Photons with the correct wavelength for the resonant modes of the cavity and the correct frequency to stimulate the laser transition are highly amplified. One photon might be generated spontaneously, and travel through the medium. It stimulates the emission of another photon, which in turn stimulates more (Fig. 14.30). The cascade of energy builds up rapidly, and soon the cavity is an intense reservoir of radiation at all the resonant modes it can sustain. Some of this radiation can be withdrawn if one of the mirrors is partially transmitting.

The resonant modes of the cavity have various natural characteristics, and to some extent may be selected. Only photons that are travelling strictly parallel to the axis of the cavity undergo more than a couple of reflections, so only they are amplified, all others simply vanishing into the surroundings. Hence, laser light generally forms a beam with very low divergence. It may also be polarized, with its electric vector in a particular plane (or in some other state of polarization), by including a polarizing filter into the cavity or by making use of polarized transitions in a solid medium.

Laser radiation is **coherent** in the sense that the electromagnetic waves are all in step. In **spatial coherence** the waves are in step across the cross-section of the beam emerging from the cavity. In **temporal coherence** the waves remain in step along the beam. The latter is normally expressed in terms of a **coherence length**, l_C , the distance over which the waves remain coherent, and is related to the range of wavelengths, $\Delta\lambda$ present in the beam:

$$l_C = \frac{\lambda^2}{2\Delta\lambda} \quad (14.8)$$

If the beam were perfectly monochromatic, with strictly one wavelength present, $\Delta\lambda$ would be zero and the waves would remain in step for an infinite distance. When many wavelengths are present, the waves get out of step in a short distance and the coherence length is small. A typical light bulb gives out light with a coherence length of only about 400 nm; a He–Ne laser with $\Delta\lambda \approx 2$ pm has a coherence length of about 10 cm.

(c) Q-switching

A laser can generate radiation for as long as the population inversion is maintained. A laser can operate continuously when heat is easily dissipated, for then the population of the upper level can be replenished by pumping. When overheating is a problem, the laser can be operated only in pulses, perhaps of microsecond or millisecond duration, so that the medium has a chance to cool or the lower state discard its population.

Fig. 14.30 A schematic illustration of the steps leading to laser action. (a) The Boltzmann population of states (see *Molecular interpretation 3.1*), with more atoms in the ground state. (b) When the initial state absorbs, the populations are inverted (the atoms are pumped to the excited state). (c) A cascade of radiation then occurs, as one emitted photon stimulates another atom to emit, and so on. The radiation is coherent (phases in step).

Fig. 14.31 The principle of Q-switching. The excited state is populated while the cavity is nonresonant. Then the resonance characteristics are suddenly restored, and the stimulated emission emerges in a giant pulse.

Fig. 14.32 The principle of a Pockels cell. When light passes through a cell that is 'on', its plane of polarization is rotated and so the laser cavity is non-resonant (its Q-factor is reduced). In this sequence, (a) the plane polarized ray becomes circularly polarized, (b) is reflected, and (c) emerges from the Pockels cell with perpendicular plane polarization. When the cell is turned off, no change of polarization occurs, and the cavity becomes resonant.

However, it is sometimes desirable to have pulses of radiation rather than a continuous output, with a lot of power concentrated into a brief pulse. One way of achieving pulses is by **Q-switching**, the modification of the resonance characteristics of the laser cavity. The name comes from the 'Q-factor' used as a measure of the quality of a resonance cavity in microwave engineering.

Example 14.2 Relating the power and energy of a laser

A laser rated at 0.10 J can generate radiation in 3.0 ns pulses at a pulse repetition rate of 10 Hz. Assuming that the pulses are rectangular, calculate the peak power output and the average power output of this laser.

Method The power output is the energy released in an interval divided by the duration of the interval, and is expressed in watts ($1 \text{ W} = 1 \text{ J s}^{-1}$). To calculate the peak power output, P_{peak} , we divide the energy released during the pulse divided by the duration of the pulse. The average power output, P_{average} , is the total energy released by a large number of pulses divided by the duration of the time interval over which the total energy was measured. So, the average power is simply the energy released by one pulse multiplied by the pulse repetition rate.

Answer From the data,

$$P_{\text{peak}} = \frac{0.10 \text{ J}}{3.0 \times 10^{-9} \text{ s}} = 3.3 \times 10^7 \text{ J s}^{-1}$$

That is, the peak power output is 33 MW. The pulse repetition rate is 10 Hz, so ten pulses are emitted by the laser for every second of operation. It follows that the average power output is

$$P_{\text{average}} = 0.10 \text{ J} \times 10 \text{ s}^{-1} = 1.0 \text{ J s}^{-1} = 1.0 \text{ W}$$

The peak power is much higher than the average power because this laser emits light for only 30 ns during each second of operation.

Self-test 14.3 Calculate the peak power and average power output of a laser with a pulse energy of 2.0 mJ, a pulse duration of 30 ps, and a pulse repetition rate of 38 MHz.
 $[P_{\text{peak}} = 67 \text{ MW}, P_{\text{average}} = 76 \text{ kW}]$

The aim of Q-switching is to achieve a healthy population inversion in the absence of the resonant cavity, then to plunge the population-inverted medium into a cavity, and hence to obtain a sudden pulse of radiation. The switching may be achieved by impairing the resonance characteristics of the cavity in some way while the pumping pulse is active, and then suddenly to improve them (Fig. 14.31). One technique is to use a **Pockels cell**, which is an electro-optical device based on the ability of some crystals, such as those of potassium dihydrogenphosphate (KH_2PO_4), to convert plane-polarized light to circularly polarized light when an electrical potential difference is applied. If a Pockels cell is made part of a laser cavity, then its action and the change in polarization that occurs when light is reflected from a mirror convert light polarized in one plane into reflected light polarized in the perpendicular plane (Fig. 14.32). As a result, the reflected light does not stimulate more emission. However, if the cell is suddenly turned off, the polarization effect is extinguished and all the energy stored in the cavity can emerge as an intense pulse of stimulated emission. An alternative technique is to use a **saturable absorber**, typically a solution of a dye that loses its ability

to absorb when many of its molecules have been excited by intense radiation. The dye then suddenly becomes transparent and the cavity becomes resonant. In practice, Q-switching can give pulses of about 5 ns duration.

(d) Mode locking

The technique of **mode locking** can produce pulses of picosecond duration and less. A laser radiates at a number of different frequencies, depending on the precise details of the resonance characteristics of the cavity and in particular on the number of half-wavelengths of radiation that can be trapped between the mirrors (the cavity modes). The resonant modes differ in frequency by multiples of $c/2L$ (as can be inferred from eqn 14.8 with $\nu = c/\lambda$). Normally, these modes have random phases relative to each other. However, it is possible to lock their phases together. Then interference occurs to give a series of sharp peaks, and the energy of the laser is obtained in short bursts (Fig. 14.33). The sharpness of the peaks depends on the range of modes superimposed, and the wider the range, the narrower the pulses. In a laser with a cavity of length 30 cm, the peaks are separated by 2 ns. If 1000 modes contribute, the width of the pulses is 4 ps.

Fig. 14.33 The output of a mode-locked laser consists of a stream of very narrow pulses separated by an interval equal to the time it takes for light to make a round trip inside the cavity.

Justification 14.4 The origin of mode locking

The general expression for a (complex) wave of amplitude $\mathcal{E}_0$ and frequency ω is $\mathcal{E}_0 e^{i\omega t}$. Therefore, each wave that can be supported by a cavity of length L has the form

$$\mathcal{E}_n(t) = \mathcal{E}_0 e^{2\pi i(\nu + nc/2L)t}$$

where ν is the lowest frequency. A wave formed by superimposing N modes with $n = 0, 1, \dots, N-1$ has the form

$$\mathcal{E}(t) = \sum_{n=0}^{N-1} \mathcal{E}_n(t) = \mathcal{E}_0 e^{2\pi i \nu t} \sum_{n=0}^{N-1} e^{i\pi n c t / L}$$

The sum is a geometrical progression:

$$\begin{aligned} \sum_{n=0}^{N-1} e^{i\pi n c t / L} &= 1 + e^{i\pi c t / L} + e^{2i\pi c t / L} + \dots \\ &= \frac{\sin(N\pi c t / 2L)}{\sin(\pi c t / 2L)} \times e^{(N-1)i\pi c t / 2L} \end{aligned}$$

The intensity, I , of the radiation is proportional to the square modulus of the total amplitude, so

$$I \propto \mathcal{E}^* \mathcal{E} = \mathcal{E}_0^2 \frac{\sin^2(N\pi c t / 2L)}{\sin^2(\pi c t / 2L)}$$

This function is shown in Fig. 14.34. We see that it is a series of peaks with maxima separated by $t = 2L/c$, the round-trip transit time of the light in the cavity, and that the peaks become sharper as N is increased.

Fig. 14.34 The function derived in Justification 14.4 showing in more detail the structure of the pulses generated by a mode-locked laser.

Mode locking is achieved by varying the Q-factor of the cavity periodically at the frequency $c/2L$. The modulation can be pictured as the opening of a shutter in synchrony with the round-trip travel time of the photons in the cavity, so only photons making the journey in that time are amplified. The modulation can be achieved by linking a prism in the cavity to a transducer driven by a radiofrequency source at a frequency $c/2L$. The transducer sets up standing-wave vibrations in the prism and modulates the

Table 14.4 Characteristics of laser radiation and their chemical applications

Characteristic	Advantage	Application
High power	Multiphoton process	Nonlinear spectroscopy Saturation spectroscopy
	Low detector noise High scattering intensity	Improved sensitivity Raman spectroscopy
Monochromatic	High resolution State selection	Spectroscopy Isotope separation Photochemically precise State-to-state reaction dynamics
Collimated beam	Long path lengths Forward-scattering observable	Sensitivity Nonlinear Raman spectroscopy
Coherent	Interference between separate beams	CARS
Pulsed	Precise timing of excitation	Fast reactions Relaxation Energy transfer

loss it introduces into the cavity. We also see in Section 20.10c that the unique optical properties of some materials can be exploited to bring about mode-locking.

14.6 Applications of lasers in chemistry

Laser radiation has five striking characteristics (Table 14.4). Each of them (sometimes in combination with the others) opens up interesting opportunities in spectroscopy, giving rise to ‘laser spectroscopy’ and, in photochemistry, giving rise to ‘laser photochemistry’. What follows is only an initial listing of applications of lasers to chemistry. We see throughout the text how lasers are also used in the study of macromolecules (Chapter 19) and reaction dynamics (Chapter 24).

(a) Multiphoton spectroscopy

The large number of photons in an incident beam generated by a laser gives rise to a qualitatively different branch of spectroscopy, for the photon density is so high that more than one photon may be absorbed by a single molecule and give rise to **multiphoton processes**. One application of multiphoton processes is that states inaccessible by conventional one-photon spectroscopy become observable because the overall transition occurs with no change of parity. For example, in one-photon spectroscopy, only $g \leftrightarrow u$ transitions are observable; in two-photon spectroscopy, however, the overall outcome of absorbing two photons is a $g \rightarrow g$ or a $u \rightarrow u$ transition.

(b) Raman spectroscopy

Raman spectroscopy was revitalized by the introduction of lasers. An intense excitation beam increases the intensity of scattered radiation, so the use of laser sources increases the sensitivity of Raman spectroscopy. A well-defined beam also implies that the detector can be designed to collect only the radiation that has passed through a sample, and can be screened much more effectively against stray scattered light, which can obscure the Raman signal. The monochromaticity of laser radiation is also a great advantage, for it makes possible the observation of scattered light that differs by only fractions of reciprocal centimetres from the incident radiation. Such high resolution is particularly useful for observing the rotational structure of Raman lines because rotational transitions are of the order of a few reciprocal centimetres. Monochromaticity

also allows observations to be made very close to absorption frequencies, giving rise to the techniques of Fourier-transform Raman spectroscopy (Section 13.1) and resonance Raman spectroscopy (Section 13.16b).

The availability of nondivergent beams makes possible a qualitatively different kind of spectroscopy. The beam is so well-defined that it is possible to observe Raman transitions very close to the direction of propagation of the incident beam. This configuration is employed in the technique called **stimulated Raman spectroscopy**. In this form of spectroscopy, the Stokes and anti-Stokes radiation in the forward direction are powerful enough to undergo more scattering and hence give up or acquire more quanta of energy from the molecules in the sample. This multiple scattering results in lines of frequency $\nu_i \pm 2\nu_M$, $\nu_i \pm 3\nu_M$, and so on, where ν_i is the frequency of the incident radiation and ν_M the frequency of a molecular excitation.

(c) Precision-specified transitions

The monochromatic character of laser radiation is a very powerful characteristic because it allows us to excite specific states with very high precision. One consequence of state-specificity for photochemistry is that the illumination of a sample may be photochemically precise and hence efficient in stimulating a reaction, because its frequency can be tuned exactly to an absorption. The specific excitation of a particular excited state of a molecule may greatly enhance the rate of a reaction even at low temperatures. The rate of a reaction is generally increased by raising the temperature because the energies of the various modes of motion of the molecule are enhanced. However, this enhancement increases the energy of all the modes, even those that do not contribute appreciably to the reaction rate. With a laser we can excite the kinetically significant mode, so rate enhancement is achieved most efficiently. An example is the reaction

which normally proceeds only above 600°C in the presence of a catalyst; exposure to 10.6 μm CO_2 laser radiation results in the formation of products at room temperature without a catalyst. The commercial potential of this procedure is considerable (provided laser photons can be produced sufficiently cheaply), because heat-sensitive compounds, such as pharmaceuticals, may perhaps be made at lower temperatures than in conventional reactions.

A related application is the study of **state-to-state reaction dynamics**, in which a specific state of a reactant molecule is excited and we monitor not only the rate at which it forms products but also the states in which they are produced. Studies such as these give highly detailed information about the deployment of energy in chemical reactions (Chapter 24).

(d) Isotope separation

The precision state-selectivity of lasers is also of considerable potential for laser isotope separation. Isotope separation is possible because two **isotopomers**, or species that differ only in their isotopic composition, have slightly different energy levels and hence slightly different absorption frequencies.

One approach is to use **photoionization**, the ejection of an electron by the absorption of electromagnetic radiation. Direct photoionization by the absorption of a single photon does not distinguish between isotopomers because the upper level belongs to a continuum; to distinguish isotopomers it is necessary to deal with discrete states. At least two absorption processes are required. In the first step, a photon excites an atom to a higher state; in the second step, a photon achieves photoionization from that state (Fig. 14.35). The energy separation between the two states involved in the first step

Fig. 14.35 In one method of isotope separation, one photon excites an isotopomer to an excited state, and then a second photon achieves photoionization. The success of the first step depends on the nuclear mass.

Fig. 14.36 An experimental arrangement for isotope separation. The dye laser, which is pumped by a copper-vapour laser, photoionizes the U atoms selectively according to their mass, and the ions are deflected by the electric field applied between the plates.

Fig. 14.37 Isotopomers may be separated by making use of their selective absorption of infrared photons followed by photodissociation with an ultraviolet photon.

Fig. 14.38 In an alternative scheme for separating isotopomers, multiphoton absorption of infrared photons is used to reach the dissociation limit of a ground electronic state.

depends on the nuclear mass. Therefore, if the laser radiation is tuned to the appropriate frequency, only one of the isotopomers will undergo excitation and hence be available for photoionization in the second step. An example of this procedure is the photoionization of uranium vapour, in which the incident laser is tuned to excite ^{235}U but not ^{238}U . The ^{235}U atoms in the atomic beam are ionized in the two-step process; they are then attracted to a negatively charged electrode, and may be collected (Fig. 14.36). This procedure is being used in the latest generation of uranium separation plants.

Molecular isotopomers are used in techniques based on **photodissociation**, the fragmentation of a molecule following absorption of electromagnetic radiation. The key problem is to achieve both mass selectivity (which requires excitation to take place between discrete states) and dissociation (which requires excitation to continuum states). In one approach, two lasers are used: an infrared photon excites one isotopomer selectively to a higher vibrational level, and then an ultraviolet photon completes the process of photodissociation (Fig. 14.37). An alternative procedure is to make use of multiphoton absorption within the ground electronic state (Fig. 14.38); the efficiency of absorption of the first few photons depends on the match of their frequency to the energy level separations, so it is sensitive to nuclear mass. The absorbed photons open the door to a subsequent influx of enough photons to complete the dissociation process. The isotopomers $^{32}\text{SF}_6$ and $^{34}\text{SF}_6$ have been separated in this way.

In a third approach, a selectively vibrationally excited species may react with another species and give rise to products that can be separated chemically. This procedure has been employed successfully to separate isotopes of B, N, O, and, most efficiently, H. A variation on this procedure is to achieve selective **photoisomerization**, the conversion of a species to one of its isomers (particularly a geometrical isomer) on absorption of electromagnetic radiation. Once again, the initial absorption, which is isotope selective, opens the way to subsequent further absorption and the formation of a geometrical isomer that can be separated chemically. The approach has been used with the photoisomerization of CH_3NC to CH_3CN .

A different, more physical approach, that of **photodeflection**, is based on the recoil that occurs when a photon is absorbed by an atom and the linear momentum of the photon (which is equal to h/λ) is transferred to the atom. The atom is deflected from

its original path only if the absorption actually occurs, and the incident radiation can be tuned to a particular isotope. The deflection is very small, so an atom must absorb dozens of photons before its path is changed sufficiently to allow collection. For instance, if a Ba atom absorbs about 50 photons of 550 nm light, it will be deflected by only about 1 mm after a flight of 1 m.

(e) Time-resolved spectroscopy

The ability of lasers to produce pulses of very short duration is particularly useful in chemistry when we want to monitor processes in time. Q-switched lasers produce nanosecond pulses, which are generally fast enough to study reactions with rates controlled by the speed with which reactants can move through a fluid medium. However, when we want to study the rates at which energy is converted from one mode to another within a molecule, we need femtosecond and picosecond pulses. These timescales are available from mode-locked lasers.

In **time-resolved spectroscopy**, laser pulses are used to obtain the absorption, emission, or Raman spectrum of reactants, intermediates, products, and even transition states of reactions. It is also possible to study energy transfer, molecular rotations, vibrations, and conversion from one mode of motion to another. We shall see some of the information obtained from time-resolved spectroscopy in Chapters 22 to 24. Here, we describe some of the experimental techniques that employ pulsed lasers.

The arrangement shown in Fig. 14.39 is often used to study ultrafast chemical reactions that can be initiated by light, such as the initial events of vision (*Impact I14.1*). A strong and short laser pulse, the *pump*, promotes a molecule A to an excited electronic state A* that can either emit a photon (as fluorescence or phosphorescence) or react with another species B to yield a product C:
